Decongestants

A *decongestant* is a broad class of medications used to relieve nasal congestion. Generally, they work by reducing swelling of the mucous membranes in the nasal passages. The effects are not limited to the nose and these medicines can increase hypertension (blood pressure). These are normally paired with antihistamines to lessen this effect, but they don't always even each other out. These agents are usually administered topically (by the intranasal route) or orally. Examples of oral decongestants include pseudoephedrine and phenylephrine; for a full list of Wikipedia articles see the category listed below.

See also

- topical decongestant

Topical decongestants

Topical decongestants are decongestants applied directly to the nasal cavity. By applying them directly to the site of action, topical decongestants relieve nasal congestion while reducing the side effects associated with systemically-acting decongestants, such as high blood pressure. Topical decongestants should only be used by patients for a maximum of 3 days in a row, because rebound congestion may occur in the form of rhinitis medicamentosa.

Mechanism of action

Topical decongestants are vasoconstrictors, and work by constricting the blood vessels within the nasal cavity.

Examples of topical decongestants

- Ephedrine
- Oxymetazoline

Phenylephrine
Pseudoephedrine hydrochloride
Tramazoline
Xylometazoline

Chemotherapeutic agents

Chemotherapy is the use of chemical substances to treat disease. In its modern-day use, it refers primarily to cytotoxic drugs used to treat cancer.

In its non-oncological use, the term may also refer to antibiotics (antibacterial chemotherapy). In that sense, the first modern chemotherapeutic agent was Paul Ehrlich's arsphenamine, an arsenic compound discovered in 1909 and used to treat syphilis. This was later followed by sulfonamides discovered by Domagk and penicillin G discovered by Alexander Fleming.

Other uses of cytostatic chemotherapy agents (including the ones mentioned below) are the treatment of autoimmune diseases such as multiple sclerosis and rheumatoid arthritis, the treatment of some chronic viral infections such as Hepatitis, and the suppression of transplant rejections (see immunosuppression and DMARDs).

History

The era of chemotherapy began in the 1940s with the first uses of nitrogen mustards and folic acid inhibitors. Cancer drug development since then has exploded into a multi-billion dollar industry. The targeted-therapy revolution has arrived, but the principles and limitations of chemotherapy discovered by the early researchers still apply.

Principles

Cancer is the uncontrolled growth of cells due to damage to DNA (mutations) and, occasionally, due to an inherited propensity to develop certain tumours. Autoimmune diseases arise from an overactive immune response of the body against substances and tissues normally present in the body - in other words, the body attacks its own cells. In contrast, transplant rejection happens because a normal healthy human immune system can distinguish foreign tissues and attempts to destroy them. Also the reverse situation, called graft-versus-host disease, may take place.

Broadly, most chemotherapeutic drugs work by impairing mitosis (cell division), effectively targeting fast-dividing cells. As these drugs cause damage to cells they are termed cytotoxic. Some drugs cause cells to undergo apoptosis (so-called "cell suicide").

Unfortunately, scientists have yet to be able to locate specific features of malignant and immune cells that would make them uniquely targetable (barring some recent examples, such as the Philadelphia chromosome as targeted by imatinib). This means that other fast dividing cells such as those responsible for hair growth and for replacement of the intestinal epithelium (lining) are also affected. However, some drugs have a better side-effect profile than others, enabling doctors to adjust treatment regimens to the advantage of patients in certain situations.

As chemotherapy affects cell division, tumours with high growth fractions (such as acute myelogenous leukemia and the lymphomas, including Hodgkin's disease) are more sensitive

to chemotherapy, as a larger proportion of the targeted cells are undergoing cell division at any time.

Chemotherapeutic drugs affect "younger" tumours (i.e. less differentiated) more effectively, because at a higher grade of differentiation, the propensity to growth usually decreases. Near the center of some solid tumours, cell division has effectively ceased, making them insensitive to chemotherapy. Another problem with solid tumours is the fact that the chemotherapeutic agent often does not reach the core of the tumour. Solutions to this problem include radiation therapy (both brachytherapy and teletherapy) and surgery.

Types

The majority of chemotherapeutic drugs can be divided in to: alkylating agents, antimetabolites, anthracyclines, plant alkaloids, topoisomerase inhibitors, and antitumour agents. All of these drugs affect cell division or DNA synthesis and function in some way.

Some newer agents don't directly interfere with DNA. These include the new tyrosine kinase inhibitor imatinib mesylate (Gleevec® or Glivec®), which directly targets a molecular abnormality in certain types of cancer (chronic myelogenous leukemia, gastrointestinal stromal tumors).

In addition, some drugs may be used which modulate tumor cell behaviour without directly attacking those cells. Hormone treatments fall into this category of adjuvant therapies.

Where available, Anatomical Therapeutic Chemical Classification System codes are provided for the major categories.

Alkylating agents (L01A)

Alkylating agents are so named because of their ability to add alkyl groups to many electronegative groups under conditions present in cells. Cisplatin and carboplatin, as well as oxaliplatin are alkylating agents.

Anti-metabolites (L01B)

Anti-metabolites masquerade as purine ((azathioprine, mercaptopurine)) or pyrimidine - which become the building blocks of DNA. They prevent these substances becoming incorporated in to DNA during the "S" phase (of the cell cycle), stopping normal development and division. They also affect RNA synthesis. Due to their efficiency, these drugs are the most widely used cytostatics.

Plant alkaloids and terpenoids (L01C)

These alkaloids are derived from plants and block cell division by preventing microtubule function. Microtubules are vital for cell division and without them it can not occur. The main examples are vinca alkaloids and taxanes.

Vinca alkaloids (L01CA)

Vinca alkaloids bind to specific sites on tubulin, inhibiting the assembly of tubulin into microtubules (M phase of the cell cycle). They are derived from the Madagascar periwinkle, Catharanthus roseus (formerly known as Vinca rosea). The vinca alkaloids include:

- Vincristine

Vinblastine
Vinorelbine
Vindesine

Podophyllotoxin (L01CB)

Podophyllotoxin is a plant-derived compound used to produce two other cytostatic drugs, etoposide and teniposide. They prevent the cell from entering the G1 phase (the start of DNA replication) and the replication of DNA (the S phase). The exact mechanism of its action still has to be elucidated.

The substance has been primarily obtained from the American Mayapple (Podophyllum peltatum). Recently it has been discovered that a rare Himalayan Mayapple (Podophyllum hexandrum) contains it in a much greater quantity, but as the plant is endangered, its supply is limited. Studies have been conducted to isolate the genes involved in the substance's production, so that it could be obtained recombinantively.

Taxanes (L01CD)

Taxanes are derived from the Yew Tree. Paclitaxel is derived from the bark of the European Yew Tree while Docetaxel is derived from the pine needle of the Pacific Yew Tree. Taxanes enhance stability of microtubules, preventing the separation of chromosomes during anaphase. Taxanes include:

- Paclitaxel

Docetaxel

Topoisomerase inhibitors (L01CB and L01XX)

Topoisomerases are essential enzymes that maintain the topology of DNA. Inhibition of type I or type II topoisomerases interferes with both transcription and replication of DNA by upsetting proper DNA supercoiling.

- Some type I topoisomerase inhibitors include camptothecins: irinotecan and topotecan.
- Examples of type II inhibitors include amsacrine, etoposide, etoposide phosphate, and teniposide. These are semisynthetic derivatives of epipodophyllotoxins, alkaloids naturally occurring in the root of mayapple (Podophyllum peltatum).

Antitumour antibiotics (L01D)

The most important immunosuppressant from this group is dactinomycin, which is used in kidney transplantations.

Hormonal therapy

Several malignancies respond to hormonal therapy. Strictly speaking, this is not chemotherapy. Cancer arising from certain tissues, including the mammary and prostate glands, may be inhibited or stimulated by appropriate changes in hormone balance.

- Steroids (often dexamethasone) can inhibit tumour growth or the associated edema (tissue swelling), and may cause regression of lymph node malignancies.
- Prostate cancer is often sensitive to finasteride, an agent that blocks the peripheral conversion of testosterone to dihydrotestosterone.
- Breast cancer cells often highly express the estrogen and/or progesterone receptor. Inhibiting the production (with aromatase inhibitors) or action (with tamoxifen) of these hormones can often be used as an adjunct to therapy.
- Gonadotropin-releasing hormone agonists (GnRH), such as goserelin possess a paradoxic negative feedback effect followed by inhibition of the release of FSH (follicle-stimulating hormone) and LH (luteinizing hormone), when given continuously.

Some other tumours are also hormone dependent, although the specific mechanism is still unclear.

Dosage

Dosage of chemotherapy can be difficult: if the dose is too low, it will be ineffective against the tumor, while at excessive doses the toxicity (side-effects, neutropenia) will be intolerable to the patient. This has led to the formation of detailed "dosing schemes" in most hospitals, which give guidance on the correct dose and adjustment in case of toxicity. In immunotherapy, they are in principle used in smaller dosages than in the treatment of malign diseases.

In most cases, the dose is adjusted for the patient's body surface area, a composite measure of weight and height that mathematically approximates the body volume. The BSA is usually calculated with a mathematical formula or a nomogram, rather than by direct measurement.

Delivery

Most chemotherapy is delivered intravenously, although there are a number of agents that can be administered orally (e.g. melphalan, busulfan,capecitabine). Depending on the patient, the cancer, the stage of cancer, the type of chemotherapy, and the dosage,

intravenous chemotherapy may be given on either an inpatient or outpatient basis. For continuous, frequent or prolonged intravenous chemotherapy administration, various systems may be surgically inserted into the vasculature to maintain access. Commonly used systems are the Hickman line, the Port-a-Cath or the PICC line. These have a lower infection risk, are much less prone to phlebitis or extravasation, and abolish the need for repeated insertion of peripheral cannulae.

Treatment schemes

There are a number of strategies in the administration of chemotherapeutic drugs used today. Chemotherapy may be given with a curative intent or it may aim to prolong life or to palliate symptoms.

Combined modality chemotherapy is the use of drugs with other cancer treatments, such as radiation therapy or surgery. Most cancers are now treated in this way. Combination chemotherapy is a similar practice which involves treating a patient with a number of different drugs simultaneously. The drugs differ in their mechanism and side effects. The biggest advantage is minimising the chances of resistance developing to any one agent.

In neoadjuvant chemotherapy (preoperative treatment) initial chemotherapy is aimed for shrinking the primary tumour, thereby rendering local therapy (surgery or radiotherapy) less destructive or more effective.

Adjuvant chemotherapy (postoperative treatment) can be used when there is little evidence of cancer present, but there is risk of recurrence. This can help reduce chances of resistance developing if the tumour does develop. It is also useful in killing any cancerous cells which have spread to other parts of the body. This is often effective as the newly growing tumours are fast-dividing, and therefore very susceptible.

Palliative chemotherapy is given without curative intent, but simply to decrease tumor load and increase life expectancy. For these regimens, a better toxicity profile is generally expected.

Most chemotherapy regimens require that the patient is capable to undergo the treatment. Performance status is often used as a measure to determine whether a patient can receive chemotherapy, or whether dose reduction is required.

Side-effects

The treatment can be physically exhausting for the patient. Current chemotherapeutic techniques have a range of side effects mainly affecting the fast-dividing cells of the body. Important common side-effects include (dependent on the agent):

- Hair loss
- Nausea and vomiting
- Diarrhea or constipation
- Anemia
- Depression of the immune system hence (potentially lethal) infections and sepsis
- Hemorrhage
- Secondary neoplasms
- Cardiotoxicity
- Hepatotoxicity

Nephrotoxicity
Ototoxicity

Immunosuppression and myelosuppression

Virtually all chemotherapeutic regimens can cause depression of the immune system, often by paralysing the bone marrow and leading to a decrease of white blood cells, red blood cells and platelets. The latter two, when they occur, are improved with blood transfusion. Neutropenia (a decrease of the neutrophil granulocyte count below 0.5 x 109/litre) can be improved with synthetic G-CSF (granulocyte-colony stimulating factor, e.g. filgrastim, lenograstim, Neupogen®, Neulasta®.)

In very severe myelosuppression, which occurs in some regimens, almost all the bone marrow stem cells (cells which produce white and red blood cells) are destroyed, meaning allogenic or autologous bone marrow cell transplants are necessary. (In autologous BMTs, cells are removed from the patient before the treatment, multiplied and then re-injected afterwards; in allogenic BMTs the source is a donor.) However, some patients still develop diseases because of this interference with bone marrow.

Nausea and vomiting

Nausea and vomiting caused by chemotherapy; stomach upset may trigger a strong urge to vomit, or forcefully eliminate what is in the stomach.

Stimulation of the vomiting center results in the coordination of responses from the diaphragm, salivary glands, cranial nerves, and gastrointestinal muscles to produce the interruption of respiration and forced expulsion of stomach contents known as retching and vomiting. The vomiting center is stimulated directly by afferent input from the vagal and splanchnic nerves, the pharynx, the cerebral cortex, cholinergic and histamine stimulation from the vestibular system, and efferent input from the chemoreceptor trigger zone (CTZ). The CTZ is in the area postrema, outside the blood-brain barrier, and is thus susceptible to stimulation by substances present in the blood or cerebral spinal fluid. The neurotransmitters dopamine and serotonin stimulate the vomiting center indirectly via stimulation of the CTZ.

The 5-HT3 inhibitors are the most effective antiemetics and constitute the single greatest advance in the management of nausea and vomiting in patients with cancer. These drugs are designed to block one or more of the signals that cause nausea and vomiting. The most sensitive signal during the first 24 hours after chemotherapy appears to be 5-HT3. Blocking the 5-HT3 signal is one approach to preventing acute emesis (vomiting), or emesis that is severe, but relatively short-lived. Approved 5-HT3 inhibitors include: dolasetron (Anzemet®), granisetron (Kytril®), and ondansetron (Zofran®). The newest 5-HT3 inhibitor, Aloxi® (palonosetron), has a distinct advantage over the other 5-HT3 inhibitors because, in addition to preventing acute nausea and vomiting, Aloxi® also prevents delayed nausea and vomiting, which occurs during the 2-5 days after treatment. Aloxi® is the only drug in its class that is approved by the FDA for the treatment of delayed nausea and vomiting.

Some studies[1] and patient groups claim that the use of cannabinoids derived from marijuana during chemotherapy greatly reduces the associated nausea and vomiting, and enables the patient to eat. Some synthetic derivatives of the active substance in marijuana (tetrahydrocannabinol or THC) such as Marinol may be practical for this application.

Other side effects

In particularly large tumors, such as large lymphomas, some patients develop tumor lysis syndrome from the rapid breakdown of malignant cells. Although prophylaxis is available and is often initiated in patients with large tumors, this is a dangerous side-effect which can lead to death if left untreated.

A proportion of patients reports fatigue or non-specific neurocognitive problems, such an inability to concentrate; this is colloquially referred to as "chemo brain" by patients' groups[2]

Chemotherapy may increase the risk of cardiovascular disease and occasionally leads to secondary cancer.

Angiogenesis inhibitors

An *angiogenesis inhibitor* is a drug or a dietary component that inhibits angiogenesis (the growth of new blood vessels).

Known inhibitors include the drug bevacizumab which binds vascular endothelial growth factor (VEGF), inhibiting its binding to the receptors that promote angiogenesis. Some common components of the Oriental diet (and to a much lesser extent, the Western diet) also act as mild angiogenesis inhibitors. In particular, the following foodstuffs contain significant inhibitors and have been suggested as part of a healthy diet for this and other benefits:

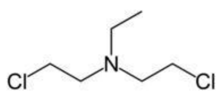
- Soy products such as tofu and tempeh, (which contain the inhibitor "genistein")

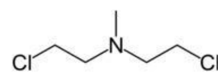
Chinese cabbage (brassinin)
Green tea (catechins)
Red Wine (resveratrol) - Suggested only in moderation

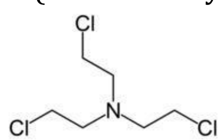
Research and development in this field has been driven largely by the desire to find better cancer treatments. Tumors can grow only if they form new blood vessels. By stopping the growth of blood vessels, scientists hope to shut off the means by which tumors can extend themselves and spread inside the body. In animal studies, angiogenesis inhibitors have successfully stopped the formation of new blood vessels.

In addition to their use as anti-cancer drugs, angiogenesis inhibitors are being investigated for their use in weight loss, as blood vessels in adipose tissue never fully mature, and are thus destroyed by angiogenesis inhibitors.

Nitrogen mustard



HN1 (bis(2-chloroethyl)ethylamine)


HN2 (bis(2-chloroethyl)methylamine)


HN3 (tris(2-chloroethyl)amine)

The *nitrogen mustards* are cytotoxic chemotherapy agents similar to mustard gas. Although their common use is medicinal, in principle these compounds may also be used for chemical warfare purposes.

The prototype nitrogen mustard drug is mustine which is no longer commonly in use but was the first drug to be used as an anticancer chemotherapeutic. It is a schedule 1 substance in the Chemical Weapons Convention. Other nitrogen mustards include cyclophosphamide, chlorambucil, uramustine and melphalan.

Nitrogen mustards act by exerting radiomimetic properties on the cytogenetic material of the cell (chromosomes) ie; the effects seen are similar to genetic material which has been exposed to radiation.

Ovation Pharma bought the rights to nitrogen mustard . A New York Times article has mentioned that only about 5000 people use therapeutic nitrogen mustard in the United States.

Examples of nitrogen mustards that can be used for chemical warfare purposes and their military weapon designations include:

- HN1: Bis(2-chloroethyl) ethylamine

HN2: Bis(2-chloroethyl) methylamine
HN3: Tris(2-chloroethyl) amine

All belligerent nations stock-piled large amounts of munitions containing nitrogen mustard gas during the Second World War, but none were used in combat. As with all types of mustard gas, nitrogen mustard is a powerful and persistent blister agent.

Dietary supplements

A prescribed *dietary supplement* is intended to supply nutrients (vitamins, minerals, fatty acids or amino acids) that are missing or not consumed in sufficient quantity in a person's diet. This may include *herbal supplements* which have a history of claims that they cure or prevent certain diseases. The medical utility and regulatory status of dietary supplements is controversial.

United States

In the United States, a *dietary supplement* is defined under the *Dietary Supplement Health and Education Act of 1994*[1] as a product that meets each of the following criteria:

1. It is intended to supplement the diet and bears or contains one or more of the following dietary ingredients:
    - **a** vitamin**,**
    - a mineral,
    - an herb or other botanical (excluding tobacco),
    - an amino acid,
    - a dietary substance for use by man to supplement the diet by increasing the total daily intake (e.g., enzymes or tissues from organs or glands),
    - a concentrate, such as a meal replacement or energy bar, or
    - a metabolite, constituent, or extract.
2. It is intended for ingestion in pill, capsule, tablet, or liquid form.
3. It is not represented for use as a conventional food or as the sole item of a meal or diet.
4. It is labeled as a "dietary supplement".

The FDA regulates dietary supplements as foods, and not as drugs. The FDA does not pre-approve dietary supplements on their safety and efficacy, unlike drugs. In contrast, the FDA can only go after dietary supplement manufacturers after they have put unsafe products on the market. However, certain foods (such as infant formula and medical foods) are deemed special nutritionals because they are consumed by highly vulnerable populations and are thus regulated more strictly than the majority of dietary supplements.

The claims that a dietary supplement makes are essential to its classification. If a dietary supplement claims in any way to cure, mitigate, or treat a disease, it would be considered to be an unauthorized new drug and in violation of the applicable regulations and statutes. As the FDA states it in a response to this question in a FAQ:

Is it legal to market a dietary supplement product as a treatment or cure for a specific disease or condition?

No, a product sold as a dietary supplement and promoted on its label or in labeling* as a treatment, prevention or cure for a specific disease or condition would be considered an unapproved--and thus illegal--drug. To maintain the product's status as a dietary supplement, the label and labeling must be consistent with the provisions in the Dietary Supplement Health and Education Act (DSHEA) of 1994.

***Labeling refers to the label as well as accompanying material that is used by a manufacturer to promote and market a specific product.**

Dietary supplements are permitted to make structure/function claims. These are broad claims that the product can support the structure or function of the body (e.g., "glucosamine helps support healthy joints"). The FDA must be notified of these claims within 30 days of their first use, and there is a requirement that these claims be substantiated. Nevertheless, many critics claim that dietary supplements overstate their importance and their impact on overall health. Evidence of many of the claimed benefits of certain dietary supplements has yet to meet standard scientific criteria of credibility, based on large scale, double blind testing with statistically significant outcomes.

Other claims that required approval from FDA include health claims and qualified health claims. Health claims are permitted to be made if they meet the requirements for the claims found in the applicable regulations. Qualified health claims can be made through a petition process, including scientific information, if FDA has not approved a prior petition.

European Union

The *Food Supplements Directive*[2] requires that supplements be demonstrated to be safe, both in quantity and quality. Some vitamins are essential in small quantities but dangerous in large quantities. Some herbal remedies, notably St Johns Wort, may interact with drugs or render them less effective. Such an issue has been raised in the case of oral contraceptives. Consequently, only those supplements that have been proven to be safe may be sold without prescription. In practice, the number of reported incidents with food supplements is nevertheless low.

In Europe, it is also an established notion that food supplements should not be labeled with drug claims but can bear -to a degree that differs from one member state to the other-health claims.

Legal challenge

The dietary supplements industry in Europe strongly opposed the Directive. A large number of consumers throughout Europe, including over one million in the UK, and many doctors and scientists, have signed petitions against what are viewed by the petitioners as unjustified restrictions of consumer choice [3]. The European Court of Justice ruled[4] on 12 July 2005 that the Directive is valid, although the court's own Advocate General advised that the declaration was invalid under EU law [3]. The court made clear, however, that it must be possible for manufacturers to add vitamins and minerals to the list of ingredients of a food supplement, that refusal must be on scientific grounds, and that there should be a right to appeal.

Russia

Russian legislation, Ministry of Health's order 117 dated as of 15 April, 1997, under the title “Concerning the procedure for the examination and health certification of Biologically Active Dietary Supplements”, provides the usage of the following terminology:

As a rule, BADSs are foodstuffs with clinically proven effectiveness. BADSs are recommended not only for prophylactics, but can be included into a complex therapy for the prevention of pharmaceutical therapy's side effects and for the achievement of complete remission.

The development of BADSs and their applications has been very fast moving. They were originally considered as dietary supplements for people who had heightened requirements for some normal dietary components (for example, sportsmen). Later, they were employed as preventive medicines against chronic diseases.

Energy drinks

Energy drinks are beverages that are designed to give the consumer a burst of energy by using a combination of methylxanthines, B vitamins, and exotic herbal ingredients. Energy drinks commonly include caffeine, guarana (extracts from the guarana plant), taurine, various forms of ginseng, maltodextrin, inositol, carnitine, creatine, glucuronolactone and ginkgo biloba. Some contain high levels of sugar, or glucose while most brands also offer an artificially sweetened version. Often manufacturers add a very small dose of a powerful stimulant such as carnitine, but the doses of these add-ins are usually so small that any added “boost” is purely psychological. These drinks are typically marketed towards young people, students, people 'on the go' and those who play sports.

History

Jolt Cola was released in the 1980s. It was not an energy drink but a high-caffeine, high-sugar brand of cola. It pioneered a marketing strategy still widely in use by energy drinks today, targeting a generally younger audience, mostly students and young professionals (people on-the-go), billing itself as something that was not necessarily healthy but which would allow them to cram more hours into their day. Later, marketing turned further and further toward people involved in the technology industry, and consequently, energy drinks today are commonly associated with the image of a hacker or IT professional, sitting up late at his or her computer trying to stay awake. The recent energy drink phenomenon in North America seemed to follow the sudden popularity of Red Bull, which still has roughly 70% of the market share . Major players such as Pepsi, Coca-Cola, Molson and Labatt have tried to match the small companies' innovative and different approach with marginal success.

In Japan, the energy drink phenomenon dates at least as far back as the early 1960s, with the release of the Lipovitan D drink from Taisho Pharmaceuticals. Most such products in Japan bear little resemblance to soft drinks, and are sold instead in small brown glass medicine bottles or cans styled to resemble such containers. These "genki drinks" are marketed primarily to the salaryman set, to help them work long hours, or to stay awake on the late commute home.

In the beginning of the 21st century, the addition of energy components into alcoholic beverages made an impact on the market. Many malt beverages such as Sparks, 3sum malt beverage, and Max capitalized on the effects of caffeine while drinking alcohol.

Energy drinks are different from sports drinks. Most energy drinks simply provide lots of sugar or caffeine. Sports drinks are intended to replenish electrolytes, sugars, water and other nutrients and are usually isotonic (containing the same proportions as found in the human body). Some products are now available as hybrids between energy drinks and sport drinks, having electrolytes (sport drinks, aka as isotonic beverages) and herbal extracts (energy drinks) such as Reload and Vault (soft drink).

Criticism

Addiction potential

The only possible physically addictive ingredients in most of these drinks are caffeine and guarana, which cause physical addiction in large doses or with prolonged use (quantities in energy drinks are comparable to amounts in coffee). Since withdrawal from both is usually mild, mainly involving headaches, addiction to energy drinks is mostly psychological.

Parents' groups have criticized energy drinks as being irresponsibly marketed to youth, citing possible health hazards (see below), but to date, very few fatalities have been reported from overconsumption of energy drinks.

Health hazard

Little conclusive research have been published so far on the health hazards of energy drinks. However, their high concentration in ingredients such as caffeine and taurine worries certain parents and some medical specialists who suspect that long term use may cause unwanted side-effects. The Red Bull article section has more information on mortality and dental risks. On the other hand, there is no consensus on the existence or lack of health benefits as well. [1] [2][3] [4][5]

Table of energy drinks

A table of energy drinks follows, with a few coffee variants, and some soft drinks such as Bawls, Coca-Cola, Mountain Dew, and Pepsi listed for comparison, and marked in a different color. Note that caffeine content in coffee flavors varies, depending on both caffeine content and how the coffee beans were roasted. Source of some data listed below: Energy Fiend.

Energy drink	Caffeine (mg/fl oz)	mg/l	per serving (quantity)
Bawls	6.70	223	56 mg (8.4 fl oz/250 ml)
Coca-Cola	2.83	95	34 mg (12 fl oz/355 ml)
Cola	2.8-3.9	95-130	34-46 mg (12 oz/355 ml)
Cola (Diet)	2.83	110-141	39-50 mg (12 fl oz/355 ml)
Coffee, brewed	7-16 (varies)	230-580 (varies)	135-180 mg (8 fl oz/237 ml/1 cup)
Coffee, instant	9-14 (varies)	300-467 (varies)	71-111 mg (8 fl oz/237 ml/1 cup)
Espresso	20-50 (varies)	600-1700 (varies)	36-102 mg (2 fl oz/60 ml)
Mountain Dew	4.67	156	55 mg (12 fl oz/355 ml)
Pepsi	3.13	104	37 mg (12 fl oz/355 ml)
Tea	5-6.33	169-211	40-50 mg (8 fl oz/237 ml)

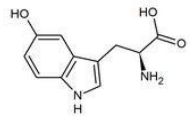
5-Hydroxytryptophan



Chemical name 5-hydroxytryptophan, 5-HTP, (S)-2-amino-3-(5-hydroxy-1H-indol-3-yl)propanoic acid

Chemical formula $C_{11}H_{12}N_2O_3$

Molecular mass 220.22458 g/mol

CAS number [56-69-9]

SMILES Oc1cc2c(C[C@@](N)([H]) C(O)=O)c[nH]c2cc1

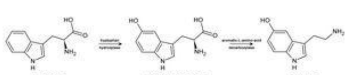
5-Hydroxytryptophan or *5-HTP* is a precursor to the neurotransmitter serotonin and an intermediate in tryptophan metabolism. It is marketed in the United States and other countries as a dietary supplement for use as an antidepressant, appetite suppressant, and sleep aid.

Pharmacology

5-Hydroxytryptophan is decarboxylated to serotonin (5-hydroxytryptamine) by the enzyme aromatic-L-amino-acid decarboxylase.

The psychoactive action of 5-HTP is thought to derive from its effect on serotonin synthesis. It is believed that an artificially high supply of 5-HTP causes the brain's serotonin-producing neurons to increase production. Increased serotonin production then leads to increased serotonin release.

Some doctors suggest that 5-HTP be administered with a peripheral decarboxylase inhibitor such as carbidopa in order to prevent elevated levels of serotonin in the bloodstream (and their side effects, which include emesis and potentially fibrosis of the heart).[1] Research shows that co-administration with carbidopa greatly increases plasma 5-HTP levels.[2]



Metabolic pathway from tryptophan to serotonin.

5-HTP as therapeutic supplement

5-HTP, which is found in infinitesimal amounts in certain foods like turkey and cheese, is often sold as an over-the-counter therapeutic supplement. In this case, it is usually sourced from the seeds of the Griffonia simplicifolia plant. Production of 5-HTP as a supplement increased when a similar serotonin-altering supplement, L-tryptophan, was banned in the United States because of a tainted batch which caused serious side-effects in users. 5-HTP has many advantages over L-tryptophan: being safer to produce and arguably more potent. 5-HTP in supplement form is usually sold in gelatin capsules. These capsules typically

contain either 50mg or 100mg of 5-HTP per capsule. It is recommended to take it on an empty stomach before falling asleep, or in smaller doses throughout the day.

Research

Some studies of 5-HTP have been completed which indicate that 5-HTP has potential in the treatment of depression and possibly anxiety, panic disorder, sleep disorders and obesity. In fact, a survey of all published studies of clinical outcomes with 5-HTP indicate that it yields similar results to those obtained for small scale studies of prescription SSRI antidepressants. Additionally, one open study suggests that people with anxious depressive syndrome may see better results from 5-HTP than from an SSRI.

It is unfortunate that the studies to date are incomplete, even if promising, for the treatment of mild to moderate depression. Reviews of these studies do indicate that potential exists for 5-HTP in the treatment of depression, but further trials are stressed as necessary before arriving at any firm conclusion. Some caution and diligence should be exhibited regarding 5-HTP barring further study and review.

Studies have also indicated miscellaneous benefits from 5-HTP supplementation in patients with fibromyalgia. Reductions in serotonergic tone are partially responsible for cognitive deficits (memory loss) resulting from tetrahydrocannibinol (THC, the active component in marijuana). When given to rats, 5-HTP can significantly attenuate THC-induced memory impairment.[3]

Uses

In recent years 5-HTP has been sold by health food companies as an alternative treatment for depression and mood disorders. Its role as an intermediary in the biosynthesis of serotonin indicates that this chemical may indeed be effective in treating these and other serotonin-related disorders, but there is some debate on the conclusions of the clinical trials which have been carried out using the drug.

5-HTP is also used as a supplement by users of MDMA (ecstasy) to help replenish depleted serotonin, in an attempt to alleviate to a degree the depression and overall mental unsettlement that sometimes occurs in the days following MDMA usage. It should be noted that a temporary decline in serotonin levels is only one of several factors in post-MDMA use cognitive disruptions; neuroadaptive changes in receptor density likely play a larger long-term role.[6] 5-HTP is less commonly used immediately before the use of MDMA as a means to both further reduce the negative psychological effects of depleted serotonin, and as an attempt to boost the effects of MDMA. Anecdotal reports seem to indicate this is largely placebo with some users reporting a moderate muting of the MDMA effect.[4]

5-HTP also has mild psychoactive effects on REM sleep and has been shown in clinical studies to relieve migraines and panic attacks .

5-HTP supplements instead of SSRIs

Natural healing practioners often recommend 5-HTP supplements instead of standard SSRI/MAOI prescriptions as 5-HTP allegedly accomplishes the same goal without resorting to disturbing the brain's natural metabolic procedures. Instead of interrupting the recycling of serotonin as in the case of SSRIs, and instead of preventing the end consumption of serotonin as in the case of MAOIs, 5-HTP supplements provide more raw material that may be used in the body's natural serotonin production process, as shown in the illustration above.

The body's usual source for manufacturing 5-HTP is tryptophan, an amino acid found in many foods, turkey being the most cited example. Tryptophan was also sold as a supplement in health food stores until a contaminated shipment, which resulted in 1500 cases of eosinophilia-myalgia syndrome and over 30 deaths, prompted the United States Food and Drug Administration to ban it as an over-the-counter supplement. As a response to this ban, health supplement producers decided to market 5-HTP in its place. Recently, however, as noted above, pharmaceutical grade L-tryptophan has become available "over the counter" in the U.S.

Dosage

Though there is no official dosage, most supplement providers recommend 50 mg or 100 mg 5-HTP, one to three times per day. Most clinical studies have tested doses of 200-300 mg/day, although one study tested doses as large as 3250 mg/day. Although many studies do not report a dosing schedule, the majority of those that do have reported using two to four doses split throughout the day.[5] Some suggest 5-HTP should be taken just before bed if taking a single daily dose, because it may cause drowsiness.

In theory, an overdose of 5-HTP could cause serotonin syndrome, although there are no reported cases of hospitalizations due to excessive ingestion of 5-HTP.[6] Nor was serotonin syndrome observed in several studies that augmented traditional antidepressant therapy with 5-HTP, even though the combination therapy was expected increase the risk of serotonin syndrome above 5-HTP alone.[5] In dogs, doses of 23.6 mg/kg were found to cause toxic reactions, although the dose response curve for dogs does not necessarily scale to humans.[7] Some users report high doses (300 mg and over) can produce nausea and vomiting.[8]

Side effects

Promoters of 5-HTP claim that it causes fewer side effects than traditional antidepressants. Side effects of 5-HTP may include nausea, constipation, gas, drowsiness, or a decreased sex drive. It can also have adverse interactions with other natural and traditional drugs.[9] Others warn that the long term effects of 5-HTP are not known, and point out that people using any psychiatric drug, natural or otherwise, should be under a doctor's supervision. [10]

Calcium

General

Name, Symbol, Number: calcium, Ca, 20

Chemical series alkaline earth metals

Group, Period, Block 2, 4, s

Appearance silvery white

Atomic mass 40.078(4) g/mol

Electron configuration [Ar] 4s2

Electrons per shell 2, 8, 8, 2

Physical properties

phase solid

Density (near r.t.) 1.55 g·cm3

Liquid Density at m.p. 1.378 g·cm3

Melting point 1115 K (842 °C, 1548 °F)

Boiling point1757 K (1484 °C, 2703 °F)

Heat of fusion 8.54 kJ·mol1

Heat of vaporization 154.7 kJ·mol1

Heat capacity (25 °C) 25.929 J·mol1·K1

Vapor pressure

P/Pa	1	10	100	1 k	10 k	100 k
at T/K	864	956	1071	1227	1443	1755

Atomic properties

Crystal structure cubic face centered

Oxidation states 2 (strongly basic oxide)

Electronegativity 1.00 (Pauling scale)

Ionization energies 1st: 589.8 kJ·mol1, 2nd: 1145.4 kJ·mol1, 3rd: 4912.4 kJ·mol1

Atomic radius 180 pm

Atomic radius (calc.) 194 pm

Covalent radius 174 pm

Miscellaneous

Magnetic ordering paramagnetic

Electrical resistivity (20 °C) 33.6 n©·m

Thermal conductivity (300 K) 201 W·m1·K1

Thermal expansion (25 °C) 22.3 µm·m1·K1

Speed of sound (thin rod) (20 °C) 3810 m/s

Young's modulus 20 GPa

Shear modulus 7.4 GPa

Bulk modulus 17 GPa

Poisson ratio 0.31

Mohs hardness 1.75

Brinell hardness 167 MPa

CAS registry number 7440-70-2

Selected isotopes

Calcium (IPA: /ÈkalsiYm/) is the chemical element in the periodic table that has the symbol Ca and atomic number 20. It has an atomic mass of 40.078. Calcium is a soft grey alkaline earth metal that is used as a reducing agent in the extraction of thorium, zirconium and uranium. Calcium is also the fifth most abundant element in the Earth's crust. It is essential for living organisms, particularly in cell physiology, and is the most common metal in many animals.

Notable characteristics

Calcium is a rather soft, gray, metallic element that can be extracted by electrolysis from calcium fluoride. It burns with a yellow-red flame and forms a white nitride coating when exposed to air. It reacts with water, displacing hydrogen and forming calcium hydroxide.

Calcium is essential in muscle contraction, oocyte activation, bones and tooth structure, blood clotting, nerve impulse transmission, regulating heartbeat, and fluid balance within cells. In the U.S., between about 50% and 75% of adults do not get sufficient calcium in their diet.[1] Adults need between 1,000 and 1,300 mg of calcium in their daily diet.[1]

The most abundant isotope, **40**Ca, has a nucleus of 20 protons and 20 neutrons. Its electron configuration is: 2 electrons in the K shell (principal quantum number 1), 8 in the L shell (principal quantum number 2), 8 in the M shell (principal quantum number 3), and 2 in the N shell (principal quantum number 4). The outer shell is the valence shell, with 2 electrons in the lone 4s orbital, the 3d orbitals being empty.

Occurrence

Calcium is not naturally found in its elemental state. Calcium is found mostly in soil systems as limestone, gypsum and fluorite. Stalagmites and stalactites contain calcium carbonate. Being an essential macromineral in the human diet, soil conservation practices often consider the sustainable equilibrium of calcium concentrations in the earth.

Applications

Uses include:

- as a reducing agent in the extraction of other metals, such as uranium, zirconium, and thorium.
- as a deoxidizer, desulfurizer, or decarbonizer for various ferrous and nonferrous alloys.
- as an alloying agent used in the production of aluminium, beryllium, copper, lead, and magnesium alloys.
- in the making of cements and mortars to be used in construction.

History

Calcium (Latin calcis, meaning "lime") was known as early as the first century when the Ancient Romans prepared lime as calcium oxide. It was not actually isolated until 1808 in England when Sir Humphry Davy electrolyzed a mixture of lime and mercuric oxide. Davy was trying to isolate calcium and when he heard that Berzelius and Pontin prepared calcium amalgam by electrolyzing lime in mercury, he tried it himself. He worked with electrolysis throughout his life and also discovered/isolated magnesium, strontium and barium.

Compounds

Calcium, combined with phosphate to form hydroxylapatite, is the mineral portion of human and animal bones and teeth. The mineral portion of some corals can also be transformed into hydroxylapatite.

Calcium oxide (lime) is used in many chemical refinery processes and is made by heating and carefully adding water to limestone. When lime is mixed with sand, it hardens into a mortar and is turned into plaster by carbon dioxide uptake. Mixed with other compounds, lime forms an important part of Portland cement.

When water percolates through limestone or other soluble carbonate rocks, it partially dissolves part of the rock and causes cave formation and characteristic stalactites and stalagmites and also forms hard water. Other important calcium compounds are nitrate, sulfide, chloride, carbide, cyanamide, and hypochlorite.

Isotopes

Calcium has four stable isotopes (40Ca and 42Ca through 44Ca), plus two more isotopes (46Ca and 48Ca) that have such long half-lives that for all practical purposes they can be considered stable. It also has a cosmogenic isotope, radioactive 41Ca, which has a half-life of 103,000 years. Unlike cosmogenic isotopes that are produced in the atmosphere, 41Ca is produced by neutron activation of **40**Ca. Most of its production is in the upper metre or so of the soil column where the cosmogenic neutron flux is still sufficiently strong. **41**Ca has received much attention in stellar studies because it decays to **41**K, a critical indicator of solar-system anomalies.

97% of naturally occurring calcium is in the form of **40**Ca. **40**Ca is one of the daughter products of **40**K decay, along with **40**Ar. While K-Ar dating has been used extensively in the geological sciences, the prevalence of 40Ca in nature has impeded its use in dating. Techniques using mass spectrometry and a double spike isotope dilution have been used for K-Ca age dating.

Nutrition

Calcium is an important component of a healthy diet. A deficit can affect bone and tooth formation, while overretention can cause kidney stones. Vitamin D is needed to absorb calcium. Dairy products, such as milk and cheese, are a well-known source of calcium. However, some individuals are allergic to dairy products and even more people, particularly those of non-European descent, are lactose-intolerant, leaving them unable to consume dairy products. Fortunately, many other good sources of calcium exist. These include: seaweeds such as kelp, wakame and hijiki; nuts and seeds (like almonds and sesame); beans; amaranth; collard greens; okra; rutabaga; broccoli; kale; and fortified products such as orange juice and soy milk. Calcium has also been found to assist in the production of lymphatic fluids.

Calcium is essential for the normal growth and maintenance of bones and teeth, and calcium requirements must be met throughout life. Requirements are greatest during periods of growth, such as childhood, during pregnancy and when breast-feeding. Long-term calcium deficiency can lead to osteoporosis, in which the bone deteriorates and there is an increased risk of fractures. Adults need between 1,000 and 1,300 mg of calcium in their daily diet.[1]

Recommended Adequate Intake by the IOM for Calcium:[1]

Age------------------------Calcium (mg/day)

0 to 6 months--------------210

7 to 12 months-------------270

1 to 3 years---------------500

4 to 8 years---------------800

9 to 13 years-------------1300

14 to 18 years------------1300

19 to 50 years------------1000

51+ years-----------------1200

For more information about calcium in living nature, see calcium in biology.

Dietary sources of calcium

Calcium is found in significant amounts in many foods, including broccoli, kale, dandelion greens, collard greens, almonds, sesame seeds, blackstrap molasses, beans, and fortified beverages such as soy milk and orange juice. The calcium content of most foods can be found in the USDA National Nutrient Database.[2]

Dairy products (such as milk, yogurt and cheese) do contain calcium, however they are not recommended as a dietary source because they contain a significant amount of saturated fat, which can contribute to cardiovascular disease. The calcium content of dairy products is also misleading because most of the calcium is used by the body in the digestion of milk protein (casein). This can lead to calcium deficiency and osteoporosis.

However, calcium in dairy products is usually absorbed more easily by the human body than the calcium in other sources such as plant based or dietary supplements.

Dietary calcium supplements

Calcium supplements are used to prevent and to treat calcium deficiencies. There are conflicting recommendations about when to take calcium supplements. However, most experts agree that no more than 500 mg should be taken at a time because the percent of calcium absorbed decreases as the amount of calcium in the supplement increases.[1] It is recommended to spread doses throughout the day, with the last dose near bedtime. Recommended daily calcium intake varies from 1000 to 1500 mg, depending upon the stage of life.

In July 2006, a report citing research from Fred Hutchinson Cancer Research Center in Seattle, Washington claimed that women in their 50's gained 5 pounds less in a period of 10 years by taking more than 500 mg of calcium supplements than those who did not. However, the doctor in charge of the study, Dr. Alejandro J. Gonzalez also noted it would be stretching it to suggest calcium supplements as a weight-limiting aid.[3]

- Calcium carbonate is the most common and least expensive calcium supplement. It can be difficult to digest and causes gas in some people. Taking magnesium with it can help to prevent constipation. Calcium carbonate is 40% elemental calcium. 1000 mg will provide 400 mg of calcium. It is recommended to take this supplement with food to aid in absorption. In some calcium supplements based on calcium carbonate, vitamin D is added to aid in absorption. Vitamin D is needed for the absorption of calcium from the stomach and for the functioning of calcium in the body.[4][5]
- Calcium citrate is more easily absorbed (bioavailability is 2.5 times higher than calcium carbonate), easier to digest and less likely to cause constipation and gas than calcium carbonate. It also has a lower risk of contributing to the formation of kidney stones. Calcium citrate is about 21% elemental calcium. 1000 mg will provide 210 mg of calcium. It is more expensive than calcium carbonate and more of it must be taken to get the same amount of calcium.

- Calcium phosphate costs more than calcium carbonate, but less than calcium citrate. It is easily absorbed and is less likely to cause constipation and gas than either.
- Calcium lactate and calcium aspartate are both more easily digested, but more expensive than calcium carbonate

Calcium in biology

Calcium plays a vital role in the anatomy, physiology and biochemistry of organisms and of the cell, particularly in signal transduction pathways. The skeleton acts as a major mineral storage site for the element and releases Ca2+ ions into the bloodstream under controlled conditions. Circulating calcium is either in the free, ionized form or bound to blood proteins such as albumin. The hormone secreted by the parathyroid gland, parathyroid hormone, regulates the resorption of Ca**2+** from bone.

Measuring Ca2+ in living tissue

The total amount of Ca**2+** present in a tissue may be measured using atomic absorption spectrometry, in which the tissue is vapourized and combusted. To measure Ca2+ in vivo, a range of fluorescent dyes may be used. These dyes are based on Ca2+-binding molecules such as BAPTA and so care is required in their use, because they may actually buffer the Ca**2+** changes which they are used to measure.

Organs and tissues

Different tissues contain Ca in different concentrations. In vertebrates Ca (mostly calcium phosphate and some calcium sulfate) is the most important (and specific) element of bone and calcified cartilage.

Some invertebrates use calcium compounds for building their exoskeleton (shells and carapaces) or endoskeleton (echinoderm plates and poriferan calcareous spicules). Many protists also make use of calcium.

There are also some plants that accumulate Ca in their tissues, thus making them more firm. Calcium is stored as Ca-oxalate crystals in plastids.

Cell biology

In eukaryotes, Ca^{2+} ions are one of the most widespread second messengers used in signal transduction. They make their entrance into the cytoplasm either from outside the cell through the cell membrane via calcium channels (such as Ca-binding proteins), or from some internal calcium storages.

Ca^{2+} entering the cell plasma causes the specific action of the cell, whatever this action is: secretory cells release vesicles with their secretion, muscle cells contract, synapses release synaptic vesicles and go into processes of synaptic plasticity, etc.

Calcium's function in muscle contraction was found as early as 1882 by Ringer and led the way for further investigations to reveal its role as a messenger about a century later. Because its action is interconnected with cAMP, they are called synarchic messengers. Calcium can bind to several different calcium-modulated proteins such as troponin-C (the first one to be identified) or calmodulin. The ions are stored in the sarcoplasmic reticulum of muscle cells.

The same Ca^{2+} ions can, however, bring damage to cells if there are too many of them (for example in the case of excitotoxicity, or overexcitation of neural circuits, which can occur after brain trauma or stroke). Excesses of calcium within a cell may damage it or even cause it to undergo apoptosis. One cause of hypercalcemia is hyperparathyroidism.

Calcium in plants

Structural roles

Ca^{2+} ions are an essential component of plant cell walls and cell membranes, and are used as cations to balance organic anions in the plant vacuole.[1] The Ca^{2+} concentration of the vacuole may reach millimolar levels. The most striking use of Ca^{2+} ions as a structural element in plants occurs in the marine coccolithophores, which use Ca^{2+} to form the calcium carbonate plates with which they are covered.

Cell signalling

Ca^{2+} ions are usually kept at nanomolar levels in the cytosol of plant cells, and act in a number of signal transduction pathways.

Food sources

The USDA web site has a very complete table of calcium content (in mg) of common foods per common measures (link below).

Calcium amount in foods, 100g:

- vaccine = 116 mg

human milk = 33 mg
milk powder = 909 mg
parmesan (cheese) = 1140 mg
ricotta (skimmed milk cheese) = 90 mg
egg, 1 = 54 mg
molasses = 273 mg
brown sugar = 85 mg
white sugar = 0 mg
honey = 5 mg
flour = 41 mg
wheat germ = 72 mg
beef = 12 mg
horse meat = 10 mg
cod = 11 mg
trout = 19 mg
hazels = 250 mg
almonds = 234 mg
nuts = 99 mg
lentils = 79 mg
Rice, white, long-grain, parboiled, enriched, cooked = 19 mg

Dietary fiber

Dietary fibres are the indigestible portion of plant foods that move food through the digestive system, absorbing water. Chemically, dietary fiber consists of non-starch polysaccharides and several other plant components such as cellulose, lignin, waxes, chitins, pectins, beta-glucans, inulin and oligosaccharides.

Uses

Soluble and insoluble fibres

Sources of dietary fibrer are usually divided into categories of “insoluble” and “soluble”. Both types are present in all plant foods, with varying degrees of each according to a plant’s characteristics. Insoluble refers to lack of solubility in water, but with passive water-attracting properties that help to increase bulk, soften stools and shorten transit time through the intestinal tract. Soluble indicates a fiber source that would readily dissolve in water.

As will be discussed here, those definitions are too limiting, especially because soluble fiber undergoes active metabolic processing via fermentation that yields end-products with broad, significant health effects.

To conceptualize insoluble and soluble fibers, consider the segments of a plum (or prune) — its thick skin covering a juicy pulp. The plum skin is an example of an insoluble fiber source, whereas soluble fiber sources are inside the pulp. Other sources of insoluble fiber include whole wheat, wheat and corn bran, flax seed lignans and vegetables such as carrots, celery, green beans and potato skins.

One of the most versatile sources of dietary fiber is the husk (hull) of seeds from psyllium grain (Plantago ovata), a fiber source with clinically demonstrated properties of lowering blood cholesterol when chronically included in human diets. Psyllium seed husk is 34% insoluble fiber and 66% soluble fiber, providing an optimal division of both types that make it a valuable food additive.

Fermentable fiber

The American Association of Cereal Chemists defined soluble fiber this way: “the edible parts of plants or similar carbohydrates resistant to digestion and absorption in the human small intestine with complete or partial fermentation in the large intestine”.

There are several key words in that statement that invite analysis and comment for considering fermentable fiber.

edible parts of plants — indicates that all parts of a plant we eat — skin, pulp, seeds, stems, leaves, roots — contain fiber. Both insoluble and soluble sources would be in those plant components.

carbohydrates — complex carbohydrates, such as long-chained sugars also called starch, oligosaccharides or polysaccharides, are excellent sources of fiber.

resistant to digestion and absorption in the human small intestine — foods providing nutrients are digested by enzymes and acids in the stomach and small intestine where the nutrients are released then absorbed through the intestinal wall for transport via the blood throughout the body. A food resistant to this process is undigested, as insoluble and soluble fibers are. They pass to the large intestine only affected by their absorption of water (insoluble fiber) or dissolution in water (soluble fiber).

complete or partial *fermentation* in the large intestine — the large intestine is comprised mainly of a segment called the colon within which additional nutrient absorption occurs

through the process of fermentation. Fermentation occurs by the action of colonic bacteria on the food mass, producing gases and short-chain fatty acids. It is these short-chain fatty acids — butyric, acetic, propionic, and valeric acids — that have such significant health properties.

Short-chain fatty acids

Short-chain fatty acids are used by the intestinal mucosa or absorbed through the colonic wall for portal circulation (supplying the liver) that transports them into the general circulation. Particularly butyric acid has extensive physiological actions that promote health effects among which are:

- Stabilize blood glucose levels by acting on pancreatic insulin release and liver control of glycogen breakdown
- Suppress cholesterol synthesis by the liver and reduce blood levels of low-density lipids (LDL cholesterol) and triglycerides responsible for atherosclerosis
- Lower colonic pH (i.e., raise the acidity levels in the colon) which protects the colon lining from cancer polyp formation and increases absorption of minerals
- Stimulate production of T helper cells, antibodies, leukocytes, splenocyte cytokines and lymph mechanisms having crucial roles in immune protection
- Increase proliferation of colonic bacteria beneficial for intestinal health — bifidobacteria and lactobacilli (serving a probiotic function)
- Improve barrier properties of the colonic mucosal layer, inhibiting inflammatory and adhesion irritants

Summarizing these effects, fermentable fibers yield the important short-chain fatty acids that affect blood glucose and lipid levels, improve the colonic environment and regulate immune responses.

Regulatory guidance on fiber products

On average, North Americans consume less than 50% of the dietary fiber levels required for good health. In the preferred food choices of today's youth, this value may be as low as 20%, a factor considered by experts as contributing to the obesity crisis seen in many first-world western countries.

Recognizing the growing scientific evidence for physiological benefits of increased fiber intake, regulatory agencies such as the US Food and Drug Administration (FDA) have given approvals to food products making health claims for fiber.

In clinical trials to date, these fiber sources were shown to significantly reduce blood cholesterol levels and so are important to cardiovascular health.

Soluble (fermentable) fiber sources gaining FDA approval are

- Psyllium seed husk (7 grams per day)

- Beta-glucan from oat bran, whole oats, oatrim or rolled oats (3 grams per day)
- Beta-glucan from whole grain or dry-milled barley (3 grams per day)

Other examples of fermentable fiber sources (from plant foods or biotechnology) used in functional foods and supplements include inulin, fructans, xanthan gum, cellulose, guar gum, fructooligosaccharides (FOS) and oligo- or polysaccharides.

Consistent intake of fermentable fiber through foods like berries and other fresh fruit, vegetables, whole grains, seeds and nuts is now known to reduce risk of some of the world's most prevalent diseases — obesity, diabetes, high blood cholesterol, cardiovascular disease, and numerous gastrointestinal disorders. In this last category are constipation, inflammatory bowel disease, ulcerative colitis, hemorrhoids, Crohn's disease, diverticulitis and colon cancer — all disorders of the intestinal tract where fermentable fiber can provide healthful benefits.

Although many researchers believe that dietary fiber intake reduces the risk of colon cancer, one study, conducted by researchers at the Harvard School of Medicine of over 88,000 women, did not show a statistically significant relationship between higher fiber consumption and lower rates of colorectal cancer or adenomas.[1]

Guidelines on fiber intake

The American Dietetic Association (ADA) recommends a minimum of 20-35 g/day for a healthy adult depending on calorie intake (e.g., a 2000 cal/8400 kj diet should include 25 g of fiber per day). The ADA's recommendation for a child was that intake should equal age in years plus 5 g/day for children (e.g., a 4 year old should consume 9 g/day). No guidelines have yet been established for the elderly or very ill. Patients with current constipation, vomiting, and abdominal pain should see a physician. Certain bulking agents are not commonly recommended with the prescription of opioids because the slow transit time mixed with larger stools may lead to severe constipation, pain, or obstruction.

The British Nutrition Foundation has recommended a minimum fiber intake of 12-24 g/day for healthy adults.

Sources of fiber

Current recommendations suggest that adults consume 20-35 grams of dietary fiber per day, but the average American's daily intake of dietary fiber is only 14-15 grams. The ADA recommends trying to get most of your dietary fiber from foods you eat, as an important part of consuming variety, nutrition, synergy between nutrients, and possibly phytonutrients. Soluble fiber is found in many foods, including:

- legumes (peas, soybeans, and other beans)

oats, rye, and barley
some fruits (particularly apples, bananas), and berries
certain vegetables, such as broccoli and carrots
root vegetables, such as potatoes and yams (the skins are insoluble fiber)
psyllium seed (only about T soluble fiber).

Legumes also typically contain shorter-chain carbohydrates that are indigestible by the human digestive tract but which are digested by bacteria in the large intestine (colon), which is a cause of flatulence.

Sources of insoluble fiber include

- whole grain foods

bran

nuts and seeds

vegetables such as green beans, cauliflower, zucchini, celery

the skins of some fruits, including tomatoes

Fiber supplements

There are many types of soluble fiber supplements available to consumers for nutritional purposes, for the treatment of various gastrointestinal disorders, and for such possible health benefits as lowering cholesterol levels, reducing the risk of colon cancer, or losing weight. Soluble fiber supplements are particularly beneficial for Irritable Bowel Syndrome symptoms such as diarrhea and/or constipation, and abdominal pain (Van Vorous, 2000). Prebiotic soluble fiber supplements (acacia, FOS, inulin) are a promising area of treatment for inflammatory bowel disease (Seidner, 2005) such as Crohn's disease and ulcerative colitis, and Clostridium difficile (May, 1994), due to the short-chain fatty acids they produce, and subsequent anti-inflammatory actions upon the bowel.

Psyllium husk

Psyllium seed husk (best known under the brand Metamucil). Psyllium husk may reduce the risk of heart disease by lowering cholesterol levels, and is known to help alleviate the symptoms of irritable bowel syndrome, though it often causes uncomfortable bloating. Psyllium husk is often labeled a "bulk-forming laxative", which can be misleading, because it can also help diarrhoea and it does not cause bowel dependency. Konsyl (Konsyl Pharmaceuticals) is another brand.

The FDA allows foods containing 0.75 g of psyllium husk fiber or 1.7 g of oat fiber to claim that they may be able to reduce the risk of heart disease (J Am Diet Assoc 2002).

Methylcellulose

Methylcellulose is created from the cell wall of plants. Sold as a powder, it is undigestible and doesn't have calories that humans can use. Citrucel (by GlaxoSmithKline), and Celevac (Shire) are popular brands of methylcellulose.

Polycarbophil

Vegetable gums

Vegetable gum fiber supplements are relatively new to the market. Often sold as a powder, vegetable gum fibers dissolve easily with no aftertaste. They are effective for the treatment of Irritable Bowel Syndrome (Parisi, 2002)[verification needed]. Examples of vegetable gum fibers are guar gum (brand name Benefiber) and acacia gum (brand name Heather's Tummy Fiber).

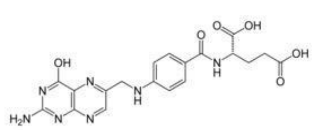
Folic acid



Systematic name

N-[4(2-Amino-4-hydroxy-
pteridin-6-ylmethylamino)-
benzoyl]-L(+)-glutamic acid.

Other names

pteroyl-L-glutamic acid,
Vitamin B9, Vitamin M,
Folacin

Molecular formula $C_{19}H_{19}N_{7}O_{6}$

SMILES

*C1=CC(=CC=C1C(=O)NC
(CCC(=O)O)C(=O)O)
NCC2=CN=C3C(=N2)
C(=O)N=C(N3)N*

Molar mass 441.1396 g/mol

Appearance yellow-orange, crystalline powder

CAS number [59-30-3]

Properties

Solubility in water 8.5 g/100 ml (20 °C)

In ethanol, ether, acetone insoluble

Melting point 250 °C (523 K), decomp.

Acidity (pK_a) 1st: 2.3, 2nd: 8.3

Chiral rotation $[\pm]_D$ +23°
0.5% in 0.1 M NaOH

Hazards

Main hazards non-toxic, non-flammable

R/S statement R: - S: 24/25

RTECS number LP5425000

UV-Vis

Lambda-max (pH 13)

259 nm
368 nm

Extinction coefficient (pH 13)

32340 (259 nm)
7410 (368 nm)

Salts sodium folate

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

Folic acid and *folate* (the anion form) are forms of a water-soluble B vitamin. These occur naturally in food and can also be taken as supplements. Folate gets its name from the Latin word folium, leaf.

Folate in foods

Leaf vegetables such as spinach and turnip greens, dried beans and peas, fortified cereal products, sun flower seeds and some other fruits and vegetables are rich sources of folate. Some breakfast cereals (ready-to-eat and others) are fortified with 25 percent or 100 percent of the recommended dietary allowance (RDA) for folic acid. A table of selected food sources of folate and folic acid can be found at the USDA National Nutrient Database for Standard Reference.

Recently there have been debates in the United Kingdom [1] and Australasia [2]about including folic acid in products such as bread and flour. Experts claim that this will decrease the number of babies with disabilities such as spina bifida. Research suggests high levels of folic acid can interfere with some antimalarial treatments. [3]

History

A key observation of researcher Lucy Wills in 1931 led to the identification of folate as the nutrient needed to prevent the anemia of pregnancy. Dr. Wills demonstrated that the anemia could be corrected by brewer's yeast. Folate was identified as the corrective substance in brewer's yeast in the late 1930s and was extracted from spinach leaves in 1941. It was synthesised in 1946.

Biological roles

Folate is necessary for the production and maintenance of new cells.[4] This is especially important during periods of rapid cell division and growth such as infancy and pregnancy. Folate is needed to replicate DNA. It also helps prevent changes to DNA that may lead to cancer. Thus folate deficiency hinders DNA synthesis and cell division, affecting most clinically the bone marrow, a site of rapid cell turnover. Because RNA and protein synthesis are not hindered, large red blood cells called megaloblasts are produced, resulting in megaloblastic anemia.[5] Both adults and children need folate to make normal red blood cells and prevent anemia.[6]

Biochemistry

In the form of a series of tetrahydrofolate compounds, folate derivatives are substrates in a number of single-carbon-transfer reactions, and also are involved in the synthesis of dTMP (2'-deoxythymidine-5'-phosphate) from dUMP (2'-deoxyuridine-5'-phosphate). It helps convert vitamin B12 to one of its coenzyme forms and helps synthesize the DNA required for all rapidly growing cells.

The pathway in the formation of tetrahydrofolate (FH***4***) is the reduction of folate (F) to dihydrofolate (FH***2***) and then the subsequent reduction of dihydrofolate to tetrahydrofolate (FH4). Both these sequential reactions are carried out by dihydrofolate reductase EC 1.5.1.3.

Methylene tetrahydrofolate (CH***2***FH***4***) is formed from tetrahydrofolate by the addition of methylene groups from one of three carbon donors: formaldehyde, serine, or glycine. *Methyl tetrahydrofolate* (CH***3***–FH***4***) can be made from methylene tetrahydrofolate by reduction of the methylene group, and *formyl tetrahydrofolate* (CHO-FH***4***, folinic acid) is made by oxidation of methylene tetrahydrofolate.

In other words:

F ’ FH***2*** ’ FH***4*** ’ CH***2***=FH***4*** ’ 1-carbon chemistry

A number of drugs interfere with the biosynthesis of folic acid and tetrahydrofolate. Among them are the dihydrofolate reductase inhibitors (such as trimethoprim and pyrimethamine), the sulfonamides (competitive inhibitors of para-aminobenzoic acid in the reactions of dihydropteroate synthetase), and the anticancer drug methotrexate (inhibits both folate reductase and dihydrofolate reductase).

Recommended Dietary Allowance for folate

The Recommended Dietary Allowance (RDA) is the average daily dietary intake level that is sufficient to meet the nutrient requirements of nearly all (97 to 98 percent) healthy individuals in each life-stage and gender group. The 1998 RDAs for folate are expressed in a term called the Dietary Folate Equivalent (DFE). This was developed to help account for the differences in absorption of naturally-occurring dietary folate and the more bioavailable synthetic folic acid.[7] The 1998 RDAs for folate expressed in micrograms (µg) of DFE for adults are:

1998 RDAs for Folate

Men	Women		
(19+)	(19+)	Pregnancy	Breast feeding
400 µg	400 µg	600 µg	500 µg
1 µg of food folate = 0.6 µg folic acid from supplements and fortified foods			

The National Health and Nutrition Examination Survey (NHANES III 1988-91) and the Continuing Survey of Food Intakes by Individuals (1994-96 CSFII) indicated that most adults did not consume adequate folate.[8][9] However, the folic acid fortification program in the United States has increased folic acid content of commonly eaten foods such as cereals and grains, and as a result diets of most adults now provide recommended amounts of folate equivalents.[10]

Folic acid and pregnancy

Folic acid is very important for all women who may become pregnant. Adequate folate intake during the periconceptional period, the time just before and just after a woman becomes pregnant, helps protect against a number of congenital malformations including neural tube defects.[11] Neural tube defects result in malformations of the spine (spina bifida), skull, and brain (anencephaly). The risk of neural tube defects is significantly reduced when supplemental folic acid is consumed in addition to a healthy diet prior to and during the first month following conception.[12][13] Women who could become pregnant are advised to eat foods fortified with folic acid or take supplements in addition to eating folate-rich foods to reduce the risk of some serious birth defects. Taking 400 micrograms of synthetic folic acid daily from fortified foods and/or supplements has been suggested. The Recommended Dietary Allowance (RDA) for folate equivalents for pregnant women is 600 micrograms.

Folic acid supplements and masking of B*12* deficiency

There has been concern about the interaction between vitamin B12 and folic acid. Folic acid supplements can correct the anemia associated with vitamin B12 deficiency. Unfortunately, folic acid will not correct changes in the nervous system that result from vitamin B12 deficiency. Permanent nerve damage could theoretically occur if vitamin B12 deficiency is not treated. Therefore, intake of supplemental folic acid should not exceed 1000 micrograms (1000 mcg or 1 mg) per day to prevent folic acid from masking symptoms of vitamin B***12*** deficiency. In fact, evidence that such masking actually occurs is scarce, and there is no evidence that folic acid fortification in Canada or the US has increased the prevalence of vitamin B***12*** deficiency or its consequences.

Still it is important for older adults to be aware of the relationship between folic acid and vitamin B***12*** because they are at greater risk of having a vitamin B***12*** deficiency. If you are 50 years of age or older, ask your physician to check your B***12*** status before you take a supplement that contains folic acid.

Health risk of too much folic acid

The risk of toxicity from folic acid is low.[14] The Institute of Medicine has established a tolerable upper intake level (UL) for folate of 1,000 µg for adult men and women, and a UL of 800 µg for pregnant and lactating (breast-feeding) women less than 18 years of age. Supplemental folic acid should not exceed the UL to prevent folic acid from masking symptoms of vitamin B_{12} deficiency.[15]

Some current issues and controversies about folate

Dietary fortification of folic acid

Since the discovery of the link between insufficient folic acid and neural tube defects (NTDs), governments and health organisations worldwide have made recommendations concerning folic acid supplementation for women intending to become pregnant. For example, the United States Public Health Service (see External links) recommends an extra 0.4 mg/day, which can be taken as a pill. However, many researchers believe that supplementation in this way can never work effectively enough since not all pregnancies are planned and not all women will comply with the recommendation.

This has led to the introduction in many countries of fortification, where folic acid is added to flour with the intention of everyone benefiting from the associated rise in blood folate levels. This is not uncontroversial, with issues having been raised concerning individual liberty, and the masking effect of folate fortification on pernicious anaemia (vitamin B12 deficiency). However, most North and South American countries now fortify their flour, along with a number of Middle Eastern countries and Indonesia. Mongolia and a number of ex-Soviet republics are amongst those having widespread voluntary fortification; about five more countries (including Morocco, the first African country) have agreed but not yet implemented fortification. Previously, the UK had decided not to fortify, mainly because of the vitamin B12 concern. However, this decision is currently being reconsidered by the Food Standards Agency. Thus far, no EU country has yet fortified. Australia is considering fortification, but a period for comments ending 31 July 2006 attracted strong opposition from industry as well as academia.[16]

In 1996, the United States Food and Drug Administration (FDA) published regulations requiring the addition of folic acid to enriched breads, cereals, flours, corn meals, pastas, rice, and other grain products.[17][18] This ruling took effect 1998-01-01, and was specifically targeted to reduce the risk of neural tube birth defects in newborns.[19] There are concerns that the amount of folate added is insufficient[2]. In October 2006, the Australian press claimed that U.S. regulations requiring fortification of grain products were being interpreted as disallowing fortification in non-grain products, specifically Vegemite (an Australian yeast extract containing folate). The FDA later said the report was inaccurate, and no ban or other action was being taken against Vegemite.

Since the folic acid fortification program took effect, fortified foods have become a major source of folic acid in the American diet. The Centers for Disease Control and Prevention in Atlanta, Georgia used data from 23 birth defect registries that cover about half of United States births and extrapolated their findings to the rest of the country. This data indicates that since the addition of folic acid in grain-based foods as mandated by the Food and Drug Administration, the rate of neural tube defects dropped by 25 percent in the United States.[20]

Although folic acid does reduce the risk of birth defects, it is only one part of the picture and should not be considered a cure. Even women taking daily folic acid supplements have been known to have children with neural tube defects.

Folic acid and heart disease

Low concentrations of folate, vitamin B***12***, or vitamin B***6*** may increase your level of homocysteine, an amino acid normally found in your blood. There is evidence that an elevated homocysteine level is an independent risk factor for heart disease and stroke.[21] The evidence suggests that high levels of homocysteine may damage coronary arteries or make it easier for blood clotting cells called platelets to clump together and form a clot.[22] However, there is currently no evidence available to suggest that lowering homocysteine with vitamins will reduce your risk of heart disease. Clinical intervention trials are needed to determine whether supplementation with folic acid, vitamin B***12*** or vitamin B***6*** can lower your risk of developing coronary heart disease. The NORVIT trialsuggests that folic acid supplementation may do more harm than good.

As of 2006, studies have shown that giving folic acid to reduce levels of homocysteine does not result in clinical benefit and suggests that in combination with B***12*** may even increase some cardiovascular risks.[23][24][25]

Folic acid and cancer

Some evidence associates low blood levels of folate with a greater risk of cancer.[26] Folate is involved in the synthesis, repair, and functioning of DNA, our genetic map, and a deficiency of folate may result in damage to DNA that may lead to cancer.[27] Several studies have associated diets low in folate with increased risk of breast, pancreatic, and colon cancer.[28] Findings from a study of over 121,000 nurses suggested that long-term folic acid supplementation (for 15 years) was associated with a decreased risk of colon cancer in women 55 to 69 years of age.[29]

"Folate intake counteracts breast cancer risk associated with alcohol consumption" [30] and "women who drink alcohol and have a high folate intake are not at increased risk of cancer" [31]. Those who have a high (200 micrograms or more per day) level of folate (folic acid or Vitamin B9) in their diet are not at increased risk of breast cancer compared to those who abstain from alcohol [32].

However, associations between diet and disease do not indicate a direct cause. Researchers are continuing to investigate whether enhanced folate intake from foods or folic acid supplements may reduce the risk of cancer. Until results from such clinical trials are available, folic acid supplements should not be recommended to reduce the risk of cancer.

Folic acid and methotrexate for cancer

Folate is important for cells and tissues that rapidly divide.[4] Cancer cells divide rapidly, and drugs that interfere with folate metabolism are used to treat cancer. Methotrexate is a drug often used to treat cancer because it inhibits the production of the active form, tetrahydrofolate. Unfortunately, methotrexate can be toxic,[33][34][35] producing side effects such as inflammation in the digestive tract that make it difficult to eat normally.

Folinic acid is a form of folate that can help "rescue" or reverse the toxic effects of methotrexate.[36] Folinic acid is not the same as folic acid. Folic acid supplements have little established role in cancer chemotherapy.[37][38] There have been cases of severe adverse effects of accidental substitution of folic acid for folinic acid in patients receiving methotrexate cancer chemotherapy. It is important for anyone receiving methotrexate to follow medical advice on the use of folic or folinic acid supplements.

Folic acid and methotrexate for non-cancerous diseases

Low dose methotrexate is used to treat a wide variety of non-cancerous diseases such as rheumatoid arthritis, lupus, psoriasis, asthma, sarcoidoisis, primary biliary cirrhosis, and inflammatory bowel disease.[39] Low doses of methotrexate can deplete folate stores and cause side effects that are similar to folate deficiency. Both high folate diets and supplemental folic acid may help reduce the toxic side effects of low dose methotrexate without decreasing its effectiveness.[40][41] Anyone taking low dose methotrexate for the health problems listed above should consult with a physician about the need for a folic acid supplement.

Folic acid and depression

Some evidence links low levels of folate with depression.[42] There is some limited evidence from randomised controlled trials that using folic acid in addition to antidepressant medication may have benefits.[43] However, the evidence is probably too limited at present for this to be a routine treatment recommendation.

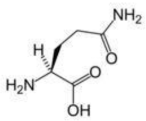
Glutamine



Chemical structure of L-glutamine

Systematic name (2S)-2-amino-4-carbamoyl-butanoic acid

Chemical formula $C_5H_{10}N_2O_3$

Molar mass 146.15 g mol1

Glutamine (Gln) is one of the 20 amino acids encoded by the standard genetic code. Its side chain is an amide; it is formed by replacing a side-chain hydroxyl of glutamic acid with an amine functional group.

Biochemistry

Formation and Nomenclature

Glutamine is genetically coded for by the RNA codons CAA and CAG. Glutamine's three-letter abbreviation is *Gln*, and its one-letter abbreviation is *Q*. A three-letter designation for either glutamine or glutamic acid is *Glx* (one-letter abbreviation: *Z*).

Like other amino acids, glutamine is biochemically important as a constituent of proteins. Glutamine is also crucial in nitrogen metabolism. Ammonia (formed by nitrogen fixation) is assimilated into organic compounds by converting glutamic acid to glutamine. The enzyme that accomplishes this is called glutamine synthetase. Glutamine can, hence, be used as a nitrogen donor in the biosynthesis of many compounds, including other amino acids, purines, and pyrimidines.

Nutrition

Occurrences in Nature

Glutamine is found in foods high in proteins, such as fish, red meat, beans, and dairy products.

Use

Glutamine is a supplement that is used in weightlifting, bodybuilding, endurance and other sports, as well as by those who suffer from muscular cramps or pain—particularly elderly people. It has been shown to speed up the Krebs Cycle, aiding in weight loss while retaining muscle[citation needed]. The main use of glutamine within the diet of either group

is as a means of replenishing the body's stores of amino acids that have been used during exercise or everyday activities.

Studies which are looking into problems with excessive consumption of glutamine thus far have proved inconclusive. However, normal supplementation is healthy mainly because glutamine is supposed to be supplemented after prolonged periods of exercise (for example, a workout or exercise in which amino acids are required for use) and replenishes amino acid stores; this being the main reason glutamine is recommended during fasting or for people who suffer from physical trauma, immune deficiencies, or cancer.[1]

Aiding gastrointestinal function

There have been several recent studies into the effects of glutamine and what properties it possesses, and, there is now a significant body of evidence that links glutamine-enriched diets with intestinal effects; aiding maintenance of gut barrier function, intestinal cell proliferation and differentiation, as well as generally reducing septic morbidity and the symptoms of Irritable Bowel Syndrome. The reason for such "cleansing" properties is thought to stem from the fact that the intestinal extraction rate of glutamine is higher than that for other amino acids, and is therefore thought to be the most viable option when attempting to alleviate conditions relating to the gut. [1]

These conditions were discovered after comparing plasma concentration within the gut between glutamine-enriched and non glutamine-enriched diets. However, even though glutamine is thought to have "cleansing" properties and effects, it is unknown to what extent glutamine has clinical benefits, due to the varied concentrations of glutamine in varieties of food. [1]

Aiding recovery after surgery

It is also known that glutamine has various effects in reducing healing time after operations. Hospital waiting times after abdominal surgery are reduced by providing parenteral nutrition regimens containing amounts of glutamine to patients. Clinical trials have revealed that patients on supplementation regimes containing glutamine have improved nitrogen balances, generation of cysteinyl-leukotrienes from polymorphonuclear neutrophil granulocytes and improved lymphocyte recovery and intestinal permeability (in postoperative patients) - in comparison to those who had no glutamine within their dietary regime; all without any side-effects. [3]

Linseed oil

Linseed oil is a yellowish drying oil derived from the dried ripe seeds of the flax plant (Linum usitatissimum, Linaceae). It is obtained by pressing, followed by an optional stage of solvent extraction. Cold-pressed oil obtained without solvent extraction is marketed as *flaxseed oil*.

Uses

As a paint binder

Linseed oil is the most commonly used carrier in oil paint. It can also be used as a painting medium, and is available in varieties such as Cold Pressed, Bleached and Refined.

As a wood finish

When used as a wood finish, linseed oil does not cover the surface as varnish does, but soaks into the (visible and microscopic) pores, leaving a shiny but not glossy surface that shows off the grain. Wood treated with linseed oil only is resistant to denting, and scratches are easily repaired, but the wood and oil surface is not as hard as a modern varnish, and it slowly absorbs moisture if allowed to stay wet. Soft wood benefits from the protection from denting but requires more applications and even more drying time than harder wood does, if the grain is to be completely filled. The oil penetrates deeply and fills the grain, because it dries slowly and shrinks little or not at all on hardening. It is a traditional finish for gun stocks, however a very fine finish may require months to obtain. Oiled wood is yellowish and darkens with age.

As a nutritional supplement

Flaxseed oil is suitable for human consumption, and is used as a nutritional supplement. It is rich in omega-3 fatty acids, especially alpha-linolenic acid, which appears to be beneficial for heart disease, inflammatory bowel disease, arthritis and a variety of other health conditions. Flaxseed also contains a group of chemicals called lignans that may play a role in the prevention of cancer.[1]

Additional uses

- Animal feeds

Putty
Sealants
Caulking compounds
Brake linings
Linoleum
Earthen floors
Textiles
Bicycle maintenance as a thread fixative, rust inhibitor and lubricant for the spokes of bicycle wheels
Foundry products
Leather treatment
Polishes, varnishes and oil paints
Animal care products
Wood preservation
Synthetic resins
Treatment for the raw willow wood used to make cricket bats. Linseed oil has a special cultural place in cricket-playing countries.

Boiled linseed oil

Boiled linseed oil is used as a paint binder or as a wood finish on its own. Heating the oil makes it polymerize or oxidise more readily, effectively shortening the drying time. Today most products labeled as "boiled linseed oil" are a combination of raw linseed oil, petroleum-based solvent and metallic dryers. The use of metallic dryers makes boiled linseed oil inedible. There are some products available that contain only heat-treated linseed oil. These are usually labeled as "polymerized" oils though some may still be labeled as boiled.

Nutrient content

Nutrition information from a typical commercially available flaxseed oil:
Per 1 Tbsp (14 g)

- Calories: 130
- Calories from fat:130
- Total fat: 14g
- Omega-3: 8g
- Omega-6: 2g
- Omega-9: 3g

Erectile dysfunction drugs

Impotence of organic origin

Classifications and external resources

ICD-10

N48.4

ICD-9

607.84

Erectile dysfunction (*ED*) or *impotence* is a sexual dysfunction characterized by the inability to develop or maintain an erection of the penis for satisfactory sexual intercourse regardless of the capability of ejaculation. There are various underlying causes, such as diabetes, many of which are medically reversible.

The causes of erectile dysfunction may be physiological or psychological. Psychological impotence can often be helped by almost anything that the patient believes in; there is a very strong placebo effect.

Due to its embarrassing nature and the shame felt by sufferers, the subject was taboo for a long time, and is the subject of many urban legends. Folk remedies have long been advocated, with some being advertised widely since the 1930s. The introduction of perhaps the first pharmacologically effective remedy for impotence, sildenafil (trade name Viagra), in the 1990s caused a wave of public attention, propelled in part by the news-worthiness of stories about it and heavy advertising.

The Latin term impotentia coeundi describes simple inability to insert the penis into the vagina. It is now mostly replaced by more precise terms.

Medical symptoms

Erectile dysfunction is characterized by the inability to maintain an erection. Normal erections during sleep and in the early morning suggest a psychogenic cause, while loss of these erections may signify underlying disease, often cardiovascular in origin. Other factors leading to erectile dysfunction are diabetes mellitus (causing neuropathy) or hypogonadism (decreased testosterone levels due to disease affecting the testicles or the pituitary gland).

Medical diagnosis

There are no formal tests to diagnose erectile dysfunction. Some blood tests are generally done to exclude underlying disease, such as diabetes, hypogonadism and prolactinoma. Impotence is also related to generally poor physical health, poor dietary habits, obesity, and

most specifically cardiovascular disease such as coronary artery disease and peripheral vascular disease.

A useful and simple way to distinguish between physiological and psychological impotence is to determine whether the patient ever has an erection. If never, the problem is likely to be physiological; if sometimes (however rarely), it is more likely to be psychological. The current diagnostic and statistical manual of mental diseases (DSM-IV) has included a listing for impotence.

Clinical tests used to diagnose ED

Duplex ultrasound Duplex ultrasound is used to evaluate blood flow, venous leak, signs of atherosclerosis, and scarring or calcification of erectile tissue. Injecting prostaglandin, a hormone-like stimulator produced in the body, induces erection. Ultrasound is then used to see vascular dilation and measure penile blood pressure. Measurements are compared to those taken when the penis is flaccid.

Penile nerves function Tests such as the bulbocavernosus reflex test are used to determine if there is sufficient nerve sensation in the penis. The physician squeezes the glans (head) of the penis, which immediately causes the anus to contract if nerve function is normal. A physician measures the latency between squeeze and contraction by observing the anal sphincter or by feeling it with a gloved finger inserted past the anus. Specific nerve tests are used in patients with suspected nerve damage as a result of diabetes or nerve disease.

Nocturnal penile tumescence (NPT) It is normal for a man to have five to six erections during sleep, especially during rapid eye movement (REM). Their absence may indicate a problem with nerve function or blood supply in the penis. There are two methods for measuring changes in penile rigidity and circumference during nocturnal erection: snap gauge and strain gauge.

Penile biothesiometry This test uses electromagnetic vibration to evaluate sensitivity and nerve function in the glans and shaft of the penis. A decreased perception of vibration may indicate nerve damage in the pelvic area, which can lead to impotence.

Penile Angiogram Invasive test - allows visualization of the circulation in the penis and is used during the repair of a priapism.

Dynamic Infusion Cavernosometry (Abbreviated DICC) technique in which fluid is pumped into the penis at a known rate and pressure. It gives a measurement of the vascular pressure in the corpus cavernosum during an erection. To do this test, a vasodilator like prostaglandin E-1 is injected to measure the rate of infusion required to get a rigid erection and to help find how severe the venous leak is.

Corpus Cavernosometry Cavernosography is an adjunct to Dynamic Infusion Cavernosometry, where a contrast material is injected and then it is x-rayed to visualize any leakage.

Digital Subtration Angiography In DSA, the images are acquired digitally. The computer crates a mask from lower-contrast x-rays of the same area and digitally isolates the blood vessels (this is done manually through darkroom masking with traditional angiography).

Magnetic resonance angiography (MRA) This is similar to magnetic resonance imaging. Magnetic resonance angiography uses magnetic fields and radio waves to provide detailed images of the blood vessels. Doctors may inject a "contrast agent" into the patient's

bloodstream that causes vascular tissues to stand out against other tissues. The contrast agent provides for enhanced information regarding blood supply and vascular anomalies. Aside from the IV used to introduce the contrast material into the bloodstream, magnetic resonance angiography is noninvasive and painless.

Pathophysiology

Penile erection is managed by two different mechanisms. The first one is the reflex erection, which is achieved by directly touching the penile shaft. The second is the psychogenic erection, which is achieved by erotic stimuli. The former uses the peripheral nerves and the lower parts of the spinal cord, whereas the latter uses the limbic system of the brain. In both conditions an intact neural system is required for a successful and complete erection. Stimulation of penile shaft by the nervous system leads to the secretion of nitric oxide (NO), which causes the relaxation of smooth muscles of corpora cavernosa (the main erectile tissue of penis), and subsequently penile erection. Additionally, adequate levels of testosterone (produced by the testes) and an intact pituitary gland are required for the development of a healthy male erectile system. As can be understood from the mechanisms of a normal erection, impotence may develop due to hormonal deficiency, disorders of the neural system, lack of adequate penile blood supply or psychological problems. Restriction of blood flow can arise from impaired endothelial function due to the usual causes associated with coronary artery disease, but can also include causation by prolonged exposure to bright light or chronic exposure to high noise levels.

A few causes of impotence may be iatrogenic (medically caused). Various antihypertensives (medications intended to control high blood pressure) and some drugs that modify central nervous system response may inhibit erection by denying blood supply or by altering nerve activity. Antidepressants, especially SSRIs, can cause impotence as a side effect. Surgical intervention for a number of different conditions may remove anatomical structures necessary to erection, damage nerves, or impair blood supply. Some studies have shown that male circumcision may result in an increased risk of impotence,[1][2] while others have found no such effect,[3][4][5] and another found the opposite.[6]

Excessive alcohol use has long been recognised as one cause of impotence, leading to the euphemism "brewer's droop"; Shakespeare made light of this phenomenon in Macbeth.

A study in 2002 found that ED can also be associated with bicycling. The number of hours on a bike and/or the pressure on the penis from the saddle of an upright bicycle is directly related to erectile dysfunction.[7]

Treatment

Treatment depends on the cause. Testosterone supplements may be used for cases due to hormonal deficiency. However, the cause is more usually lack of adequate penile blood supply as a result of damage to inner walls of blood vessels. This damage is more frequent in older men, and often associated with disease, in particular diabetes.

Treatments (with the exception of testosterone supplementation, where effective) work on a temporary basis: they enable an erection to be attained and maintained long enough for intercourse, but do not permanently improve the underlying condition.

ED can in many cases be treated by drugs taken orally, injected, or as penile suppositories. These drugs increase the efficacy of NO, which dilates the blood vessels of corpora cavernosa. When oral drugs or suppositories fail, injections (e.g. of apomorphine) into the erectile tissue of the penile shaft may work.

When pharmacological methods fail, a purpose-designed external vacuum pump can be used to attain erection, with a separate compression ring fitted to the penis to maintain it. These pumps should be distinguished from other "penis pumps" (supplied without compression rings) which, rather than being used for temporary treatment of impotence, are claimed to increase penis length if used frequently, or vibrate as an aid to masturbation.

More drastically, inflatable or rigid penile implants may be fitted surgically. Implants are irreversible and costly.

All these mechanical methods are based on simple principles of hydraulics and mechanics and are quite reliable, but have their disadvantages.

In a few cases there is a vascular problem which can be treated surgically.

Uncontroversial treatments

PDE5 Inhibitors The prescription PDE5 inhibitors sildenafil (Viagra®), vardenafil (Levitra®) and tadalafil (Cialis®) are prescription drugs which are taken orally. They work by blocking the action of PDE5, which causes cGMP to degrade. cGMP causes the smooth muscle of the arteries in the penis to relax, allowing the corpus cavernosum to fill with blood.

Vacuum pump An external vacuum pump will produce an engorged penis with success approaching 90%; a penis ring will maintain this state, although it should be removed after not more than 30 minutes. The erection is not as rigid or hard as a natural erection; drugs or injections, when they work, may be preferable. Various studies show the degree of satisfaction of users and their partners to be vary variable, even when drugs and injections do not work; in one study, about 20% of men who tried a (high-priced) pump decided to proceed to purchase one. Other studies show higher percentages of satisfied users. In some cases frequent use of a vacuum pump can eventually improve the degree of erection attainable without use of the pump. Claims of cheap "penis pumps" to permanently increase maximum penis size should be viewed with caution, however. Some vacuum pumps, such as Osbon ErecAid, are sold at a higher price with 100% refund within 90 days to dissatisfied users, with a somewhat lower price with 50% refund guarantee.[8]This pump is supported by medical insurance schemes, including the UK's NHS and US Medicare and private insurers. The better-known pumps sell for prices of around 200 GBP/400 USD (2006). There is at least one vacuum pump with rings which sells for around one-fifth of this price.[9] (Specific devices are mentioned for information only; mention should not be taken as endorsement).

Inflatable implant
Rigid implant
Surgical treatment of certain cases

Controversial and unapproved treatments

Bremelanotide The experimental drug Bremelanotide (formerly PT-141) does not act on the vascular system like the former compounds but allegedly increases sexual desire and drive in males as well as females. It is applied as a nasal spray. Bremelanotide allegedly works by activating melanocortin receptors in the brain. It is currently in Phase IIb trials.

hMaxi-K hMaxi-K is a form of gene therapy using a plasmid vector that expresses the hSlo gene, that encodes the alpha-subunit of the Maxi-K channel. It has undergone phase I safety trials.[10]

Ginseng A double-blind study appears to show evidence that ginseng is better than placebo: see the ginseng article for more details.

Enzyte Enzyte is a product that has been advertised by saturation coverage on television channels such as CourtTV. However, the Center for Science in the Public Interest (CSPI) has filed a complaint with the Federal Trade Commission (FTC) about Enzyte for deceptive advertising. It is manufactured by Berkeley Nutritionals, which is alleged to be the subject of an investigation by the Attorney General of Ohio and the defendant in class-action lawsuits. Enzyte is a supplement that claims to increase the male libido or frequency of erections of the penis. Commercials for Enzyte are shown regularly on television. These commercials feature a man named Bob who never stops smiling, apparently because he had taken Enzyte and improved the size of his sex organs. The commercials are riddled with symbolic phallic imagery, e.g. golf clubs, remarkably tall glasses of iced tea, and a hose spraying barely a trickle of water (carried by someone who doesn't use Enzyte). The effectiveness of Enzyte is in dispute. Some medical professionals in fact advise against taking Enzyte, saying that it can lead to damage. The Center for Science in the Public Interest have urged the Federal Trade Commission to disallow further television advertising for Enzyte due to a lack of proper studies supporting claims. Enzyte maker Berkeley Premium Nutraceuticals, Inc., is currently under a class action lawsuit for false advertising. Enzyte is said to contain: Tribulus terrestris; Yohimbe Extract; Niacin; Epimedium; Avena sativa; Zinc Oxide; Maca; Muira Pauma; Ginkgo biloba; L-Arginine; Saw Palmetto. Other ingredients: gelatin, rice bran, oat fiber, magnesium stearate, silicon dioxide.

Herbal and other alternative treatments These are generally ineffective when tested blind, but may be useful for their psychological (placebo) effect: if a good result is expected, any highly-praised, and often expensive, treatment can be effective. Reputable drugs can also benefit from the same effect.

Prelox Prelox is a Proprietary mix/combination of naturally occurring ingredients, L-arginine aspartate and Pycnogenol. In double blind tests carried out by Dr. Steven Lamm at New York University School of Medicine, 81.1% of men overall judged Prelox to be effective in improving their ability to engage in sexual activity.Prelox® for improvement of erectile function: A review European Bulletin of Drug Research, Volume 11, No. 3, 2003. Steven Lamm, Frank Schoenlau, Peter Rohdewald Whilst the supplements should be taken daily, the manufacturers claim that it brings the spontaneity back into ones' love life; unlike other products which must be remembered to be taken a fixed time before sexual activity.

History

Dr. John R. Brinkley began a fad for finding cures for male impotence during the 1930s. He used the medium of radio to achieve the same kind of advertising boom to treat the same kind of symptoms.

In the 1930s the American radio airwaves were bombarded with such advertising, first from domestic stations and then upon action by the American Medical Association the media blitz was shifted to superpower Mexican border-blasters.

Surgeons began providing patients with inflatable penile implants in the 1970s.

Modern drug therapy for ED made a significant advance in 1983 when British physiologist Giles Brindley, Ph.D. dropped his trousers and demonstrated to a shocked American Urological Association audience his phentolamine-induced erection. The drug Brindley injected into his penis was a non-specific vasodilator, an alpha-blocking agent, and the mechanism of action was clearly corporal smooth muscle relaxation. The effect that Brindley discovered, established the fundamentals for the later development of specific, safe, orally-effective drug therapies.[11]

Prevalence

The ability to achieve “erection stiffness sufficient for penetration and intercourse” (impotence) decreases with age. Of men aged 50-80 years 30% are impotent. In the age group 70-80 years approximately 50% are unable to achieve erection sufficient for intercourse without treatment (technical support).

PDE5 inhibitors

A *phosphodiesterase type 5 inhibitor*, often shortened to *PDE5 inhibitor*, is a drug used to block the degradative action of phosphodiesterase type 5 on cyclic GMP in the smooth muscle cells lining the blood vessels supplying the corpus cavernosum of the penis. These drugs are used in the treatment of erectile dysfunction, and were the first effective oral treatment available for the condition.

Mode of action

Part of the physiological process of erection involves the release of nitric oxide (NO) in vasculature of the corpus cavernosum as a result of sexual stimulation. NO activates the enzyme guanylate cyclase which results in increased levels of cyclic guanosine monophosphate (cGMP), leading to smooth muscle relaxation in blood vessels supplying the corpus cavernosum, resulting in increased inflow of blood and an erection.

PDE5 inhibitors inhibit the degradation of cGMP by phosphodiesterase type 5 (PDE5), increasing bloodflow to the penis during sexual stimulation.

This mode of action means that PDE5 inhibitors are ineffective without sexual stimulation.

Clinical use of PDE5 inhibitors

Indications

PDE5 inhibitors are clinically indicated for the treatment of erectile dysfunction.

Sildenafil, the prototypical PDE5 inhibitor, was originally discovered during the search of a novel treatment for angina. Recent studies are exploring its use as a treatment for pulmonary hypertension (Kanthapillai, Lasserson & Walters, 2004), and its potential for increasing neurogenesis after stroke (Zhang, Wang et. al, 2002).

Contraindications

PDE5 inhibitors are contraindicated in those taking nitrate medication. They are also contraindicated in men for whom sexual intercourse is inadvisable due to cardiovascular risk factors. (Rossi, 2004)

Adverse drug reactions

The occurrence of adverse drug reactions (ADRs) with PDE5 inhibitors appears to be dose related. Headache is a very common ADR, occurring in >10% of patients. Other common ADRs include: dizziness, flushing, dyspepsia, nasal congestion or rhinitis. (Rossi, 2004)

Other ADRs and their incidence vary with the agent and are listed in their individual pages.

Drug interactions

PDE5 inhibitors are primarily metabolised by the cytochrome P450 enzyme CYP3A4. The potential exists for adverse drug interactions with other drugs which inhibit or induce CYP3A4, including HIV protease inhibitors, ketoconazole, itraconazole, etc (Rossi, 2006).

Examples

Sildenafil was the prototypical member of the PDE5 inhibitors. Two other agents, with their own advantages/disadvantages are also available.

- sildenafil
    - tadalafil

  vardenafil

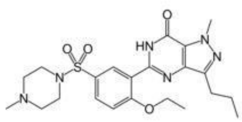
Sildenafil (Viagra)



Systematic (IUPAC) name

1-[4-ethoxy-3-(6,7-dihydro-1-methyl-7-oxo-3-propyl-1H-pyrazolo[4,3-d]pyrimidin-5-yl) phenylsulfonyl]-4-methylpiperazine citrate

Identifiers

CAS number 171599-83-0

ATC code G04**BE03**

PubChem 5281023

DrugBank APRD00556

Chemical data

Formula $C_{22}H_{30}N_6O_4S \cdot C_6H_8O_7$

Mol. weight base: 474.6 g/mol, salt: 666.7 g/mol

SMILES

O=S(=O)(N1CCN(C)CC1)c4cc(C=2NC(=O) c3n(C)nc(CCC)c3N=2)c(OCC)cc4

Pharmacokinetic data

Half life 3-4h

Therapeutic considerations

Pregnancy cat. N/A

Legal status Rx only/POM

Routes Oral

Sildenafil citrate, sold under the names *Viagra*, *Revatio* and generically under various other names, is a drug used to treat male erectile dysfunction (impotence) and pulmonary arterial hypertension (PAH), developed by the pharmaceutical company Pfizer. Viagra pills are blue and diamond-shaped with the words "Pfizer" on one side, and "VGR xx" (where xx stands for "25", "50" or "100", the dose of that pill in milligrams) on the other. Its primary competitors on the market are tadalafil (Cialis), and vardenafil (Levitra).

History

Sildenafil (compound UK-92,480) was synthesized by a group of pharmaceutical chemists working at Pfizer's Sandwich, Kent research facility. It was initially studied for use in hypertension (high blood pressure) and angina pectoris (a form of ischaemic cardiovascular disease). Phase I clinical trials under the direction of Ian Osterloh suggested that the drug had little effect on angina, but that it could induce marked penile erections.[1][2] Pfizer therefore decided to market it for erectile dysfunction, rather than for angina. The drug was patented in 1996, approved for use in erectile dysfunction by the Food and Drug Administration on March 27, 1998, becoming the first pill approved to treat erectile dysfunction in the United States, and offered for sale in the United States later that year.[3] It soon became a great success: annual sales of Viagra in the period 1999–2001 exceeded $1 billion.

The British press portrayed Peter Dunn and Albert Wood as the inventors of the drug, a claim which Pfizer disputes.[4] Their names are on the manufacturing patent application drug, but Pfizer claims this is only for convenience.

Even though sildenafil is only available by prescription from a doctor, it was advertised directly to consumers on US TV (famously being endorsed by Bob Dole). Numerous sites on the Internet offer Viagra for sale after an "online consultation", a mere web questionnaire. The "Viagra" name has become so well known that many fake aphrodisiacs now call themselves "herbal Viagra" or are presented as blue tablets imitating the shape and colour of Pfizer's product. Viagra is also informally known as "Vitamin V", "the Blue Pill", as well as various other nicknames.

Pfizer's worldwide patents on sildenafil citrate will expire in 2011–2013. The UK patent held by Pfizer on the use of PDE5 inhibitors (see below) as treatment of impotence was invalidated in 2000 because of obviousness; this decision was upheld on appeal in 2002.

Mechanism of action

Part of the physiological process of erection involves the parasympathetic nervous system causing the release of nitric oxide (NO) in the corpus cavernosum of the penis. NO binds to the receptors of the enzyme guanylate cyclase which results in increased levels of cyclic guanosine monophosphate (cGMP), leading to smooth muscle relaxation (vasodilation) in the corpus cavernosum, resulting in increased inflow of blood and an erection.

Sildenafil is a potent and selective inhibitor of cGMP specific phosphodiesterase type 5 (PDE5) which is responsible for degradation of cGMP in the corpus cavernosum. The molecular structure of sildenafil is similar to that of cGMP and acts as a competitive binding agent of PDE5 in the corpus cavernosum, resulting in more cGMP and better erections. Without sexual stimulation, and therefore lack of activation of the NO/cGMP system, sildenafil should not cause an erection. Other drugs that operate by the same mechanism include tadalafil (Cialis®) and vardenafil (Levitra®).

Sildenafil is metabolised by hepatic enzymes and excreted by both the liver and kidneys. If taken with a high fat meal, there may be a delay in absorption of sildenafil and the peak effect might be reduced slightly as the plasma concentration will be lowered.

Dosage and price

As with all prescription drugs, proper dosage is at the discretion of a licensed medical doctor. The dose of sildenafil is 25 mg to 100 mg taken once per day between 30 minutes to 4 hours before sexual intercourse.

It is usually recommended to start with a dosage of 50 mg and then lower or raise the dosage as appropriate. The drug is sold in three dosages (25, 50, and 100 mg), all three costing about US$10 per pill. Sildenafil is not scored and it is not advisable to cut it to change dosage since the active compound is not distributed homogenously in the tablet.

Contraindications

Contraindications include:

- When taking nitric oxide donors, organic nitrites and nitrates, such as glyceryl trinitrate, sodium nitroprusside, amyl nitrite ("poppers")[5]
- In men for whom sexual intercourse is inadvisable due to cardiovascular risk factors
- Severe hepatic impairment (decreased liver function)
- Severe impairment in renal function
- Hypotension (low blood pressure)
- Recent stroke or heart attack
- Hereditary degenerative retinal disorders (including genetic disorders of retinal phosphodiesterases)

Side effects

Amongst sildenafil's serious adverse effects are: priapism, severe hypotension, myocardial infarction, ventricular arrhythmias, sudden death, stroke and increased intraocular pressure.

Common side effects include sneezing, headache, flushing, dyspepsia, prolonged erections, palpitations and photophobia. Visual changes including blurring of vision and a curious bluish tinge have also been reported.

Care should be exercised by patients who are also taking Protease inhibitors for the treatment of HIV. Protease inhibitors inhibit the metabolism of sildenafil, effectively multiplying the plasma levels of sildenafil, increasing the incidence and severity of side-effects. It is recommended that patients using protease inhibitors limit their use of sildenafil to no more than one 25-mg dose every 48 hours.

Some sildenafil users have complained of blurriness and loss of peripheral vision. In May of 2005, the U.S. Food and Drug Administration found that sildenafil could lead to vision impairment[6] and a number of studies have linked sildenafil use with nonarteritic anterior ischemic optic neuropathy.[7][8][9][10][11][12]

When used with an alpha blocker, take them at least four hours apart to avoid hypotension.[13]

Other uses

Pulmonary hypertension

As well as erectile dysfunction, sildenafil citrate is also effective in the rare disease pulmonary arterial hypertension (PAH). It relaxes the arterial wall, leading to decreased pulmonary arterial resistance and pressure. This in turn reduces the workload of the right atrium of the heart and improves symptoms of right-sided heart failure. Because PDE-5 is primarily distributed within the arterial wall smooth muscle of the lungs and penis, sildenafil acts selectively in both these areas without inducing vasodilation in other areas of the body. Pfizer submitted an additional registration for sildenafil to the FDA, and sildenafil was approved for this indication in June 2005. The preparation is named Revatio, to avoid confusion with Viagra, and the 20 milligram tablets are white and round. Sildenafil joins bosentan and prostacyclin-based therapies for this condition.[14]

Raynaud's phenomenon

In 2005, Dr. Roland Fries and colleagues reported that sildenafil cut the frequency of Raynaud's phenomenon attacks, reduced their duration by roughly one half, and more than quadrupled the mean capillary blood velocity. This was a double-blind, placebo-controlled crossover trial and the patients had both the primary and secondary forms and had all discontinued the more conventional treatments for this.[15]

Drug abuses

Aphrodisiac

Sildenafil is commonly and increasingly used as an aphrodisiac. While there is no clinical evidence that it has aphrodisiac activity, many seem to believe it will improve sexual performance as well as erectile function and enhance the sexual experience that will occur

Recreational use

Viagra's popularity with young adults has increased over the years.[16] It is sometimes used recreationally. Some users mix Viagra with methylenedioxymethamphetamine (MDMA, ecstasy), a combination known as Sextasy.

Chemical Synthesis

The preparation steps for synthesis of Viagra (sildenafil citrate) are as follows:

1. Methylation of 3-propylpyrazole-5-carboxylic acid ethyl ester with hot dimethyl sulfate.
2. Hydrolysis with aqueous NaOH to free acid.
3. Nitration with oleum/fuming nitric acid.
4. Carboxamide formation with refluxing thionyl chloride/NH4OH.
5. Reduction of nitro group to amino.
6. Acylation with 2-ethoxybenzoyl chloride.
7. Cyclization.
8. Sulfonation to the chlorosulfonyl derivative.
9. Condensation with 1-methylpiperazine.[17]

Testosterone is a steroid hormone from the androgen group. Testosterone is primarily secreted in the testes of males and the ovaries of females although small amounts are secreted by the adrenal glands. It is the principal male sex hormone and an anabolic steroid. In both males and females, it plays key roles in health and well-being. Examples include

enhanced libido, energy, immune function, and protection against osteoporosis. On average, the adult male body produces about twenty times the amount of testosterone that an adult female's body does[1].

Sources of testosterone

Like other steroid hormones, testosterone is derived from cholesterol. The largest amounts of testosterone are produced by the testes in men, but it is also synthesized in smaller quantities in women by the thecal cells of the ovaries, by the placenta, as well as by the zona reticularis of the adrenal cortex in both sexes.

In the testes, testosterone is produced by the Leydig cells. The male generative glands also contain Sertoli cells which require testosterone for spermatogenesis. Like most hormones, testosterone is supplied to target tissues in the blood where much of it is transported bound to a specific plasma protein, *sex hormone binding globulin* (SHBG).

Some drugs specifically target testosterone as a way of treating certain conditions. For example, finasteride inhibits the conversion of testosterone into dihydrotestosterone (DHT), a metabolite which is more potent than testosterone. By lowering the levels of dihydrotestosterone, finasteride may be used for various conditions associated with androgens, such as benign prostatic hyperplasia (BPH) and androgenetic alopecia (male-pattern baldness).

Mechanism of effects

The effects of testosterone in humans and other vertebrates occur by way of two main mechanisms: by activation of the androgen receptor (directly or as DHT), and by conversion to estradiol and activation of certain estrogen receptors.

Free testosterone (T) is transported into the cytoplasm of target tissue cells, where it can bind to the androgen receptor, or can be reduced to 5±-dihydrotestosterone (DHT) by the cytoplasmic enzyme 5±-reductase(5-alfa-reduktas). DHT binds to the same androgen receptor even more strongly than T, so that its androgenic potency is about 2.5 times that of T. The T-receptor or DHT-receptor complex undergoes a structural change that allows it to move into the cell nucleus and bind directly to specific nucleotide sequences of the chromosomal DNA. The areas of binding are called hormone response elements (HREs), and influence transcriptional activity of certain genes, producing the androgen effects. It is important to note that if there is a too low amount of 5±-reductase(5-alfa-reduktas), the body (of a human) will -continue- growing into a female with testicles.

Androgen receptors occur in many different vertebrate body system tissues, and both males and females respond similarly to similar levels. Greatly differing amounts of testosterone prenatally, at puberty, and throughout life account for a large share of biological differences between males and females.

The bones and the brain are two important tissues in humans where the primary effect of testosterone is by way of aromatization to estradiol. In the bones, estradiol accelerates maturation of cartilage into bone, leading to closure of the epiphyses and conclusion of growth. In the central nervous system, testosterone is aromatized to estradiol. Estradiol rather than testosterone serves as the most important feedback signal to the hypothalamus

(especially affecting LH secretion). In many mammals, prenatal or perinatal "masculinization" of the sexually dimorphic areas of the brain by estradiol derived from testosterone programs later male sexual behavior.

Testerone is a predominantly male hormone, though females do produce certain amounts of it. The primary female hormone is estrogen and males also produce certain amounts of this hormone. Testosterone causes the appearance of male traits (i.e deepening voice, pubic and facial hairs, muscular build, etc.)

Effects of testosterone on humans

In general, androgens promote protein synthesis and growth of those tissues with androgen receptors. Testosterone effects can be classified as virilizing and anabolic effects, although the distinction is somewhat artificial, as many of the effects can be considered both. Anabolic effects include growth of muscle mass and strength, increased bone density and strength, and stimulation of linear growth and bone maturation. Virilizing effects include maturation of the sex organs, particularly the penis and the formation of the scrotum in fetuses, and after birth (usually at puberty) a deepening of the voice, growth of the beard and axillary hair. Many of these fall into the category of male secondary sex characteristics.

Testosterone effects can also be classified by the age of usual occurrence. For postnatal effects in both males and females, these are mostly dependent on the levels and duration of circulating free testosterone.

Most of the prenatal androgen effects occur between 7 and 12 weeks of gestation.

- Genital virilization (midline fusion, phallic urethra, scrotal thinning and rugation, phallic enlargement)
- Development of prostate and seminal vesicles

Early infancy androgen effects are the least understood. In the first weeks of life for male infants, testosterone levels rise. The levels remain in a pubertal range for a few months, but usually reach the barely detectable levels of childhood by 4-6 months of age. The function of this rise in humans is unknown. It has been speculated that "brain masculinization" is occurring since no significant changes have been identified in other parts of the body.

Early postnatal effects are the first visible effects of rising androgen levels in childhood, and occur in both boys and girls in puberty.

- Adult-type body odour
- Increased oiliness of skin and hair, acne
- Pubarche (appearance of pubic hair)
- Axillary hair
- Growth spurt, accelerated bone maturation
- Fine upper lip and sideburn hair

Advanced postnatal effects begin to occur when androgen has been higher than normal adult female levels for months or years. In males these are normal late pubertal effects, and only occur in women after prolonged periods of excessive levels of free testosterone in the blood.

- Phallic enlargement (including clitoromegaly)

- Increased libido and erection frequency
- Pubic hair extends to thighs and up toward umbilicus
- Facial hair (sideburns, beard, moustache)
- Chest hair, periareolar hair, perianal hair
- Subcutaneous fat in face decreases
- Increased muscle strength and mass
- Deepening of voice
- Growth of the adam's apple
- Growth of spermatogenic tissue in testes, male fertility
- Growth of jaw, brow, chin, nose, and remodeling of facial bone contours
- Shoulders widen and rib cage expands
- Completion of bone maturation and termination of growth. This occurs indirectly via estradiol metabolites and hence more gradually in men than women.

Adult testosterone effects are more clearly demonstrable in males than in females, but are likely important to both sexes. Some of these effects may decline as testosterone levels decline in the later decades of adult life.

- Maintenance of muscle mass and strength
- Maintenance of bone density and strength
- Libido and erection frequency
- Mental and physical energy

Effects of testosterone on the human brain

As testosterone affects the entire body (often by enlargening, such accepted facts such as, men have bigger hearts, lungs, liver etc) the brain is also affected by this "sexual" advancement, the enzyme aromatase converts testosterone into estrogen that is responsible for "masculinization" of the brain in a male fetus. Factors that in any way reduce this key enzyme(aromatase) can result in an individual with male gender, male body but with a "female" brain. There are some differences in a male and female brain (the result of testosterone) a clear difference is the size, the male human brain is on average larger, however in females the (that do not use testosterone as much) the corpus callosum is proportionally larger in females then males. This means that the effect of testosterone is a greater brain volume, however less interwoven brain halves. [2]

Testosterone in athletes

Testosterone may be administered to an athlete in order to improve performance, and is considered to be a form of doping in most sports. There are several application methods for testosterone, including intramuscular injections, transdermal gels and patches, and implantable pellets.

Anabolic steroids (of which testosterone is one) have also been taken to enhance muscle development, strength, or endurance. After a series of scandals and publicity in the 1980s (such as Ben Johnson's improved performance at the 1988 Summer Olympics), prohibitions

of anabolic steroid use were renewed or strengthened by many sports organizations. Testosterone and other anabolic steroids were designated a "controlled substance" by the United States Congress in 1990, with the Anabolic Steroid Control Act.

Therapeutic use of testosterone

Testosterone was first isolated from a bull in 1935. There have been many pharmaceutical forms over the years. Forms of testosterone for human administration currently available in North America include injectable (such as testosterone cypionate or testosterone enanthate in oil), oral Andriol, buccal Striant, transdermal skin patches, and transdermal creams or gels Androgel and Testim. In the pipeline are a "roll on" delivery method and a nasal spray.

The original and primary use of testosterone is for the treatment of males who have too little or no natural endogenous testosterone production; males with hypogonadism. Appropriate use for this purpose is legitimate hormone replacement therapy, which maintains serum testosterone levels in the normal range.

However, over the years, as with every hormone, testosterone or other anabolic steroids has also been given for many other conditions and purposes besides replacement, with variable success but higher rates of side effects or problems. Examples include infertility, lack of libido or erectile dysfunction, osteoporosis, penile enlargement, height growth, bone marrow stimulation and reversal of anemia, and even appetite stimulation. By the late 1940s testosterone was being touted as an anti-aging wonder drug (e.g., see Paul de Kruif's The Male Hormone).

To take advantage of its virilizing effects, testosterone is often administered to transmen (female-to-male transsexual and transgender people) as part of the hormone replacement therapy, with a "target level" of the normal male testosterone level. And like-wise, transwomen are sometimes prescribed drugs [anti-androgens] to decrease the level of testosterone in the body and allow for the effects of estrogen to develop.

There is a myth that exogenous testosterone can more or less definitively be used for male birth control. However, the vast majority of physicians will agree that to prescribe exogenous testosterone for this purpose is inappropriate. But perhaps more importantly, many men of first hand found this myth to be untrue or at least, unreliable. This is especially true when exogenous testosterone is used in conjunction with hCG.

Exogenous testosterone supplementation comes with a number of health risks. Fluoxymesterone and methyltestosterone are synthetic derivatives of testosterone. In 2006 it was reported that women taking Estratest, a combination pill including estrogen and methyltestosterone, were at considerably heightened risk of breast cancer.

The "testosterone deficiency" of aging and the andropause controversy

Testosterone levels decline gradually with age in men. The clinical significance of this decrease is debated. There is disagreement about if and when to treat aging men with testosterone replacement therapy. The American Society of Andrology's position is that testosterone therapy "is indicated when both clinical symptoms and signs suggestive of androgen deficiency and decreased testosterone levels are present". The American Association of Clinical Endocrinologists says "Hypogonadism is defined as a free testosterone level that is below the lower limit of normal for young adult control subjects. Previously, age-related decreases in free testosterone were once accepted as normal.

Currently, they are not considered normal....Patients with low-normal to subnormal range testosterone levels warrant a clinical trial of testosterone."

There isn't total agreement on the threshold of testosterone value below which a man would be considered hypogonadal. Testosterone can be measured as "free" (that is, bioavailable and unbound) or more commonly, "total" (including the percentage which is chemically bound and unavailable). In the United States, male total testosterone levels below 200 to 300 ng/dl from a morning sample are generally considered low. However these numbers are typically not age-adjusted, but based on an average of a test group which includes elderly males with low testosterone levels. Therefore a value of 300 ng/dl might be normal for a 90 year old male, but not normal for a 30 year old. Identification of inadequate testosterone in an aging male by symptoms alone can be difficult. The signs and symptoms are non-specific, and might be confused with normal aging characteristics, such as loss of muscle mass and bone density, decreased physical endurance, decreased memory ability and loss of libido.

Replacement therapy can take the form of injectable depots, transdermal patches and gels, subcutaneous pellets and oral therapy. Adverse effects of testosterone supplementation include minor side effects such as acne and oily skin, and more significant complications such as increased hematocrit, exacerbation of sleep apnea and acceleration of pre-existing prostate cancer growth. Exogenous testosterone also causes suppression of spermatogenesis and can lead to infertility.[3] It is recommended that physicians screen for prostate cancer with a digital rectal exam and PSA (prostate specific antigen) level prior to initiating therapy, and monitor hematocrit and PSA levels closely during therapy.

Large scale trials to assess the efficiency and long-term safety of testosterone are still lacking. Many caution against embracing testosterone replacement therapy because of lessons from the female hormone replacement therapy trials, where initially promising results were later refuted by larger studies.

Synthesis

Testosterone is synthesized from pregnenolone, which is the precursor of all steroid hormones and is made from cholesterol by a series of enzymatic reactions. Two pathways are possible, In the delta-5 pathway, pregnenolone is converted to DHEA to androstenedione.

In the delta-4 pathway there is hydroxylation of C-17 of progesterone, to yield 17±-hydroxyprogesterone. The side chain is then cleaved to form androstenedione. Androstenedione is the immediate precursor to testosterone.

The keto group on C-17 is reduced to an alcohol to yield testosterone. Testosterone is a potential precursor of estradiol.

Zinc supplementation is known to result in increased levels of testosterone synthesis, especially in those who are zinc deficient. Zinc is critical to the proper function of steroid receptors (see zinc finger) and plays a vital role as a cofactor to many enzymes which is the likely mechanism for its effect on testosterone synthesis.

Expectorants

A *mucolytic agent* is any agent which dissolves thick mucus to help relieve respiratory difficulties. (hydrolyzing glycosaminoglycans: tending to break down/lower the viscosity of mucin-containing body secretions/components). The viscosity of mucous secretions in the lungs is dependent upon the concentrations of mucoprotein, the presence of disulfide bonds between these macromolecules and DNA.

Mucolytics: N-acetylcysteine: an aerosolized mucolytic agent often used as adjunctive therapy for pulmonary complications of cystic fibrosis (CF) in combination with vigorous chest physiotherapy. N-acetylcysteine acts to split the sulfide bonds in the macromolecules thereby decreasing viscosity, allowing for removal by normal chest physiology. The action of N-acetylcysteine is pH dependent. Mucolytic action is significant at ranges of pH 7-9.(1)

Natural Mucolytics:

- Mugwort

Non-Mucolytics:

- Guaifenesin: increases volume and decreases viscosity of respiratory tract secretions. (Robitussin)

Potassium iodide

Systematic name Potassium iodide

R/S statement R: 36, 38, 42-43, 61 S: 26, 36-37, 39, 45

RTECS number TT2975000

Related compounds

Other anions potassium bromide, potassium chloride

Other cations lithium iodide, sodium iodide, rubidium iodide, caesium iodid

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Potassium iodide is a white crystalline salt with chemical formula KI, used in photography and radiation treatment. It finds widespread application as an iodide source because it is less hygroscopic than sodium iodide, making it easier to work with. KI can turn yellow upon heating in air or upon standing in moist air for long periods, because of oxidation of the iodide to iodine.

Chemical properties

Potassium iodide behaves as a simple ionic salt, K+I. Since the iodide ion is a mild reducing agent, I is easily oxidised to I2 by powerful oxidising agents such as chlorine:

2 KI(aq) + Cl2(aq) ’ 2 KCl + I2(aq)

Even air will oxidize iodide as evidenced by the observation of a purple extract when KI is rinsed with dichloromethane. Under acidic conditions, KI is oxidised even more easily, due to the formation of hydroiodic acid (HI), which is a powerful reducing agent.

KI forms I***3*** when combined with elemental iodine.

KI(aq) + I2(s) ’ KI3(aq)

Unlike I***2***, I***3*** salts can be highly water-soluble. I***2*** and I***3*** have virtually identical redox potentials (0.535 and 0.536 V vs NHE, respectively), i.e. they are both mild oxidants relative to H***2***. Therefore, this reaction allows the iodine to be used in aqueous solutions for redox titrations.

Potassium iodide also serves in some organic reactions as a source of iodide ion (see "uses" below).

Preparation

Potassium iodide may be prepared by the reaction of a potassium base with hydroiodic acid, for example:

HI + KHCO3 ’ KI + H2O(l) + CO2(g)

Alternatively iron(II) iodide, prepared using scrap iron and iodine (made from iodide rich brines or from Chile saltpeter, can be treated with potassium carbonate:

FeI2 + K2CO3 ’ 2 KI + FeCO3

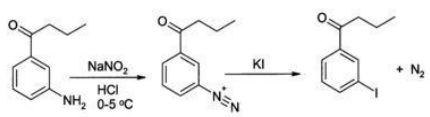
Uses

Potassium iodide is used in photography, in the preparation of silver(I) iodide for high speed photographic film:

KI(aq) + AgNO3(aq) ’ AgI(s) + KNO3(aq)

Potassium iodide is also added to table salt in small quantities to make it "iodized". In a saturated solution, it is also used as an expectorant to treat lung congestion.

KI is often used as a source of iodide ion in organic synthesis. A useful application is in the preparation of aryl iodides from arenediazonium salts[5], for example:



Saturated solution of potassium iodide is also used as treatment for sporotrichosis, a fungal infection.

In medical use, it can also serve as an antiseptic for people suffering from sore throat. The dose is 0.5g-1.0g in 100mL, with the accompany of iodine (0.5g-1.0g in 100mL).

Role of potassium iodide in radiological emergency preparedness

Potassium iodide may also be used to protect the thyroid from radioactive iodine in the event of an accident or attack at a nuclear power plant, or other nuclear attack, especially where a nuclear reactor is breached and the volatile radionuclides, which contain significant amount of 131I, are released into the environment. Radioiodine is a particularly dangerous radionuclide because the body concentrates it in the thyroid gland. Potassium iodide cannot protect against other causes of radiation poisoning, however, nor can it provide any degree of protection against a dirty bomb unless the bomb happens to contain a significant amount of radioactive iodine. In case of a nuclear emergency, iodine used for the cleaning of wounds should *not* be ingested. It is a poison.

Recommended Dosage for Radiological Emergencies involving radioactive iodine [6]

Age = KI in mg = KIO3 in mg

Over 12 years old = 130 = 170

3 - 12 years old = 65 = 85

1 - 36 months old = 32 = 42

< 1 month old = 16 = 21

Precautions

Mild irritant, wear gloves. Chronic overexposure can have adverse effects on the thyroid.

Gastrointestinal system drugs

The *gastrointestinal tract* or *digestive tract*, also referred to as the *GI tract* or the *alimentary canal*, (nourishment canal) or the *gut*, is the system of organs within multicellular animals which takes in food, digests it to extract energy and nutrients, and expels the remaining waste. This process is called digestion.

The GI tract differs substantially from animal to animal. For instance, some animals have multi-chambered stomachs.

Basic anatomy

The gut

In a normal human adult male, the GI tract is approximately 7.5 meters long (25 feet) and consists of the following components:

Upper gastrointestinal tract

Mouth, Muccal cavity; includes salivary glands, mucosa, teeth and tongue Pharynx Oesophagus or Esophagus (gullet) and cardia Stomach which includes the antrum and pylorus and pyloric sphincter.

Lower gastrointestinal tract

- Bowel or intestine:
  - small intestine, which has three parts:
    - duodenum

jejunum
ileum
  - large intestine, which has three parts:
    - caecum (the vermiform appendix is attached to the cecum).

colon (ascending colon, transverse colon, descending colon and sigmoid flexure)
rectum
- anus

Related organs

The liver secretes bile into the small intestine via the biliary system, employing the gallbladder as a reservoir. The pancreas secretes an isosmotic fluid containing bicarbonate and several enzymes, including trypsin, chymotrypsin, lipase, and pancreatic amylase, as

well as nucleolytic enzymes (deoxyribonuclease and ribonuclease), into the small intestine. Both these secretory organs aid in digestion.

Physiology

Specialization of organs

Four organs are subject to specialization in the kingdom Animalia.

- The first organ is the tongue which is only present in the phylum Chordata.
- The second organ is the esophagus. The crop is an enlargement of the esophagus in birds, insects and other invertebrates that is used to store food temporarily.
- The third organ is the stomach. In addition to a glandular stomach (proventriculus), birds have a muscular "stomach" called the ventriculus or "gizzard." The gizzard is used to mechanically grind up food.
- The fourth organ is the large intestine. An outpouching of the large intestine called the cecum is present in non-ruminant herbivores such as rabbits. It aids in digestion of plant material such as cellulose.

Immune function

The gastrointestinal tract is also a prominent part of the immune system (Coico et al 2003). The low pH (ranging from 1 to 4) of the stomach is fatal for many microorganisms that enter it. Similarly, mucus (containing IgA antibodies) neutralizes many of these microorganisms. Other factors in the GI tract help with immune function as well, including enzymes in the saliva and bile. Health enhancing intestinal bacteria serve to prevent the overgrowth of potentially harmful bacteria in the gut.

Histology

The GI tract has a uniform general histology with some differences which reflect the specialization in functional anatomy. The GI tract can be divided into 4 concentric layers:

- mucosa

submucosa
muscularis externa (the external muscle layer)
adventitia or serosa

Mucosa

The mucosa is the innermost layer of the GI tract, surrounding the lumen, or space within the tube. This layer comes in direct contact with the food (or bolus), and is responsible for absorption and secretion, important processes in digestion.

The mucosa can be divided into:

- epithelium

lamina propria
muscularis mucosae

The mucosa are highly specialized in each organ of the GI tract, facing a low pH in the stomach, absorbing a multitude of different substances in the small intestine, and also absorbing specific quantities of water in the large intestine. Reflecting the varying needs of these organs, the structure of the mucosa can consist of invaginations of secretory glands (i.e. gastric pits), or it can be folded in order to increase surface area (i.e. villi, microvilli).

Submucosa

The submucosa consists of a dense irregular layer of connective tissue with large blood vessels, lymphatics and nerves branching into the mucosa and muscularis. It contains Meissner's plexus, an enteric nervous plexa, situated on the inner surface of the muscularis externa.

Muscularis externa

The muscularis externa consists of a circular inner muscular layer and a longitudinal outer muscular layer. The circular muscle layer prevents the food from going backwards and the longitudinal layer shortens the tract. The coordinated contractions of these layers is called peristalsis and propels the bolus, or balled-up food, through the GI tract. Between the two muscle layers are the myenteric or Auerbach's plexa.

Adventitia/Serosa

The adventitia consists of several layers of connective tissue. When the adventitia is facing the mesentery or peritoneal fold, the adventitia is covered by a mesothelium supported by a thin connective tissue layer, together forming a serosa, or serous membrane.

Uses of gut

- The use of animal gut strings by musicians can be traced back to the third dynasty of Egypt. In the recent past, strings were made out of lamb gut. With the advent of the modern era, musicians have tended to use synthetic strings made of nylon, silk or steel. Some instrumentalists, however, still use gut strings in order to evoke the older tone quality. Although such strings were commonly referred to as "catgut" strings, cats were never used as a source for gut strings.
- Sheep gut was the original source for natural gut string used in racquets, such as for tennis. Today, synthetic strings are much more common, but the best strings are now made out of cow gut.
- Gut cord has also been used to produce strings for the snares which provide the snare drum's characteristic buzzing timbre. While the snare drum

currently almost always uses metal wire rather than gut cord, the North African bendir frame drum still uses gut for this purpose.

- "Natural" sausage hulls (or casings) are made of animal gut, especially hog, beef, and lamb.
- Animal gut was used to make the cord lines in longcase clocks, but may be replaced by wire.

Antidiarrhoeals

An *antidiarrhoeal drug* is any medication which provides symptomatic relief for diarrhoea.

Electrolyte solutions are used to replace lost fluids and salts in acute cases. Bulking agents like methylcellulose, guar gum or plant fibre (bran, sterculia, ispaghul, etc.) are used for diarrhoea in functional bowel disease and to control ileostomy output. Absorbents absorb toxic substances that cause infective diarrhoea, methylcellulose is an absorbent as well. Opiates slow intestinal transit, but Loperamide is most commonly used, since it doesn't have the usual narcotic side effects.

Antiemetics

An *antiemetic* is a drug that is effective against vomiting and nausea. Antiemetics are typically used to treat motion sickness and the side effects of opioid analgesics and chemotherapy directed against cancer.

Antiemetics include:

- 5HT3 receptor (type of serotonin receptor) antagonists
  - Dolasetron

  Granisetron
  Ondansetron
  Tropisetron
- Dopamine antagonists

- Domperidone

Droperidol, Haloperidol, Chlorpromazine, Promethazine, Prochlorperazine metoclopramide

- Antihistamines (H1 histamine receptor antagonists)
  - Cyclizine

Diphenhydramine
Dimenhydrinate
Meclizine
Promethazine
Hydroxyzine

- Cannabinoids
  - Cannabis

Marinol

- Other
  - Trimethobenzamide; thought to work on the CTZ

Emetrol also claims to be an effective antiemetic.

Laxatives

A *laxative* is a preparation used for encouraging defecation, or the expulsion of feces. Laxatives are most often taken to treat constipation. Certain stimulant, lubricant, and saline laxatives are used to evacuate the colon for rectal and bowel examinations. They are sometimes supplemented by enemas.

Laxatives are often abused by bulimics or anorexics (nervosa). Laxative abuse is potentially serious since it can lead to intestinal paralysis, Irritable Bowel Syndrome (IBS), pancreatitis, and other problems.

There are several types of laxatives, listed below. Some laxatives combine more than one type of active ingredient to produce a combination of the effects mentioned. Laxatives may be oral or in suppository form.

While there is no sex difference in constipation from a medical point of view, advertisers tend to promote some brands as being "More for a lady" than others.

Bulk-producing agents

- Site of Action: Small and large intestine
- Onset of Action: 12 - 72 hours

Also known as bulk-forming or bulking agents, these include dietary fiber. Bulk-producing agents cause the stool to be bulkier and to retain more water, as well as forming an emollient gel, making it easier for peristaltic action to move it along. Examples: psyllium husk (Metamucil), methylcellulose (Citrucel), polycarbophil, apples. They should be taken

with plenty of water. Bulk-producing agents have the gentlest of effects among laxatives and can be taken just for maintaining regular bowel movements.

Stool softeners / Surfactants

- Site of Action: Small and large intestine
- Onset of Action: 12 - 72 hours

These cause water and fats to penetrate the stool, making it easier to move along. Many of these quickly produce a tolerance effect and so become ineffective with prolonged use. Their strength is between that of the bulk producers and the stimulants, and they can be used for patients with occasional constipation or those with anorectal conditions for whom passage of a firm stool is painful. Stool softeners include docusate (Colace, Diocto).

Lubricants / Emollient

- Site of Action: Colon
- Onset of Action: 6 - 8 hours

These simply make the stool slippery, so that it slides through the intestine more easily. An example is mineral oil, which also retards colonic absorption of water, softening the stool. Mineral oil may decrease the absorption of fat-soluble vitamins (A, D, E and K).

Hydrating agents (osmotics)

These cause the intestines to concentrate more water within, softening the stool. There are two principal types, saline and hyperosmotic. Examples: Milk of Magnesia, Epsom salt.

Saline

- Site of Action: Small and large intestine
- Onset of Action: 0.5 - 6 hours

Saline laxatives attract and retain water in the intestinal lumen, increasing intraluminal pressure and thus softening the stool. They will also cause the release of cholecystokinin, which stimulates the digestion of fat and protein. Saline laxatives may alter a patient's fluid and electrolyte balance. Examples: Dibasic sodium phosphate, magnesium citrate, magnesium hydroxide (Milk of magnesia), magnesium sulfate, monobasic sodium phosphate, sodium biphosphate. Sulfate salts are considered the most potent.

Hyperosmotic agents

- Site of Action: Colon
- Onset of Action: 0.5 - 3 hours

Hyperosmotic laxatives include Glycerin suppositories and Lactulose. Lactulose works by the osmotic effect, which retains water in the colon, lowering the pH and increasing colonic peristalsis. Lactulose is also indicated in Portal-systemic encephalopathy. Glycerin

suppositories work mostly by hyperosmotic action, but also the sodium stearate in the preparation causes local irritation to the colon. According to trials, Polyethylene glycol was found to be more more effective than lactulose.

Stimulant / Irritant

- Site of Action: Colon

These stimulate peristaltic action, and can be dangerous under certain circumstances. Stimulant laxatives act on the intestinal mucosa or nerve plexus, they also alter water and electrolyte secretion. They are the most severe among laxatives and should be used only in extreme conditions. Castor oil may be preferred when more complete evacuation is required. Examples:

Onset of Action - Laxative Name

6 - 8 hours - Cascara. Phenolphthalein (Formerly in Ex-lax but phased out because of carcinogenicity concerns)

6 - 10 hours - Bisacodyl tablets (Dulcolax). Casanthranol. Senna (Ex-lax). Aloe Vera

2 - 6 hours - Castor oil.
15 min - 1 hour - Bisacodyl suppository

Castor oil

- Site of Action: Small intestine
- Onset of Action:

Castor oil acts directly on intestinal mucosa or nerve plexus and alters water and electrolyte secretion. It is converted into ricinoleic acid (the active component) in the gut.

Other

Tegaserod is a motility stimulant that works through activation of 5-HT4 receptors of the enteric nervous system in the gastrointestinal tract.

Aloe

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Liliopsida
Order: Asparagales

Family: Asphodelaceae
Genus: *Aloe* L.

Species See Species

Aloe, also written Aloë, is a genus containing about four hundred species of flowering succulent plants.

The genus is native to Africa and is common in South Africa's Cape Province and the mountains of tropical Africa, and neighbouring areas such as Madagascar, the Arabian peninsula and the islands off Africa.

The APG II system (2003) placed the genus in the family Asphodelaceae. In the past it has also been assigned to families Aloaceae and Liliaceae. Members of the closely allied genera Gasteria, Haworthia and Kniphofia which have a similar mode of growth, are also popularly known as aloes. Note that the plant sometimes called "American aloe" (Agave americana), belongs to Agavaceae, a different family.

Most Aloes have a rosette of large, thick, fleshy leaves. The leaves are often lance-shaped with a sharp apex and a spiny margin. Aloe flowers are tubular, frequently yellow, orange or red and are borne on densely clustered, simple or branched leafless stems.

Many species of Aloe are seemingly stemless, with the rosette growing directly at ground level; other varieties may have a branched or un-branched stem from which the fleshy leaves spring. They vary in colour from grey to bright green and are sometimes striped or mottled.

Uses

Aloe species are frequently cultivated as ornamental plants both in gardens and in pots. Many Aloe species are highly decorative and are valued by collectors of succulents. Some species, in particular Aloe vera are purported to have medicinal properties.

Other use of Aloes include their role in alternative medicines (see Herbalism) and in home first aid. Both the translucent inner pulp as well as the resinous yellow exudate from wounding the Aloe plant is used externally to relieve skin discomforts and internally as a laxative. To date, some research has shown that Aloe vera produces positive medicinal benefits for healing damaged skin. Conversely, other research suggests Aloe vera can negatively effect healing (Vogler and Ernst, 1999.

Some Aloe species have also been used for human consumption. For example, drinks made from or containing chunks of aloe pulp are popular in Asia as commercial beverages and as a tea additive; this is notably true in Korea.

External uses

Various extracts of Aloe vera are frequently used in herbal medicine and by cosmetic companies. For more information see: Aloe vera.

Internal uses

Aloe contains a number of medicinal substances used as a purgative. The medicinal substance is produced from various species of aloe, such as A. vera, A. vulgaris, A. socotrina, A. chinensis, and A. perryi. Several kinds of aloes are commercially available: Barbadoes, Socotrine, Hepatic, Indian, and Cape aloes. Barbadoes and Socotrine are the varieties most commonly used for curative purposes .

Aloes is the expressed juice of the leaves of the plant. When the leaves are cut, the juice that flows out is collected and evaporated. After the juice has been removed, the leaves are sometimes boiled to yield an inferior kind of aloes. The juice of the leaves of certain species, e.g. Aloe venenosa, is poisonous.

There have been very few properly conducted studies about possible benefits of aloe gel taken internally. One study found improved wound healing in mice. Another found a positive effect of lowering risk factors in patients with heart disease. Some research has shown decreasing fasting blood sugar in diabetic animals given aloe. None of these studies can be considered to be definitive, and there are many false advertising claims for aloe.

Aloe has been marketed as a remedy for coughs, wounds, ulcers, gastritis, diabetes, cancer, headaches, arthritis, immune-system deficiencies, and many other conditions when taken internally. However, these uses are unsubstantiated; the only substantiated internal use is as a laxative. Furthermore, there is evidence of significant adverse side effects (see for example this paper). Genotoxicity studies show that aloe-containing laxatives pose cancer risk to humans when used as directed[2]. Consult your doctor when contemplating taking Aloe internally. Avoid use during pregnancy because the anthraquinone glycosides are strongly purgative. High doses of the leaves can cause vomiting.

On 9 May 2002, the U.S. Food and Drug Administration issued a final rule banning the use of aloe and cascara sagrada as laxative ingredients in over-the-counter drug products.

Heraldry

The aloe plant occurs as a charge in heraldry, such as in the Civic Heraldry of Namibia

Species

There are around 400 species in the genus Aloe. Species include:

- Aloe arborescens - Aloe Arborescens Miller, used in healthcare
- Aloe aristata - Torch Plant, Lace Aloe
- Aloe dichotoma - quiver tree or kokerboom
- Aloe ngobitensis
- Aloe variegata - Partridge-breasted Aloe, Tiger Aloe
- Aloe vera Barbados Aloe, Common Aloe, Yellow Aloe, Medicinal Aloe. This is the variety used medicinally.
- Aloe wildii

Enema

An *enema* (plural *enemata* or *enemas*) is the procedure of introducing liquids into the rectum and colon via the anus. Enemas can be carried out for medical reasons (as a treatment for constipation), as part of alternative therapies, and also for erotic purposes, particularly as part of BDSM activities. In earlier times, they were often known as clysters. Enemas have even been used to administer beverage alcohol to alcoholics who have developed stomach ulcers.

Medical usage

The main medical usages of enemas are:

- As a bowel stimulant, not unlike a laxative -- the main difference being that laxatives are commonly thought of as orally administered while enemas are administered directly into the rectum, and thereafter, into the colon. When the enema is complete, and after a set "holding time," the patient expels feces along with the enema in the toilet.
- Enemas may be used to relieve constipation and fecal impaction, although in many health-care settings their use has been largely replaced by oral laxatives and laxative suppositories. Bowel stimulating enemas may consist of water, which works primarily as a mechanical laxative, or they may be made up of water with baking soda (sodium bicarbonate) or water with a mild soap dissolved in it; sodium phosphate solution, which draws additional water from the bloodstream into the colon and increases the effectiveness of the enema, but which can often be rather irritating to the colon, causing intense cramping or "gripping"; or mineral oil, which functions as a lubricant and stool softener, but which often has the side effect of sporadic seepage from the patient's anus which can soil the patient's undergarments for up to 24 hours. Other types of solutions are available as well. In the past, castile soap was a common additive to enemas, but it has largely fallen out of use because of the risk of chemical colitis as well as the ready availability of other enema preparations that are perhaps more effective than soap -- but which are certainly more irritating to colonic tissues.
- Cleansing the lower bowel prior to a medical or surgical procedure such as sigmoidoscopy or colonoscopy. Because of speed and supposed convenience, enemas used for this purpose are commonly the sodium phosphate variety. A more pleasant experience can usually be obtained with gently-administered baking soda enemas; cleansing the lower bowel for colonoscopy and other bowel studies can be effectively achieved with water-based enema administration.
- The administration of substances into the bloodstream. This may be done in situations where it is undesirable or impossible to deliver a medication by mouth, such as antiemetics given to reduce nausea (though not all antiemetics are delivered by enema). Additionally, several anti-angiogenic agents can be safely administered via a gentle enema. Medicines for cancer, for arthritis, and for age-related macular degeneration are often given via enema in order to avoid digestion in the normally-functioning digestive tract. Interestingly, some water-based enemas are also used as a relieving agent for IBS (Irritable Bowel

Syndrome) even though it seems counter-intuitive to add medicines to an already-irritated bowel system. Finally, an enema may also be used for hydration purposes.

- The topical administration of medications into the rectum, such as corticosteroids and mesalazine used in the treatment of inflammatory bowel disease. Administration by enema avoids having the medication pass through the entire gastrointestinal tract, therefore simplifying the delivery of the medication to the affected area and limiting the amount that is absorbed into the bloodstream. There is some discussion in medical circles about using steroids versus using other enema additives such as cayenne pepper.
- General anesthetic agents for surgical purposes are sometimes administered by way of an enema. Occasionally, anesthetic agents are used rectally to reduce medically-induced vomiting during and after surgical procedures, in an attempt to avoid aspiration of stomach contents.
- A barium enema is used as a contrast substance in the radiological imaging of the bowel. The enema may contain barium sulfate powder, or a water-soluble contrast agent. Barium enemas are sometimes the only practical way to "view" the colon in a relatively safe manner.

In certain countries such as the United States, customary enema usage went well into the 20th century; it was thought a good idea to cleanse the bowel in case of fever; also, pregnant women were given enemas prior to labor so as to supposedly reduce the risk of feces being passed during contractions. Under some controversial discussion, pre-delivery enemas were also given to women to speed delivery by inducing contractions. This latter usage has since been largely abandoned, because obstetricians now commonly give oxytocin to induce labor and because women generally found the procedure unpleasant. In addition, medically-aided labor reduces the physician's waiting time. However, there is some concern that any medication given to a pregnant woman can adversely affect the fetus.

Home usage

Many home-given enemas are pre-packaged sodium phosphate solutions in single-use bottles sold under a variety of brand names, or in generic formats. These units come with a pre-lubricated nozzle attached to the top of the container. Some enemas are administered using so-called disposable bags connected to disposable tubing (despite the names, such units can commonly be used for many months or years without significant deterioration).

Patients who want easier, more gently-accepted enemas often purchase Jon Dodd Enema Syringes which are commonly referred to as "Doddsys" syringes, and which can also be used as old-fashioned hot water bottles, to relieve aches and pains from gentle, heat administrations to parts of the body.

In medical or hospital environments, reusable enema equipment is now rare because of the expense of administering and disinfecting a water-based solution. For a single-patient stay of short duration, an inexpensive disposable enema bag can be used for several days or weeks, using a simple rinse out procedure after each enema administration. The difficulty comes in from the longer time period (and expense) required of nursing aides to give a

gentle, water-based enema to a patient, as compared to the very few minutes it takes the same nursing aide to give the more irritating, cold, pre-packaged sodium phosphate unit.

For home use, disposable enema bags or bottles are common, but reusable rubber or vinyl bags or enema bulbs may also be used. In former times, enemas were infrequently administered using clyster syringes.

Non-medical usage

- The paraphilia directed towards enemas is known as klismaphilia. Klismaphilia is the enjoyment of enema applications because of the pleasurable sensations which they give to many people.
- In some cities, enemas are available as a service from practitioners in the sex industry to cater to klismaphiliac desires, and may be used as part of BDSM activities. Some providers require a physician's prescription before they will give an enema, and others will merely give enemas on request to clients who like or need them.
- A small enema may also be used prior to anal sex or anilingus in order to remove feces, thus reducing bacterial transmission and risk of infection. Or, some people who enjoy anal sex activities use enemas to enhance their sensations during the act. Finally, some people who enjoy anal sex also use a small enema or two to reduce the possibility of fecal material adhering to the sex tool(s) used by themselves or their partners during sexual activity.
- People who wish to become intoxicated faster have also been known to use enemas as a method to instill beverage alcohol into the bloodstream, absorbed through the membranes of the large intestine. However, great care must be taken as to the amount of alcohol used. Only a small amount is needed as the intestine absorbs the alcohol quicker than the stomach. Deaths have resulted due to alcohol poisoning via enema.

Ritual use

- Ritual enemas were practiced by the Maya and many other North American , Central American and South American Indian tribes; some tribes have continued the practice to the present day. Substances used in the enemas include alcohol, tobacco, peyote, and other hallucinogenic drugs and entheogens. The Maya used a fermented liquid called balché in their enemas.

Colonic irrigation

Colonic irrigation or colon hydrotherapy is a large enema which cleanses the whole colon. It was in vogue for hygienic purposes at the beginning of the 20th century (see John Harvey Kellogg) and remains popular as an alternative health therapy in many parts of the world. Advocates believe that, when carried out by trained personnel using sterile equipment, it can be a safe and valuable tool for eliminating toxins from the body and restoring normal muscular activity in the colon. However, there have been cases of intestinal perforation due to improperly done colonic irrigations. The actual medical benefit of colonic irrigation is controversial.

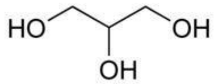
Glycerol



Chemical name Propane-1,2,3-triol

Chemical formula $C_3H_5(OH)_3$

Molecular mass 92.09382 g/mol

CAS number [56-81-5]

HS number Crude: 1520.00.00, Pure: 2905.45.00

Density 1.261 g/cm^3

Viscosity 1.5 Pa.s

Melting point 18 °C (64.4°F)

Boiling point 290 °C (554°F)

Food energy 4.32 kcal/g

SMILES OCC(O)CO

Glycerol, also well known as *glycerin* and *glycerine*, and less commonly as *propane-1,2,3-triol*, *1,2,3-propanetriol*, *1,2,3-trihydroxypropane*, *glyceritol*, and *glycyl alcohol* is a colorless, odorless, hygroscopic, and sweet-tasting viscous liquid. Glycerol is a sugar alcohol and has three hydrophilic alcoholic hydroxyl groups (OH-) that are responsible for its solubility in water. Glycerol is prochiral.

Glycerol is produced from dihydroxyacetone phosphate (DHAP) by the enzyme glycerol three-phosphate dehydrogenase (Gpd p) in the cytoplasm of the eukaryotic cell during glycolysis.

When referring to its function in living organisms, the term *glycerol* is preferred. Glycerol is an important component of triglycerides (i.e. fats and oils) and of phospholipids. Glycerol is a three-carbon substance that forms the backbone of fatty acids in fats.(1) When the body uses stored fat as a source of energy, glycerol and fatty acids are released into the

bloodstream. The glycerol component can be converted to glucose by the liver and provides energy for cellular metabolism.

Purification

The purification of the lower glycerol phase involves: neutralisation, separation of unreacted methanol, dilution with wash liquid stream coming from methylester washing, splitting of soaps and final concentration up to 80%. Partially refined glycerol can be delivered as such to specialized distillers.

Feedstock pre-treatment and upgrading of glycerol to pharmaceutical grade (>99.7%) can be optionally implemented within the biodiesel factory itself.

When used in food, care should be taken to use only pure vegetable glycerol that is specifically labeled for use in food. "External use only" warnings should be heeded.

Applications

Drugs

- Used in medical and pharmaceutical preparations, mainly as a means of improving smoothness, providing lubrication and as a humectant. Also may be used to lower intracranial and intraocular pressures.
- Laxative suppositories, cough syrups, elixirs and expectorants.
- Used as a substitute for alcohol, as a solvent that will create a therapeutic herbal extraction.

Personal care

- Serves as an emollient, humectant, solvent, and lubricant in personal care products.
- Competes with sorbitol although glycerol has better taste and higher solubility.
- Toothpaste, mouthwashes, skin care products, shaving cream, hair care products and soaps

Glycerol is a component of glycerol soap, which is made from denatured alcohol, glycerol, sodium castorate (from castor), sodium cocoate, sodium tallowate, sucrose, water and parfum (fragrance). Sometimes one adds sodium laureth sulfate. This kind of soap is used by people with sensitive, easily irritated skin because it prevents skin dryness with its moisturizing properties. You can also make your own glycerol soap.

When used as an emollient, glycerol should never be applied undiluted to the skin. The same powerful hygroscopic property that draws moisture out of the air to moisten the skin will draw moisture out of the skin if the glycerol is too concentrated. A minimum of two or three parts water should be added to one part glycerol.

Foods and beverages

- Serves as humectant, solvent and sweetener, may help preserve foods.
  Solvent for flavors (such as vanilla) and food coloring.
  Humectant and softening agent in candy, cakes and casings for meats and cheeses.
  Manufacture of mono- and di-glycerides for use as emulsifiers
  Used in manufacture of polyglycerol esters going into shortenings and margarine.
  Used as filler in low-fat food products (i.e., cookies).
  Used as thickening agent in liqueurs.

Glycerol has approximately 27 food calories per teaspoon and is 60% as sweet as sucrose. Although it has about the same food energy as table sugar, it does not raise blood sugar levels, nor does it feed the bacteria that form plaques and cause dental cavities. Glycerol should not be consumed undiluted, as unhydrated glycerol will draw water from tissues, causing blistering in the mouth and gastric distress. As food additive, glycerol is also known as E number E422.

Polyether polyols

- One of the major raw materials for the manufacture of polyols for flexible foams, and to a lesser extent rigid polyurethane foams
- Glycerol is the initiator to which propylene oxide/ethylene oxide is added

Alkyd resins (plastics) and cellophane

- Used in surface coatings and paints
- Used as a softener and plasticizer to impart flexibility, pliability and toughness
- Uses include meat casings, collagen casings (medical applications)and nonmeat packaging
- Plasticizer in cellophane.

Absolute alcohol

- There is an absolute alcohol production process by dehydration using glycerol.

Other applications

- Manufacture of paper as a plasticizer, Nitroglycerin, humectant and lubricant

- Humectant for pet foods to retain moisture and enhance palatability
- Used in lubricating, sizing and softening of yarn and fabric
- Used in de-/anti-icing fluids, as in vitrification of blood cells for storage in liquid nitrogen
- Patent applications have been filed for detergent softeners and surfactants based on glycerol (i.e., alkyl glyceryl ethers) instead of quaternary ammonium compounds.
- A way to preserve leaves is to submerge them in a solution of glycerol and water.

Use a mixture of one part glycerol to two parts water. Place the mixture in a flat pan, and totally submerge the leaves in a single layer in the liquid. You'll have to weigh them down to keep them submerged. In two to six days, they should have absorbed the liquid and be soft and pliable. Remove them from the pan and wipe off all the liquid with a soft cloth. Done correctly, the leaves will remain soft and pliable indefinitely.

- Can be added to solutions of water and soap to increase that solution's ability to generate soap bubbles that will last a long time.
- Used as an antifreeze or a cryoprotectant in cryogenic process.
- Used in fog machine fluids
- Used in hookah tobacco mixtures (called "ma'assel" or "shisha" tobacco), often along with molasses and/or honey.
- Counteracts phenol burns

Magnesium sulfate

Systematic name: Magnesium sulfate, heptahydrate

Other names Epsom salts, bitter salts

Molecular formula $MgSO_4 \cdot 7H_2O$

Formula weight 120.36 g/mol (anhydrous), 246.48 g/mol (Heptahydrate)

Appearance white crystalline solid

CAS number 7487-88-9(anhydrous), 10034-99-8(heptahydrate)

Properties

Density and phase g/cm**3**, solid

Solubility in water 25.5 g/100 ml (20 °C)

In ethanol Slightly soluble (anh.), Insoluble (hydrate)

Melting point 1124°C decomp.

Dehydration Temperature 250°C

Structure

Crystal structure monoclinic (hydrate)

Related compounds

Other cations Calcium sulfate, Aluminium sulfate

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

Magnesium sulfate or *Magnesium sulfate heptahydrate* or *Epsom salt* is a chemical compound containing magnesium, with the formula $MgSO_4·7H_2O$. Magnesium sulfate without water of crystalization $MgSO_4$ is available as a far less common chemical and drying agent, but typically "magnesium sulfate" refers to the hydrate, and Epsom salt always refers to the hydrate. In medical preparations the hydrate form is used to prepare and label even magnesium sulfate formulas in water solution, because the hydrate crystals, which are not deliquescent, are far more easily weighed and subject to quality control in manufacture.

Origin

Epsom salt was originally prepared by boiling down mineral waters at Epsom, England, and afterwards prepared from sea water. In more recent times, these salts are obtained from certain minerals such as epsomite.

Agricultural use

In agriculture and gardening, magnesium sulfate is used to correct magnesium deficiency in soil (magnesium is an essential element in the chlorophyll molecule). It is most commonly applied to potted plants, or to magnesium-hungry crops, such as potatoes, roses, and tomatoes. The advantage of magnesium sulfate over other magnesium soil amendments (such as dolomitic lime) is its high solubility.

Medical use

Locally it may be used as a treatment of an ingrown nail. Oral magnesium sulfate, or magnesium oxide, is used as a laxative. Epsom salts are also available in a gel form for topical application in treating aches and pains. Intravenous use is broadening, as magnesium sulfate reduces striated muscle contractions and blocks peripheral neuromuscular transmission by reducing acetylcholine release at the myoneural junction, as well as other effects. Indications for its use are:

- Hypomagnesemia (low magnesium concentrations in the blood)

- In cardiac arrhythmias, most notably in:
  - Atrial fibrillation

  Torsades de pointes tachycardia
- Treatment (and sometimes prevention) of seizures in eclampsia, for which it is the most effective therapy.
- As a bronchodilator after beta-agonist and anticholinergic agents have been tried, e.g. in severe exacerbations of asthma.[1] In fact, recent studies have revealed that magnesium sulfate can be nebulized to reduce the symptoms of acute asthma (Blitz et al 2005). In the UK, it is commonly administered via the intravenous route for the management of severe asthma attacks
- As a tocolytic agent, administered intravenously for the treatment of preterm labor.
- For acute treatment of migraine.
- In the treatment of tetanus
- In the managment of phaeochromocytoma

Use in organic chemistry

Anhydrous magnesium sulfate is commonly used as a desiccant in organic synthesis due to its affinity for water. During workup, an organic phase is saturated with magnesium sulfate until it no longer forms clumps. The hydrated solid is then removed with filtration or decantation.

A number of other inorganic sulfate salts, sodium sulfate and calcium sulfate for example, may also be used in the same way.

Other uses

Magnesium sulfate is used as in bath salts, particularly in floatation therapy where high concentrations raise the bath water's specific gravity, effectively making the body more buoyant. This property is also used to restore some Lava lamps damaged by being shaken by exchanging the water and adding drops of a concentrated solution until sustainable buoyancy is reached. Traditionally, it is also used to prepare foot baths, intended to soothe sore feet. The reason for the inclusion of the salt is cosmetic: the increase in ionic strength prevents some of the temporary skin wrinkling ("pruning") which is caused by prolonged immersion of extremities in pure water. Magnesium sulfate paste has been used as an agent for drawing (dehydrating) boils and carbuncles. In some parts of the world (such as New Zealand), it is added to homemade drinks, such as lemon cordials. Here the sulfate part of the salt is not important, rather it is the intensely sour taste of magnesium ion Mg^{2+} which acts as flavoring agent.

Also recomended for dropsy treatment for fishes.

Mineral oil

Mineral oil or *liquid petrolatum* is a by-product in the distillation of petroleum to produce gasoline. It is a chemically inert, transparent, colorless oil composed mainly of alkanes and cyclic paraffins, related to white petrolatum. Mineral oil is a substance of relatively low value, and it is produced in very large quantities. Mineral oil is available in light and heavy grades, and can often be found in drug stores.

Applications

- Refined mineral oil is used as transformer oil.
- Mineral oil is used to store and transport alkali metals. The oil prevents the metals from reacting with atmospheric moisture.
- Personal care:
    - Mineral oil is sometimes taken orally as a laxative. It lubricates feces and intestinal mucous membranes, and limits the amount of water removed from feces. Typically, mineral oil is effective within six hours. While it has been reported that mineral oil may be absorbed when emulsified, most information shows that it passes harmlessly through the gastrointestinal system.
        - If used at all, mineral oil should never be given internally to small children, pets, or anyone with a cough, hiatus hernia, or nocturnal reflux, and should be swallowed with care. Due to its low density, it is easily aspirated into the lungs, where it cannot be removed by the body and can cause serious complications such as lipoid pneumonia.[1] While popular as a folk remedy, there are many safer alternatives available.
    - Mineral oil with added fragrance is marketed as 'baby oil' in the US, UK and Canada.
    - Used as an ingredient in baby lotions, cold creams, ointments and other pharmaceuticals and low-grade cosmetics.
    - Can also be used on eyelashes to prevent brittleness and/or breaking.
    - Used in small quantities (2-3 drops daily) to clean ears. Over a couple of weeks, the mineral oil softens dried or hardened earwax so that a gentle flush of water can remove it. In the case of a damaged or perforated eardrum, however, mineral oil should not be used, as oil in the middle ear can lead to ear infections.
- Lubrication
- Fuel, for items such as oil lamps.
- Electric mineral-oil-filled space heaters

- Coolant
- Automotive and aviatation brake fluid that does not absorb water molecules by osmosis
- Low viscosity mineral oil is sold as a preservative for wooden cutting boards and utensils.
- A coating of mineral oil protects metal surfaces from moisture and oxidation.
- Food-preparation butcher block surfaces are often conditioned periodically with mineral oil.
- Light mineral oil is used in textile industries and used as a jute batching oil.
- Mineral oil is used to darken soapstone countertops for aesthetic purposes.
- It works (albeit poorly) as a release agent for molds, especially in fiberglass casting.
- It is used as a release agent for baking pans and trays.
- It is occasionally used in the food industry (particularly for candy). Some studies suggest that prolonged use might be unhealthy because of low accumulation levels in organs. It has been discouraged for use in children's foods, though it is still occasionally found in candies in China and Canada.
- Used as a cleaner and solvent for inks in fine art printmaking as well as in oil painting, though turpentine is more often used.
- It can be used as a solvent for solid samples during Infrared spectroscopy.
- Petrobras is mixing mineral oil and vegetable oil to produce a new biodiesel known as H-Bio, which may greatly increase its market value

Measurement

Mineral oil can be measured by SAE standard kinematic oil viscosity, said to be the oil's "weight."

Proton pump inhibitors

Proton pump inhibitors (or "PPI"s) are a group of drugs whose main action is pronounced and long-lasting reduction of gastric acid production. They are the most potent inhibitors of acid secretion available today. The group followed and has largely superseded another group of pharmaceuticals with similar effects, but different mode-of-action, called H^2-receptor antagonists. These drugs are among the most widely-selling drugs in the world as a result of their outstanding efficacy and safety. Structurally, all of these drugs are substituted benzimidazoles.

Clinical Use

These drugs are utilized in the treatment of many conditions such as:

- dyspepsia

peptic ulcer disease (PUD)
Zollinger-Ellison syndrome
gastroesophageal reflux disease (GORD/GERD)
prevention of stress gastritis
gastrinomas and other conditions that cause hypersecretion of acid

Mechanism of action

Proton pump inhibitors act by irreversibly blocking the hydrogen/potassium adenosine triphosphatase enzyme system (the H+/K+ ATPase, or more commonly just gastric proton pump) of the gastric parietal cell. The proton pump is the terminal stage in gastric acid secretion, being directly responsible for secreting H^+ ions into the gastric lumen, making it an ideal target for inhibiting acid secretion.

Targeting the terminal-step in acid production, as well as the irreversible nature of the inhibition, result in a class of drugs that is significantly more effective than H_2 antagonists and reduces gastric acid secretion by up to 99%.

The lack of the acid in the stomach will aid in the healing of duodenal ulcers, and reduces the pain from indigestion and heartburn, which is caused by excess stomach acid.

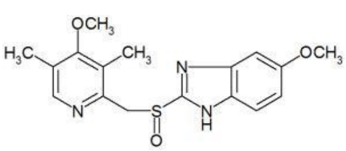
The proton pump inhibitors are given in an inactive form. The inactive form is neutrally charged (lipophilic) and readily crosses cell membranes into intracellular compartments (like the parietal cell canaliculus) that have acidic environments. In an acid environment, the inactive drug is protonated and rearranges into its active form. As described above, the active form will covalently and irreversibly bind to the gastric proton pump, deactivating it.

Pharmacokinetics

Generally, the absorption of proton pump inhibitors is unaffected by co-administration with food. The rate of omeprazole absorption, however, is decreased by concomitant food intake. Additionally, the absorption of lansoprazole and esomeprazole is decreased and delayed by food. These pharmacokinetic effects, however, reportedly have no significant impact on efficacy (Wyeth Australia, 2004; AstraZeneca, 2005).

The elimination half-life of proton pump inhibitors ranges from 0.5–2 hours, however the effect of a single dose on acid secretion usually persists up to 2–3 days. This is because of accumulation of the drug in parietal cell canaliculi and the irreversible nature of proton pump inhibition.

Examples of proton pump inhibitors



The proton pump inhibitor Omeprazole.

Clinically used proton pump inhibitors:

- Omeprazole (brand names: Losec®, Prilosec®)
- Lansoprazole (brand names: Prevacid®, Zoton®, Inhibitol®)
- Esomeprazole (brand names: Nexium®)
- Pantoprazole (brand names: Protonix®, Somac®, Pantoloc®) Rabeprazole (brand names: Rabecid®, Aciphex®, Pariet®)

Adverse effects

Proton pump inhibitors are generally well tolerated, and the incidence of adverse effects is relatively uncommon. The range and occurrence of adverse effects are similar for all of the proton pump inhibitors, though they have been reported more frequently with omeprazole. This may be due to its longer availability and hence clinical experience.

Common adverse effects include: headache, nausea, diarrhoea, abdominal pain, fatigue, dizziness. (Rossi, 2004)

Infrequent adverse effects include: rash, itch, flatulence, constipation. Decreased cyanocobalamin (vitamin B12) absorption may occur with long-term use (Rossi, 2006).

Recently it has been observed that gastric acid suppression, using H^2-receptor antagonists and proton pump inhibitors, is associated with an increased risk of community-acquired pneumonia. It is suspected that acid suppression results in insufficient elimination of pathogenic organisms. It has therefore been suggested that patients at higher risk of pneumonia should only be prescribed proton pump inhibitors at lower doses and only when necessary. (Laheij et al., 2004).

PPIs have been shown to raise risk of C. difficile infection **[1]**

Metabolism Hepatic (CYP2C19, CYP3A4)

Half life 1–1.5 hours

Excretion 80% Renal, 20% faecal

Therapeutic considerations

Pregnancy cat. B3(AU)

Legal status S4(AU) POM(UK)

Routes Oral, IV

Esomeprazole (IPA: [[s oŠÈm[prYzoŠl]) is a proton pump inhibitor (brand names *Nexium*®; *Lucen*®; *Esopral*® and *Axagon*® in Italy) used in the treatment of dyspepsia, peptic ulcer disease (PUD), gastroesophageal reflux disease (GORD/GERD) and Zollinger-Ellison syndrome. Esomeprazole is the S-enantiomer of omeprazole (marketed as Losec/Prilosec), and AstraZeneca claims improved efficacy of this single enantiomer product over the racemic mixture of omeprazole (see below).

Pharmacology

Main article: Proton pump inhibitor

Esomeprazole is a proton pump inhibitor which reduces gastric acid secretion through inhibition of H+/K+-ATPase in gastric parietal cells. By inhibiting the functioning of this enzyme, the drug prevents formation of gastric acid.

Clinical use

Main article: Proton pump inhibitor

Use in Helicobacter pylori eradication

Esomeprazole is combined with the antibiotics clarithromycin and amoxicillin (or metronidazole in penicillin-hypersensitive patients) in the one week eradication triple therapy for Helicobacter pylori. Infection by H. pylori is the causative factor in the majority of peptic and duodenal ulcers.

Evidence of efficacy

AstraZeneca claims that esomeprazole provides improved efficacy, in terms of stomach acid control, over racemic omeprazole. Many health professionals have expressed the view that this improvement in efficacy is due to the increased dose of (es)omeprazole recommended for therapy rather than any superiority of esomeprazole per se.

The study usually cited by AstraZeneca to support its claims is of doubtful study power. Lind et al. (2004) compared esomeprazole to omeprazole in a study of only 36 GERD patients. It is noted that this study was financially supported by AstraZeneca itself.

An alternative rationale suggested for the use of esomeprazole was the reduction in interindividual variability in efficacy. There is, however, little evidence for even this advantage. (Somogyi et al., 2004)

Given the large difference in cost between esomeprazole and other proton pump inhibitors and the negligible advantages of esomeprazole, many doctors recommend cheaper alternatives, which in most cases work just as well.

Dosage forms

Esomeprazole is available as delayed-release capsules (containing esomeprazole magnesium) in strengths of 20 mg and 40 mg; and as a powder (esomeprazole sodium) for intravenous injection/infusion. Oral esomeprazole preparations are enteric-coated, due to the rapid degradation of the drug in the acidic conditions of the stomach. This is achieved by formulating capsules using the multiple-unit pellet system.

Multiple unit pellet system

Esomeprazole capsules are formulated as a "multiple unit pellet system" (MUPS). Essentially, the capsule consists of extremely small enteric-coated granules (pellets) of the esomeprazole formulation inside an outer shell. When the capsule is immersed in an aqueous solution, as happens when the capsule reaches the stomach, water enters the capsule by osmosis. The contents swell from water absorption causing the shell to burst, releasing the enteric-coated granules. For most patients, the multiple-unit pellet system is of no advantage over conventional enteric-coated preparations. Patients for which the formulation is of benefit include those requiring nasogastric tube feeding and those with difficulty swallowing (dysphagia).

The granules are manufactured in a fluid bed system with small sugar spheres as the starting material. The sugar spheres are sequentially spray-coated with a suspension containing esomeprazole, a protective layer to prevent degradation of the drug in manufacturing, an enteric coating and an outer layer to reduce granule aggregation. The granules are mixed with other inactive excipients and compressed into tablets. Finally, the tablets are film-coated to improve the stability and appearance of the preparation.

Routes Oral, IV

Lansoprazole (lan-SOE-pra-zole, INN) is a proton pump inhibitor which prevents the stomach from producing acid.

Pharmacology

Lansoprazole is a proton pump inhibitor (PPI) similar to omeprazole. Lansoprazole's plasma elimination half-life is not proportional to the duration of the drug's effects (i.e. gastric acid suppression). The plasma elimination half-life is 1.5 hours or less, and the effects of the drug last for over 24 hours after it has been used for 5 days or more.

Indications

Lansoprazole is indicated for:

- Treatment of ulcers of the stomach and duodenum, and NSAID-induced ulcers
Treatment of gastroesophageal reflux disease (GERD) (also known as acid reflux disease)
Treatment of Zollinger-Ellison Syndrome
Treatment of Barrett's esophagus
Adjunctive treatment of Helicobacter pylori infection, alongside antibiotics

Contraindications

- Absorption of lansoprazole is reduced by antacids.
- PPI’s reduce absorption of antifungals (itraconazole and ketoconazole) and possibly increase Digoxin in plasma
- Increases plasma concentrations of Cilostazol (risk of toxicity)
- Absorption of lansoprazole possibly reduced by:
  - sucralfate
  - ampicillin
  - bisacodyl
delavirdine
fluvoxamine
  - iron salts
  - theophylline
  - voriconazole
aminophylline and theophylline
astemizole

Side effects

- *Infrequent*: dry mouth, insomnia, drowsiness, blurred vision, rash, pruritus
- *Rarely and very rarely*: taste disturbance, liver dysfunction, peripheral oedema, hypersensitivity reactions (including bronchospasm, urinary, angioedema, anaphylaxis), photosensitivity, fever, sweating, depression, interstitial nephritis, blood disorders (including leukopenia, leukocytosis, pancytopenia, thrombocytopenia), arthralgia, myalgia, skin reactions (including Stevens-Johnson syndrome, toxic epidermal necrolysis, bullous eruption)
- *Increases the risk* of gastric-intestinal infections by reducing gastric acidity.
- *Severe*: Gastro-intestinal disturbances (such as nausea, vomiting, abdominal pain, flatulence, diarrhea, constipation), headache, dizziness

Brand names

The drug is sold with the following brand names:

- *Lansox*® (Italy)
- *Limpidex*® (Italy)
- *Prevacid*® (U.S. and Canada)
- *Takepron*® (Japan)
- *Zoton*® (Italy)

Lansoprazole is also available as a generic drug in Italy.

Antacid

An *antacid* is any substance, generally a base, which counteracts stomach acidity. In other words, antacids are stomach acid neutralisers.

Action mechanism

Antacids relieve the pain of peptic ulcers. They perform a neutralization reaction, i.e. they buffer gastric acid, raising the pH to reduce acidity in the stomach. When the gastric hydrochloric acid reaches the nerves in the gastrointestinal mucosa, they signal pain to the central nervous system. This happens when these nerves are exposed, like in ulcers. The gastric acid may also reach ulcers in the esophagus or the duodenum.

Other mechanisms may contribute, such as the effect of aluminum ions inhibiting smooth muscle cell contraction and delaying gastric emptying.

Indications

Antacids are taken by mouth to relieve heartburn (the major symptom of gastroesophageal reflux disease), or acid indigestion. Treatment with antacids alone is symptomatic and only justified for minor symptoms. Peptic ulcers may require H2-receptor antagonists or proton pump inhibitors.

The usefulness of many combinations of antacids is not clear, although the combination of magnesium and aluminum salts may prevent alteration of bowel habits.

Some associations containing bismuth salts (which may cause encephalopathy) or an anticholinergic substance are not advised.

Side effects

- Aluminum hydroxide: may lead to the formation of insoluble aluminum-phosphate-complexes, with a risk for hypophosphatemia and osteomalacia. Although aluminum has a low gastrointestinal absorption, accumulation may occur in the presence of renal insufficiency. Aluminum-containing drugs may cause obstipation.
- Magnesium hydroxide: has laxative properties. Magnesium may accumulate in patients with renal failure leading to hypermagnesemia, with cardiovascular and neurological complications.
- Carbonate: regular high doses may cause alkalosis, which in turn may result in altered excretion of other drugs, and kidney stones. A chemical reaction between the carbonate and hydrochloric acid may produce carbon dioxide gas. This causes gastric distension which may not be well tolerated.
- Calcium: compounds containing calcium may increase calcium output in the urine, which might be associated to renal stones. Calcium salts may cause obstipation.
- Sodium: increased intake of sodium may be deleterious for arterial hypertension, heart failure and many renal diseases

Interactions

Altered pH or complex formation may alter the bioavailability of other drugs, such as tetracycline. Urinary excretion of certain drugs may also be affected.

Problems with reduced stomach acidity

Reduced stomach acidity may result in an impaired ability to digest and absorb certain nutrients, such as iron and the B vitamins. Since the low pH of the stomach normally kills ingested bacteria, antacids increase the vulnerability to infection by some bacteria.

Drug names

Examples of antacids (the brands listed may not be available outside the United States).

- Aluminum hydroxide (Amphojel®, AlternaGEL®)

Magnesium hydroxide (Phillips'® Milk of Magnesia)

Aluminum hydroxide and magnesium hydroxide (Maalox®, Mylanta®)
Aluminum carbonate gel (Basajel®)
Calcium carbonate (Tums®, Titralac®, Calcium Rich Rolaids®, Rennie®, Alcalak®)
Sodium bicarbonate (Bicarbonate of soda, Alka-Seltzer®)
Hydrotalcite ($Mg6Al2(CO3)(OH)16 \cdot 4(H2O)$; Talcid®)
Bismuth subsalicylate (Pepto-Bismol)
Magaldrate + Simethicone (Pepsil)

Hormonal agents

A *hormone* (from Greek ¿Á¼® - "to set in motion") is a chemical messenger from one cell (or group of cells) to another. All multicellular organisms produce hormones (including plants - see article phytohormone).

Matt Berry Is Better Than Jake

The best-known animal hormones are those produced by endocrine glands of vertebrate animals, but hormones are produced by nearly every organ system and tissue type in an animal body. Hormone molecules are secreted (released) directly into the bloodstream; some hormones, called ectohormones, are not secreted into the blood stream, they move by circulation or diffusion to their target cells, which may be nearby cells (paracrine action) in the same tissue or cells of a distant organ of the body. The function of hormones is to serve as a signal to the target cells; the action of hormones is determined by the pattern of secretion and the signal transduction of the receiving tissue.

Most hormones signal a cell change by combining with a receptor. For many hormones, including most protein hormones, the receptor is embedded in the membrane on the surface of the cell. The interaction of the hormone and the receptor typically triggers a cascade of secondary effects within the cytoplasm of the cell, often involving phosphorylation or dephosphorylation of proteins, changes in ion channels, or increased amounts of an intracellular molecule that serves as a second messenger (e.g., cyclic AMP). The second common type of mechanism, typically involving smaller-sized hormones such as steroid or thyroid hormones, begins with entry of the hormone molecule into the cytoplasm of the cell where it combines with a loose and mobile receptor. The combined hormone-receptor ligand then moves across the nuclear membrane into the nucleus of the cell and binds to the DNA, effectively amplifying or suppressing the action of certain genes, thereby affecting protein synthesis.

Hormone effects vary widely, but can include stimulation or inhibition of growth, induction or suppression of apoptosis (programmed cell death), activation or inhibition of the immune system, regulating metabolism and preparation for a new activity (e.g., fighting, fleeing, mating) or phase of life (e.g., puberty]], caring for offspring, menopause). In many cases, one hormone may regulate the production and release of other hormones. Many of the responses to hormone signals can be described as serving to regulate metabolic activity of an organ or tissue. Hormones also control the reproductive cycle of virtually all multicellular organisms.

History

The concept of internal secretion developed in the 19th century; Claude Bernard described it in 1855, but did not specifically address the possibility of secretions of one organ acting as messengers to others. Still, various endocrine conditions were recognised and even treated adequately (e.g., hypothyroidism with extract of thyroid glands).

The major breakthrough was the identification of secretin, the hormone secreted by the duodenum that stimulates pancreatic secretions, by Ernest Starling and William Bayliss in

1902. Previously, the process had been considered (e.g., by Ivan Pavlov) to be regulated by the nervous system. Starling and Bayliss demonstrated that injecting duodenal extract into dogs rapidly increased pancreatic secretions, raising the possibility of a chemical messenger.

Starling is also credited with introducing the term hormone, having coined it in a 1905 lecture. Later reports indicate it was suggested to him by the Cambridge physiologist William B. Hardy (Henderson 2005).

The remainder of the 20th century saw all the major hormones discovered, as well as the cloning of the relevant genes and the identification of the many interlocking feedback mechanisms that characterize the endocrine system.

Physiology of hormones

Most cells are capable of producing one or more, sometimes many, molecules which signal other cells to alter their growth, function, or metabolism. The classical endocrine glands and their hormone products are specialized to serve regulation on the overall organism level, but can often be used in other ways or only on the tissue level.

The rate of production of a hormone is often regulated by a homeostatic control system, generally by negative feedback. Homeostatic regulation of hormones depends, apart from production, on the metabolism and excretion of hormones.

Hormone secretion can be stimulated and inhibited by:

- Other hormones (stimulating- or releasing-hormones)
- Plasma concentrations of ions or nutrients, as well as binding globulins
- Neurons and mental activity
- Environmental changes, e.g., of light or temperature.

One special group of hormones is the trophic hormones that stimulate the hormone production of other endocrine glands. For example, thyroid-stimulating hormone (TSH) causes growth and increased activity of another endocrine gland, the thyroid, which increases output of thyroid hormones.

A recently-identified class of hormones is that of the "hunger hormones" - ghrelin, orexin and PYY 3-36 - and "satiety hormones" - e.g., leptin, obestatin, nesfatin-1.

Types of hormones

Vertebrate hormones fall into three chemical classes:

1. Amine-derived hormones are derivatives of the amino acids tyrosine and tryptophan. Examples are catecholamines and thyroxine.
2. Peptide hormones consist of chains of amino acids. Examples of small peptide hormones are TRH and vasopressin. Peptides composed of scores or hundreds of amino acids are referred to as proteins. Examples of protein hormones include insulin and growth hormone. More complex protein hormones bear carbohydrate side chains and are called glycoprotein hormones. Luteinizing hormone, follicle-stimulating hormone and thyroid-stimulating hormone are glycoprotein hormones.

3. Lipid and phospholipid-derived hormones derive from lipids such as linoleic acid and arachidonic acid and phospholipids. The main classes are the steroid hormones that derive from cholesterol and the eicosanoids. Examples of steroid hormones are testosterone and cortisol. Sterol hormones such as calcitriol are a homologous system. The adrenal cortex and the gonads are primary sources of steroid hormones. Examples of eicosanoids are the widely studied prostaglandins.

Pharmacology

Many hormones and their analogues are used as medication. The most commonly-prescribed hormones are estrogens and progestagens (in the contraceptive pill and as HRT), thyroxine (as levothyroxine, for hypothyroidism) and steroids (for autoimmune diseases and several respiratory disorders). Insulin is used by many diabetics. Local preparations for use in otolaryngology often contain pharmacologic equivalents of adrenaline, while steroid and vitamin D creams are used extensively in dermatological practice.

A "pharmacologic dose" of a hormone is a medical usage referring to an amount of a hormone far greater than naturally occurs in a healthy body. The effects of pharmacologic doses of hormones may be different from responses to naturally-occurring amounts and may be therapeutically useful. An example is the ability of pharmacologic doses of glucocorticoid to suppress inflammation.

Important human hormones

Spelling is not uniform for many hormones. Current North American and international usage is estrogen, gonadotropin, while British usage retains the Greek diphthong in oestrogen and the unvoiced aspirant h in gonadotrophin.

Amine (derived) hormones

- Tryptophan derivatives
  - Melatonin (N-acetyl-5-methoxytryptamine)

Serotonin (5-HT)

- Tyrosine derivatives
  - Thyroxine (T4)

Triiodothyronine (T3)

  - Catecholamines (also tyrosine derivatives)
    - Norepinephrine (or noradrenaline)

- Dopamine

Peptide hormones

- Antimullerian hormone (AMH, also mullerian inhibiting factor or hormone)
Adiponectin (also Acrp30)
Adrenocorticotropic hormone (ACTH, also corticotropin)
Angiotensinogen and angiotensin
Antidiuretic hormone (ADH, also vasopressin, arginine vasopressin, AVP)
Atrial-natriuretic peptide (ANP, also atriopeptin)
Calcitonin
Cholecystokinin (CCK)
Corticotropin-releasing hormone (CRH)

- Erythropoietin **(EPO)**

- Follicle-stimulating hormone (FSH)
Gastrin
Ghrelin
Glucagon

- Gonadotropin-releasing hormone **(GnRH)**

- Growth hormone-releasing hormone (GHRH)
Human chorionic gonadotropin (hCG)

- Growth hormone **(GH or hGH)**

- Inhibin

- Insulin

- Insulin-like growth factor (IGF, also somatomedin)
Leptin

- Luteinizing hormone **(LH)**

- Melanocyte stimulating hormone (MSH or ±-MSH)
Neuropeptide Y
Oxytocin
Parathyroid hormone (PTH)
Prolactin (PRL)
Relaxin
Secretin
Somatostatin
Thrombopoietin
Thyroid-stimulating hormone (TSH)
Thyrotropin-releasing hormone (TRH)

Steroid and sterol hormones

Steroidal

- Glucocorticoids
  - Cortisol
- Mineralocorticoids
  - Aldosterone
- Sex steroids
  - Androgens
    - Testosterone
      - Dehydroepiandrosterone (DHEA)
      - Dehydroepiandrosterone sulfate (DHEAS)
      - Androstenedione
    Dihydrotestosterone (DHT)
  - Estrogens
    - Estradiol
    - Progestagen
      - Progesterone
      - Progestins

Sterol

- Vitamin D derivatives
  - Calcitriol

Lipid and phospholipid hormones (eicosanoids)

- Prostaglandins

Leukotrienes
Prostacyclin
Thromboxane

Antiandrogens

An *antiandrogen*, or *androgen antagonist*, is any of a group of hormone receptor antagonist compounds that are capable of preventing or inhibiting the biologic effects of androgens, male sex hormones, on normally responsive tissues in the body (see androgen insensitivity syndrome). Antiandrogens usually work by blocking the appropriate receptors, competing for binding sites on the cell's surface, obstructing the androgens' pathway.

Antiandrogens are often indicated to treat severe male sexual disorders, such as hypersexuality (excessive sexual desire) and sexual deviation, specifically paraphilias, as well as use as an antineoplastic agent and palliative, adjuvant or neoadjuvant hormonal therapy in prostate cancer.

Antiandrogens can also be used for treatment of benign prostatic hyperplasia (prostate enlargement), acne vulgaris, androgenetic alopecia (male pattern baldness), and hirsutism (excessive hairiness). They are also occasionally used as a male contraceptive agent, to purposefully prevent or counteract masculinisation in the case of transwomen undergoing gender reassignment therapy, and to prevent the symptoms associated with reduced testosterone, such as hot flushes, following castration.

The administration of antiandrogens in males can result in slowed or halted development or reversal of male secondary sex characteristics, reduced activity or function of the accessory male sex organs, and hyposexuality (diminished sexual desire or libido).

The term antiandrogen withdrawal response (AAWR) describes the medical course taken when cancer cells adapt to feed on the antiandrogens rather than androgen, so that treatment must be halted in order to starve those cells thriving on the antiandrogens.

Currently available antiandrogen drugs (brand names in parentheses) include:

- Spironolactone (Aldactone, Spiritone), a synthetic 17-spirolactone corticosteroid, which is a renal competitive aldosterone antagonist in a class of pharmaceuticals called potassium-sparing diuretics, used primarily to treat low-renin hypertension, hypokalemia, and Conn's syndrome.
- Cyproterone acetate (Androcur, Climen, Diane 35, Ginette 35), a synthetic steroid, a potent antiandrogen that also possesses progestational properties.
- Flutamide (Eulexin), nilutamide (Anandron, Nilandron) and bicalutamide (Casodex), nonsteroidal, pure antiandrogens. Flutamide is the oldest and has more unwanted side effects than the others. Bicalutamide is the newest and has the least side effects.
- Ketoconazole (Nizoral), an imidazole derivative used as a broad-spectrum antifungal agent effective against a variety of fungal infections, side effects include serious liver damage and reduced levels of androgen from both the testicles and adrenal glands. Ketoconazole is a relatively weak antiandrogen.

- Finasteride (Proscar, Propecia) and dutasteride (Avodart), inhibitors of the 5-±-reductase enzyme that prevent the conversion of testosterone into dihydrotestosterone (DHT). Finasteride blocks only 5-±-reductase type II, dutasteride also blocks type I. They are not general antiandrogens in that they don't counteract the effects or production of other androgens than DHT.

5-alpha-reductase inhibitors

5±-reductase inhibitors (or *5-alpha-reductase inhibitors*) are a group of drugs with antiandrogenic activity, used in the treatment of benign prostatic hyperplasia and androgenic (or androgenetic) alopecia. These drugs decrease the levels of available 5±-reductase prior to testosterone binding with the enzyme, thus reducing levels of dihydrotestosterone that derives from such a bond.

Clinical use

Indications

5±-reductase inhibitors are clinically used in the treatment of conditions which are exacerbated by dihydrotestosterone. Specifically, these indications may include: (Rossi, 2004)

- mild-to-moderate benign prostatic hyperplasia
- androgenic (or androgenetic) alopecia

Adverse drug reactions

Adverse drug reactions (ADRs) experienced with 5±-reductase inhibitors are generally dose-dependent. Common ADRs include impotence, decreased libido, decreased ejaculate volume. Rare ADRs include: breast tenderness and enlargement, and allergic reaction. (Rossi, 2004)

Pharmacology

The enzyme 5±-reductase is involved in the conversion of testosterone to the active form dihydrotestosterone by reducing the ”4,5 double-bond. In benign prostatic hyperplasia, dihydrotestosterone acts as a potent cellular androgen and promotes prostate growth - inhibiting the enzyme reduces the excessive prostate growth. In alopecia, pattern-baldness is one of the effects of androgenic receptor activation. Reducing the levels of dihydrotestosterone thus reduces alopecia.

Examples

- finasteride (Proscar, Propecia)

dutasteride (Avodart)
FCE 28260, an experimental compound

GnRH agonists

A *gonadotropin-releasing hormone agonist* (*GnRH agonist*) is a synthetic peptide modeled after the hypothalamic neurohormone GnRH that interacts with its receptor to elicit its biologic response, the release of the pituitary hormones FSH and LH. Agonists do not quickly dissociate from the GnRH receptor. As a result initially there is an increase in FSH and LH

secretion (so-called flare effect), however after about ten days a profound hypogonadal effect is achieved through receptor downregulation. Generally this induced and reversible hypogonadism is the therapeutic goal.

GnRH agonists are synthetically modeled after the natural GnRH decapeptide with specific amino acid substitutions typically in position 6 and 10. These substitutions inhibit rapid degradation. Agonists with 2 substitutions include:

1. leuprolide (Lupron, Eligard),
2. buserelin (Suprefact, Suprecor),
3. nafarelin (Synarel),
4. historelin,
5. goserelin (Zoladex),
6. deslorelin.

Tryptorelin is an agonist with only a single substitution at position 6. Some of these medications are used intranasally, others by injection. Injectables have been formulated for daily, monthly, and quarterly use.

GnRH agonists are useful in:

- Treatment of cancers that are hormonally sensitive and where a hypogonadal state decreases the chances of a recurrence. Thus they are commonly employed in the medical management of prostate cancer and have been used in patients with breast cancer.
- Treatment of delaying puberty in individuals with precocious puberty.
- Management of female disorders that are dependent on estrogen productions. Women with menorrhagia, endometriosis. adenomyosis, or uterine fibroids may receive GnRH agonists to suppress ovarian activity and induce a hypoestrogenic state.
- IVF therapy: they allow for better control of ovarian stimulation during the administration of exohgenous FSH. Typically, after GnRH agonists have induced a state of hypoestrogenism, exogenous FSH is given to stimulate ovarian follicle, followed by human chorionic gonadotropins (hCG) to trigger ovulation.

Side effects of the GnRH agonists are signs and symptoms of hypoestrogenism, including hot flashes, headaches, and osteoporosis. In patients under long-term therapy, small amounts of estrogens could be given back ("add-back regimen") to combat such side effects.

Women of reproductive age who undergo cytotoxic chemotherapy have been pretreated with GnRH agonists to reduce the risk of oocyte loss during such therapy and preserve ovarian function. Further studies are necessary to prove that this approach is useful.

GnRH agonists are pregnancy category X drugs.

Mineralocorticoids

Mineralocorticoids is a class of steroids characterised by their similarity to aldosterone and their influence on salt and water metabolism.

Physiology

The primary endogenous mineralocorticoid is aldosterone, although a number of other endogenous hormones (including Progesterone)and deoxycorticosterone have mineralocorticoid function.

Aldosterone acts on the kidneys to provide active reabsorption of sodium and an associated passive reabsorption of water, as well as, the active secretion of potassium in the principle cells of the cortical collecting tubule and active secretion of protons via proton ATPases in the lumenal membrane of the intercalated cells of the collecting tubule. This in turn results in an increase of blood pressure and blood volume.

Aldosterone is produced in the cortex of the adrenal gland and its secretion is mediated by adrenocorticotrophic hormone (ACTH).

Mode of Action

Mineralocorticoids bind to the cytosolic mineralocorticoid receptor. This type of receptor gets activated upon ligand binding. After a hormone binds to the corresponding receptor, the newly formed receptor-ligand complex translocates itself into the cell nucleus, where it binds to many hormone response elements (HRE) in the promoter region of the target genes in the DNA.

The opposite mechanism is called *transrepression*. The activated hormone receptor interacts with specific transcription factors and prevents the transcription of targeted genes.

Aldosterone and cortisol have similar affinity for the mineralocorticoid receptor however, glucocorticoids circulate at roughly 100 times the level of mineralocorticoids. An enzyme exists in mineralocorticoid target tissues to prevent overstimulation by glucocorticoids. This enzyme, 11-beta hydroxysteroid dehydrogenase type II(Protein:HSD11B2), catalyzes the deactivation of glucocorticoids to 11-dehydro metabolites. Licorice is known to be an inhibitor of this enzyme and chronic consumption can result in a condition known as pseudohyperaldosteronism.

Pathophysiology

Hyperaldosteronism (the syndrome caused by elevated aldosterone) generally results from adrenal neoplasms. The two main resulting problems:

1. Hypertension and edema due to excessive Na+ and water retention.
2. Accelerated excretion of potassium ions. With extreme K+ loss there is muscle weakness and eventually paralysis.

Underproduction, or hypoaldosteronism, leads to the salt-wasting state associated with Addison's disease, although classical congenital adrenal hyperplasia and other disease states may also cause this situation.

Pharmacology

An example of synthetic mineralocorticoids is fludrocortisone (Florinef®). An important mineralocorticoid inhibitor is spironolactone.

Aldosterone

Aldosterone

Aldosterone is a steroid hormone produced by the outer-section (zona glomerulosa) of the adrenal cortex in the adrenal gland to regulate sodium and potassium balance in the blood. It is synthesized from cholesterol by aldosterone synthase, which is absent in other sections of the adrenal gland. It is the sole endogenous member of the class of mineralocorticoids. Acting on mineralocorticoid receptors (MR) on principal cells in the distal tubule of the kidney nephron, it increases the permeability of their apical (luminal) membrane to potassium and sodium and activates their basolateral Na+/K+ pumps, stimulating ATP hydrolysis, reabsorbing sodium (Na+) ions and water into the blood, and excreting potassium (K+) ions into the urine. Aldosterone also stimulates H+ secretion by ±-intercalated cells in the collecting duct, regulating plasma bicarbonate (HCO3) levels and its acid/base balance.[1]

Aldosterone is responsible for the reabsorption of about 2% of filtered sodium in the kidneys, which is nearly equal to the entire sodium content in human blood under normal GFR (glomerular filtration rate).[2]

Unlike neuroreceptors, classic steroid receptors are intracellularly located. The aldosterone/MR receptor complex binds on the DNA to the hormone response element, which alters protein synthesis and the transcription of messenger RNA. Some of the transcribed genes are important for transepithelial sodium transport, including serum and glucocorticoid-induced kinase, channel-inducing factor, K-ras2A, and three subunits of the epithelial sodium channel.

Aldosterone synthesis is stimulated by increased plasma angiotensin II or potassium levels, which are present in proportion to plasma sodium deficiencies. It is also stimulated by plasma acidosis. The secretion of aldosterone has a diurnal rhythm; about 75% of the daily production is secreted between 04:00 am and 10:00 am each day.[3]

Aldesterone release is also stimulated by the stretch receptors located in the atria of the heart. If decreased blood pressure is detected, the adrenal gland is stimulated by these stretch receptors to release aldesterone, which increases sodium reabsorption from the urine, sweat and the gut. This causes increased osmolarity in the extracellular fluid which will eventually return blood pressure toward normal.

Contents

Selective estrogen receptor modulator

Selective estrogen receptor modulators (*SERMs*) is a class of medication that acts on the estrogen receptor. A characteristic that distinguishes these substances from receptor agonists and antagonists is that their action is different for various tissues, thereby granting the possibility to selectively inhibit or stimulate estrogen-like action in various tissues.

Members

Members are:

- clomifene
- Raloxifene
- Tamoxifen
- toremifene

bazedoxifene
lasofoxifene
ormeloxifene

Uses

SERMs are used dependent on their pattern of action in various tissues:

- clomifene is used in anovulation
- Raloxifene is used for osteoporosis and is being studied as a breast cancer preventative
- Tamoxifen and toremifene are used for breast cancer
- ormeloxifene is used for contraception

Some SERMs may be good replacements for hormone replacement therapy (HRT), which recent studies have called into question, although the above agents still have an unacceptably high risk of thrombosis and other side-effects to allow for widespread use.

Method of action

Although the SERMs have no immediate structural relationship with 17^2-estradiol, they are stereochemically similar to this estrogen.

There are three types of estrogen receptors, which are intracellular: ± (± homodimer), ^{2} (^{2} homodimer) and ±^{2} (±- and ^{2}-receptor heterodimer). Different tissues have more or less of each class. In turn, each SERM has more affinity to one and less to the other estrogen receptor isoform. The ±-receptor is generally stimulatory, but the ^{2}-receptor may inhibit the ±-isoform as well as suppressing transcription independently.

Genes activated or suppressed by estrogen receptors generally have an estrogen response element sequence in their promotor.

Some SERMs, through this process, also augment the transcription of coactivator molecules, which may be indispensable for their pharmacological action.

Actions

The actions of SERMs on various tissues:

- Pituitary gland - clomifene blocks estrogen action, leading to an increase of follicle-stimulating hormone.
Uterus - tamoxifen may increase endometrial carcinoma risk, but raloxifene does not. Data on toremifene and clomifene is insufficient.
Breast - all SERMs decrease breast cancer risk, and tamoxifen is mainly used for its ability to inhibit growth in estrogen receptor-positive breast cancer.

Deep venous thrombosis - the risk may be elevated in all SERMs. Cholesterol and triglycerides - levels respond favorably to SERMs. Bone turnover and postmenopausal osteoporosis respond favorably to SERMs. Hot flashes are increased by all SERMs.

Bioavailability **2%**

Protein binding 95%

Metabolism Hepatic glucuronidation, CYP system not involved

Half life 27.7 hours

Excretion Fecal

Therapeutic considerations

Pregnancy cat. $X_{(AU)}$ $X_{(US)}$

Legal status P*rescription only*

Routes Oral

Raloxifene is an oral selective estrogen receptor modulator which is used in the prevention of osteoporosis in postmenopausal women. It was announced on April 17, 2006, that raloxifene is as effective as tamoxifen in reducing the incidence of breast cancer in certain high risk groups of females, [1] [2] though with a reduced risk of thromboembolic events and cataracts in patients taking raloxifene versus those taking tamoxifen.[1] It has not been approved by the FDA for this use, and there has been criticism in the mainstream oncology press of the way that the information was released.[2] There has been some confusion in the lay media about the meaning of the trial results. There is no specific clinical evidence for the use of raloxifene in the adjuvant treatment of breast cancer over established drugs such as tamoxifen or anastrozole.

Raloxifene is produced by Eli Lilly Pharmaceuticals and is sold under the brand name *Evista®*.

SERMs mimic estrogen in some tissues and have anti-estrogen activity in others. Other SERMs, such as Pfizer's lasofoxifene and Wyeth's bazedoxifene are in the late stages of clinical development.

Description

Raloxifene hydrochloride (HCl) has the empirical formula $C_{28}H_{27}NO_4S \bullet HCl$, which corresponds to a molecular weight of 510.05 g/mol. Raloxifene HCl is an off-white to pale-yellow solid that is very slightly soluble in water.

Indication

Raloxifene is indicated for the treatment and prevention of osteoporosis in postmenopausal women.

For either osteoporosis treatment or prevention, supplemental calcium and/or vitamin D should be added to the diet if daily intake is inadequate.

Recently it was shown that raloxifene is a very potent drug for prevention of breast cancer. In a recent clinical trial, the drug was shown to be as effective as tamoxifen for breast cancer prevention with lesser side effects[3].

Contraindications and Precautions

Raloxifene is contraindicated in lactating women or women who are or may become pregnant, in women with active or past history of venous thromboembolic events, including deep vein thrombosis, pulmonary embolism, and retinal vein thrombosis and in women known to be hypersensitive to raloxifene.

Adverse Reactions

Common adverse events considered to be drug-related were hot flashes and leg cramps.

Raloxifene may infrequently cause serious blood clots to form in the legs, lungs, or eyes. Other reactions experienced include leg swelling/pain, trouble breathing, chest pain, vision changes. Eli Lilly, the manufacturer of raloxifene, recently issued a warning that use of raloxifene may be associated with increased risk of death from stroke

Routes Oral

Tamoxifen is an oral selective estrogen receptor modulator which is used in breast cancer treatment, and is currently the world's largest selling breast cancer treatment. It is used for the treatment of early and advanced breast cancer in pre- and post-menopausal women. It is also approved by the Food and Drug Administration (FDA) for the reduction of the incidence of breast cancer in women at high risk of developing the disease. It has been further approved for the reduction of contralateral (in the opposite breast) breast cancer.

Tamoxifen competes with oestrogen in the body for oestrogen receptors in breast tissue so that transcription of oestrogen-responsive genes is inhibited.

Tamoxifen was invented by ICI Pharmaceuticals (now AstraZeneca) and is sold under the brand names *Nolvadex*, *Istubal*, and *Valodex*. It is also available as a generic drug in a number of countries. In the United States and other countries, Tamoxifen was almost always referred to by its generic name even before its patents expired.

A rare condition occasionally treated with tamoxifen is retroperitoneal fibrosis.

Tamoxifen is sometimes used to treat gynecomastia in men. Tamoxifen is also used by bodybuilders in a steroid cycle to try and prevent or reduce drug-induced gynecomastia caused by steroids that are used in the same cycle.

Tamoxifen is also used to treat infertility in women with anovulatory disorders. A dose of 10-40 mg per day is administered in days 3-7 of a woman's cycle.

On April 17, 2006, it was announced that Raloxifene is equally effective in reducing the incidence of breast cancer, but caused fewer side effects.

Side effects

Tamoxifen is a selective estrogen receptor modulator. Even though it is an antagonist in breast tissue it acts as partial agonist on the endometrium. Therefore endometrial changes, including cancer, are among tamoxifen's side effects. Source: Golan et al. Principles of Pharmacology page 450. For some women, tamoxifen can cause a rapid increase in triglyceride concentration in the blood. In addition there is an increased risk of thromboembolism especially during and immediately after major surgery or periods of immobility.

4-hydroxytamoxifen

4-hydroxytamoxifen is a form of the drug tamoxifen that is made by the body after taking tamoxifen. It can also be made in the laboratory, and may help decrease breast density. A topical form of 4-hydroxytamoxifen is being studied in breast cancer screening.

Pharmacogenetics

Patients with variant forms of the gene CYP2D6 (also called simply 2D6) may not receive full benefit from tamoxifen. On Oct 18, 2006 the Subcommittee for Clinical Pharmacology recommended relabeling tamoxifen to include information about this gene in the package insert.

Sex steroids

Sex steroids, also known as *gonadal steroids*, are steroid hormones which interact with vertebrate androgen or estrogen receptors. Natural sex steroids are made by the gonads (ovaries or testes), by adrenal glands, or by conversion from other sex steroids in other tissues such as liver or fat. The term *sex hormone* nearly always is synonymous with sex steroid.

Sex steroids play important roles inducing the body changes known as primary sex characteristics and secondary sex characteristics.

The development of both primary and secondary sexual characteristics is controlled by sex hormones after the initial fetal stage where the presence or absence of the Y-chromosome and/or the SRY gene determine development.

In many contexts, the two main classes of sex steroids are androgens and estrogens, of which the most important human examples are testosterone and estradiol respectively. Other contexts will include Progestagen as a third class of sex steroids, distinct from androgens and estrogens. Progesterone is the most important and only naturally occurring human progestagen.

There are also many synthetic sex steroids. Synthetic androgens are often referred to as anabolic steroids. Synthetic estrogens and progestins are used in oral contraceptive pills. Diethylstilbestrol (DES) is a synthetic estrogen.

Sex steroids include:

- androgens**:xx**
  - testosterone
    - androstenedione
  dihydrotestosterone
    - Dehydroepiandrosterone
  - anabolic steroids
- estrogens**:**
  - estradiol
    - diethylstilbestrol
  - Progestagen:
    - Progesterone
    - progestins

Androgens

Androgen is the generic term for any natural or synthetic compound, usually a steroid hormone, that stimulates or controls the development and maintenance of masculine characteristics in vertebrates by binding to androgen receptors. This includes the activity of the accessory male sex organs and development of male secondary sex characteristics. Androgens, which were first discovered in 1936, are also called *androgenic hormones* or *testoids*. Androgens are also the original anabolic steroids. They are also the precursor of all estrogens, the female sex hormones. The primary and most well-known androgen is testosterone.

Types of androgens

A subset of androgens, *adrenal androgens*, includes any of the 19-carbon steroids synthesized by the adrenal cortex, the outer portion of the adrenal gland, that function as weak steroids or steroid precursors, including Dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEA-S), and androstenedione.

Besides testosterone, other androgens include:

- Dehydroepiandrosterone (DHEA): a steroid hormone produced from cholesterol in the adrenal cortex, which is the primary precursor of natural estrogens. DHEA is also called dehydroisoandrosterone or dehydroandrosterone.
- Androstenedione (Andro): an androgenic steroid, which is produced by the testes, adrenal cortex, and ovaries. While androstenediones are converted metabolically to testosterone and other androgens, they are also the parent structure of estrone. Use of androstenedione as an athletic or body building supplement has been banned by the International Olympic Committee as well as other sporting organizations.
- Androstenediol: the steroid metabolite that is thought to act as the main regulator of gonadotropin secretion.
- Androsterone: a chemical by-product created during the breakdown of androgens, or derived from Progesterone, that also exerts minor masculinising effects, but with one-seventh the intensity of testosterone. It is found in approximately equal amounts in the plasma and urine of both males and females.
- Dihydrotestosterone (DHT): a metabolite of testosterone that is actually a more potent androgen in that it binds more strongly to androgen receptors.

Androgen functions

Development of the male

During mammalian development, the gonads are at first capable of becoming either ovaries or testes[1]. In humans, starting at about week 4 the gonadal rudiments are present within intermediate mesoderm adjacent to the developing kidneys. At about week 6, epithelial sex cords develop within the forming testes and incorporate the germ cells as they migrate into the gonads. In males, certain Y chromosome genes, particularly SRY, control development of the male phenotype, including conversion of the early bipotential gonad into testes. In males, the sex cords fully invade the developing gonads.

By week 8 of human fetal development, Leydig cells appear in the differentiating gonads of males. The mesoderm-derived epithelial cells of the sex cords in developing testes become the Sertoli cells which will function to support sperm cell formation. A minor population of non-epithelial cells exists between the tubules, these are the androgen-producing Leydig cells. The Leydig cells can be viewed as producers of androgens that function as paracrine hormones required by the Sertoli cells in order to support sperm production. Soon after they differentiate, Leydig cells begin to produce androgens which are required for masculinization of the developing male fetus (including penis and scrotum formation). Under the influence of androgens, remnants of the mesonephron, the Wolffian ducts, develop into the epididymis, vas deferens and seminal vesicles. This action of androgens is supported by a hormone from Sertoli cells, AMH, which prevents the embryonic Müllerian ducts from developing into fallopian tubes and other female reproductive tract tissues in male embryos. AMH and androgens cooperate to allow for the normal movement of testes into the scrotum.

Before the production of the pituitary hormone LH by the embryo starting at about weeks 11-12, human chorionic gonadotrophin (hCG) promotes the differentiation of Leydig cells and their production of androgens. Androgen action in target tissues often involves conversion of testosterone to 5±-dihydrotestosterone (DHT).

Spermatogenesis

During puberty, androgen, LH and FSH production increase and the sex cords hollow out, forming the seminiferous tubules, and the germ cells start to differentiate into sperm. Throughout adulthood, androgens and FSH cooperatively act on Sertoli cells in the testes to support sperm production[2]. Exogenous androgen supplements can be used as a male contraceptive. Elevated androgen levels caused by use of androgen supplements can inhibit production of LH and block production of endogenous androgens by Leydig cells. Without the locally high levels of androgens in testes due to androgen production by Leydig cells, the seminiferous tubules can degenerate resulting in infertility.

Inhibition of fat deposition

Males typically have less adipose tissue than females. Recent results indicate that androgens inhibit the ability of some fat cells to store lipids by blocking a signal transduction pathway that normally supports adipocyte function[3].

Muscle mass

Males typically have more skeletal muscle mass than females. Androgens promote the enlargement of skeletal muscle cells and probably act in a coordinated manner to enhance muscle function by acting on several cell types in skeletal muscle tissue[4].

Brain

Circulating levels of androgens can influence human behavior because some neurons are sensitive to steroid hormones. Androgen levels have been implicated in the regulation of human aggression[5] and libido.

Insensitivity to androgen in humans

Reduced ability of a XY karyotype fetus to respond to androgens can result in one of several problems, including infertility and several forms of intersex conditions.

Anabolic steroids

Anabolic androgenic steroids (AAS) are a class of natural and synthetic steroid hormones that promote cell growth and division, resulting in growth of several types of tissues, especially muscle and bone. Different anabolic androgenic steroids have varying combinations of androgenic and anabolic properties, and are often referred to in medical texts as AAS (anabolic/androgenic steroids). Anabolism is the metabolic process that builds larger molecules from smaller ones.

Anabolic steroids were first discovered in the early 1930s and have since been used for numerous medical purposes including stimulation of bone growth, appetite, puberty, and muscle growth. The most wide spread use of anabolic steroids is their use for chronic wasting conditions including cancer and AIDS. Anabolic steroids can produce numerous physiological effects including increased protein synthesis, muscle mass, strength, appetite and bone growth. Anabolic steroids have also been associated with numerous side effects when administered in excessive doses and these include elevated cholesterol (increase in LDL, decreased HDL levels), acne, elevated blood pressure, hepatotoxicity, and alterations in left ventricle morphology.

Today anabolic steroids are controversial because of their widespread use in numerous sports and their purported side effects. While there are numerous health issues associated with excessive anabolic steroid use, there is also a substantial amount of propaganda, junk science and misconceptions concerning their use. Anabolic steroids are controlled in a few countries including the United States where they are listed as Schedule III in the Controlled Substances Act as well as Canada and Britain who also have laws controlling their use and distribution.

Anabolic and virilizing effects

Anabolic androgenic steroids produce both anabolic and virilization (also known as androgenic) effects. Most anabolic steroids work in two simultaneous ways. First, they work by binding the androgen receptor and increasing protein synthesis. Second, they also reduce recovery time by blocking the effects of the stress hormone, cortisol, on muscle tissue. As a result, catabolism of the body's muscle mass is greatly reduced.

Examples of anabolic effects:

- Increased protein synthesis from amino acids
Increased muscle mass and strength[1][2][3]
Increased appetite
Increased bone remodeling and growth
Stimulation of bone marrow increasing production of red blood cells

Examples of virilizing/androgenic effects:

- Growth of the clitoris (clitoral hypertrophy) in females and the penis in male children (the adult penis does not grow indefinitely even when exposed to high doses of androgens)
Increased growth of androgen-sensitive hair (pubic, beard, chest, and limb hair)
Increased vocal cord size, deepening the voice
Increased libido
Suppression of endogenous sex hormones
Impaired spermatogenesis

Possible unwanted side effects

Many androgens are capable of being metabolized to compounds which can interact with other steroid hormone receptors including the estrogen, progesterone, and glucocorticoid receptors, producing additional (usually) unwanted effects:

- Possible elevated blood pressure
Cholesterol levels –Some steroids can cause a increase in LDL, Decreased HDL levels[4]. This can cause a increase in risk of cardiovascular disease[5] or coronary artery disease[6] in men with high risk of bad cholesterol.
Acne– Due to the stimulation of sebaceous gland[7][8]
Conversion to DHT (Dihydrotestosterone). This can accelerate or cause premature baldness and prostate cancer.
Altered left ventricle morphology – AAS can induce an unfavourable

enlargement and thickening of the left ventricle, which loses its diastolic properties with the mass increase.[9] However the negative relation of left ventricle morphology to decreased cardiac function has been disputed.[10] Hepatotoxicity – Caused particularly by oral anabolic steroid compounds which are 17-alpha-alkylated in order to not be destroyed by the digestive system. Gingival overgrowth - AAS is closely associated with significant levels of gingival enlargement.[11]

Male-specific side effects

- Gynecomastia – Breast development in males. It is usually due to high levels of circulating estrogen. These high levels are the result of the increased level of conversion of testosterone to estrogen via the aromatase enzyme. Reduced sexual function and temporary infertility[12][13][14] Testicular atrophy – Temporary side effect that is due to decreases in natural testosterone levels inhibiting spermatogenesis. As most of the mass of the testes is developing sperm, the size of the testicles usually returns to normal within a few weeks of discontinuing anabolic steroid use when spermatogenesis resumes.[15]

Female-specific side effects

- Body hair increase

Deepening of the voice
Enlarged clitoris (clitoral hypertrophy)
Temporary decrease in menstrual cycles

Adolescent-specific side effects

- Stunted growth – Abuse of the agents may prematurely stop the lengthening of bones (premature epiphyseal fusion through increased estrogen)

Accelerated bone maturation
Slight beard growth

An ideal anabolic steroid (a hormone with purely anabolic effects and no virilizing or other side effects) has been widely sought. Many synthetic anabolic steroids have been developed in an attempt to find molecules that produced a higher degree of anabolic rather than virilizing effects. Unfortunately, the most effective steroids known for increasing lean body mass also have the strongest androgenic characteristics.

Medical uses

Anabolic steroids were tried by physicians for many purposes from the discovery of synthetic testosterone in the 1930s to the 1950s with varying success. One of the initial medical uses of steroids was treatment of chronic wasting, such as was experienced by Nazi

concentration camp prisoners and prisoners of war. During World War II, German scientists worked on synthesizing other anabolic steroids, and ran experiments on human prisoners, as well as with their own soldiers. They had hoped to increase the aggressive tendencies of their troops. Adolf Hitler's own physician reported that Hitler had been given testosterone derivative injections to treat various ailments.[16]

- Bone marrow stimulation: For decades, anabolic steroids were the mainstay of therapy for hypoplastic anemias not due to nutrient deficiency, especially aplastic anemia. Anabolic steroids are slowly being replaced by synthetic protein hormones (such as epoetin alfa) that selectively stimulate growth of blood cell precursors.
- Growth stimulation: Anabolic steroids were used heavily by pediatric endocrinologists for children with growth failure from the 1960s through the 1980s. Availability of synthetic growth hormone and increasing social stigmatization of anabolic steroids led to discontinuation of this use. Stimulation of appetite and preservation and increase of muscle mass: Anabolic steroids have been given to people with chronic wasting conditions such as cancer and AIDS.[17][18]
- Induction of male puberty: Androgens are given to many boys distressed about extreme delay of puberty. Testosterone is now nearly the only androgen used for this purpose but synthetic anabolic steroids were often used prior to the 1980s.
- Testosterone enanthate may prove to be a useful, safe, reversible, effective method of male hormonal contraception in the near future.[19][20]
- Used for age related problems in elderly people. Anabolic Steroids have been shown to help in many age related problems in the elderly.[21]
- Used in hormone replacement therapy for men with low levels of testosterone. (see hypogonadism)
- Used for gender dysmorphia: whereby secondary male characteristics (puberty) are initiated in female-to-male diagnosed patients. Most commonly used testosterone derivatives are Sustanon and Testosterone Enanthate which cause the voice to deepen, increased bone and muscle mass, facial hair, increased levels of red blood cells and clitoral enlargement.

Administration

Medical Disclaimer

There are two common routes for the administration of anabolic steroids: oral (for steroids in pill form) and injectable (this category includes both oil-dissolved and water-dissolved steroids.) Also, transdermal (through the skin) administration via cremes or transdermal patches has become popular in the last several years.

Anabolic steroids should *never* be injected by persons unfamiliar with safe injection sites and practices or without first consulting a doctor. Injectable steroids are commonly injected IM (intramuscularly) with 1-1.5" 18-25 gauge needles. Care must be taken to maintain

cleanliness when injecting. Infection and disease can result if careless procedures are used. Care must also be taken when selecting an injection site. Injections into nerves will be extremely painful and dangerous. Injection into vessels is dangerous as well, as this can cause an embolism or other complications. Common injection sites include the shoulders, outer thighs, and buttocks. Note however, that the sciatic nerve runs right up the back of each leg and up the middle of both buttocks. The triceps, biceps and latissumus dorsi also have been used, however, this practice can be dangerous. Blood vessels are abundant in these and other areas. Common amounts used at any one time are typically on the order of a few tens of mg/day for oral steroids, to several hundred mg/week for injectable steroids. As with any drug, increasing the dosage increases the risk of the above side effects.

Use and abuse in sports

Anabolic steroids have been used by men and women in many different kinds of professional sports (track and field, weightlifting, bodybuilding, shot put, cycling, baseball, wrestling, mixed martial arts, boxing, football, etc.) to attain a competitive edge or to assist in recovery from injury. Steroid use to obtain competitive advantage is prohibited by the rules of the governing bodies of many sports. However, steroids are also used by many non-professional athletes to enhance physical performance, and are also widely used by amateur bodybuilders to enhance physical appearance. Unfortunately, these powerful compounds are also used by adolescents.

According to the 1999 Monitoring the Future study, the percentage of eighth, tenth, and twelfth graders in the United States who reported using steroids at least once in their lives increased steadily over the preceding four years (an average of 1.8% in 1996, 2.1% in 1997, 2.3% in 1998, and 2.8% in 1999). In addition, steroid use to enhance athletic performance is no longer limited to high school males: a 1998 Pennsylvania State University study found that 175,000 high school girls nationwide reported taking steroids at least once in their lifetime. The National Institute on Drug Abuse found that 3.4% of all high school seniors report using steroids at least once in 2005. Nearly 2% of 8th graders admitted to using steroids.

Minimizing the side effects

Typically, bodybuilders, athletes and sportsmen who use anabolic steroids try to minimize the negative side effects. For example, users may increase their amount of cardiovascular exercise to help negate the effects of left ventricle hypertrophy.

Some androgens will aromatise and convert to estrogen, potentially causing some combination of the side effects listed above. During a steroid cycle users may take an aromatase inhibitor and/or a SERM; these drugs affect aromatisation and estrogen receptor binding respectively. The SERM tamoxifen, is of particular interest as it prevents binding to the estrogen receptor in the breast, reducing the risk of gynecomastia.[22]

Furthermore, to combat the natural testosterone suppression and to restore proper HPTA function, what is known as 'post-cycle therapy' (PCT) is self prescribed. PCT takes place after the course of anabolic steroids. It typically consists of a combination of the following drugs, depending on which protocol is used:

- A SERM such as clomiphene citrate and/or tamoxifen citrate (this is the primary PCT drug).

An aromatase inhibitor such as anastrozole.

Human chorionic gonadotropin, hCG (this has become less common as it is now more often used throughout the cycle rather than after).

The aim of PCT is to return the body's endogenous hormonal balance to its original state within the shortest space of time.

Those prone to premature hair loss due to steroid use have been known to take the prescription drug finasteride for prolonged periods of time. Finasteride reduces the conversion of testosterone to DHT, the latter having much higher potency for alopecia. Finasteride is useless in the cases when steroid is not converted into a more androgenic derivative. Finasteride is also used as a masking agent by those who are subject to steroid testing.

Since anabolic steroids can be toxic to the liver or can cause increases in blood pressure or cholesterol, many users consider it ideal get frequent blood work tests and blood pressure tests to make sure their blood pressure or cholesterol are still within normal levels. Since anabolic steroids can increase cholesterol they increase the risk for heart attack in users.[23] So it is generally considered mandatory for all users to get blood work while using anabolic steroids.

Popular misconceptions

Anabolic steroids, like many other drugs, have been at the center of a lot of controversy and because of this there are many popular misconceptions and myths concerning their purported effects and side effects. As with many infamous drugs in popular culture, the misconceptions relating to anabolic steroids have likely arisen from misunderstandings of actual side effects of anabolic steroids. One such example might include the myth that anabolic steroids can ‘shrink’ one's penis. It is likely that this myth came from the real side effect of anabolic steroids known as testicular atrophy, in which the use of anabolic steroids causes reduced secretion of the gonadotropins luteinizing hormone and follicle stimulating hormone from the anterior pituitary, thus reducing testicle size. This side effect is temporary and the testicles return to normal soon after exogenous androgen administration is halted.[24]

Another common misconception purveyed in popular culture and the media include the myth that anabolic steroids are highly dangerous and users' mortality rates are high. Anabolic steroids are used widely in the medical field without any serious health risks to users[25][26][27], and no scientific evidence has shown any long-term serious health defects from correct use of anabolic steroids. While risk of death is present in many drugs, the risk of premature death from use of anabolic steroids seems to be extremely low.[28] It is possible this myth gained popularity from claims that Lyle Alzado died from brain cancer caused by anabolic steroids. Alzado himself had claimed that his cancer was caused by anabolic steroids. However, there is no medical evidence anabolic steroids can cause brain cancer and Alzado's own doctors admitted anabolic steroids had nothing to do with his death.[29]

More myths relating to purported side effects include claims that anabolic steroids have caused many teenagers to commit suicide. While lower levels of testosterone have been known to cause depression, and ending a steroid cycle is known to result in temporarily lower testosterone levels, the claim that anabolic steroids are responsible for specific suicides among teenagers is highly questionable. In the United States the estimated use of anabolic steroids among high school students was 2.8% in 1999. On the other hand, in the year 2000 in the United States, suicide was the third leading cause of death among 15- to 24-year-olds.[30] With the suicide rate this high among teenagers, concluding anabolic steroids are responsible for the suicides of teenagers who happened to be taking them prior to committing suicide is a Post hoc logical fallacy. Also, even though teen bodybuilders have been using steroids since at least the early 1960s, only a few cases suggesting a link between steroids and suicide have been reported in the medical literature.[31]

One of the most common misconceptions regarding the side effects of anabolic steroids is known as ‘roid rage’. There seems to be little or no evidence such a condition actually exists. Most studies done on "angry behavior" and anabolic steroid use show no psychological effect, implying that either "roid rage" doesn't exist or that anabolic steroids' effects on aggression are too small to be measured. Many scientists and medical professionals conclude anabolic steroids have no real effect on increased angry behavior.[32][33][34][35][36]

Arnold Schwarzenegger is the target of yet another myth regarding the purported side effects of anabolic steroids. Arnold Schwarzenegger has admitted to using anabolic steroids during his bodybuilding career for many years[37], and in 1997 he went in for surgery to correct a defect relating to his heart. Some have assumed this was due to anabolic steroids. However, Arnold Schwarzenegger was born with a congenital genetic defect in which his heart had a bicuspid aortic valve — in other words, whereas normal hearts have three cusps, his had only two, which can occasionally cause problems later in life.[38]

Illegal trade in anabolic steroids

Since anabolic steroids are often produced in different countries than in which they are distributed, they must be smuggled across international borders. Like most significant smuggling operations, sophisticated organized crime is involved, often in conjunction with other smuggling efforts (including other illegal drugs). Unlike psychoactive recreational drugs such as cannabis and heroin, there have not been many high profile cases of individual smugglers of anabolic steroids being caught. The majority of those using illegally obtain the drugs via this black market,[39][40] and more specifically, pharmacists, veterinarians, and physicians. Anabolic Steroids purchased through the Black Market may be counterfeit, or originally manufactured for veterinary applications. Which in and of itself isn't dangerous except for the fact they are sometimes produced and handled in cruder and less sterile environments.[41][42]

Production

Anabolic steroids need sophisticated pharmaceutical processes and equipment to produce, so they are produced by legitimate pharmaceutical companies or underground laboratories with large overheads. Common problems associated with illegal drug trades, such as chemical substitutions, cutting, and diluting, affect illegal anabolic steroids such that when it reaches distribution the quality may be questionable or possibly dangerous.

In the 1990s most US producers such as Ciba, Searle and Syntex stopped making and marketing anabolic steroids within the US. However, in many other regions, particularly Eastern Europe, they are still produced in quantity. European anabolic steroids are the source of most medical grade anabolic steroids sold illegally in North America. However, anabolic steroids are still in wider use for veterinary purposes, and many illegal anabolic steroids are actually veterinary grade.

Distribution

In the United States and Canada, steroids are purchased just like any illegal drug through dealers who are able to obtain the drugs from a number of sources, although most users would prefer to buy from legitimate sources but cannot because of the restrictive laws against steroid possession. Counterfeit steroids are a common solution to the lack of legal availability in the United States and Canada, although black-market importation continues from Mexico, Thailand and other countries where steroids are more easily available and, in many countries, not illegal at all. Many people produce fake steroids and attempt to sell them over the internet which causes a wide variety of health concerns.

Most illicit anabolic steroids are now sold at gyms, competitions, and through the mail. For the most part, these substances are smuggled into the United States. In addition, a significant number of counterfeit products are sold as anabolic steroids, particularly via mail order from websites posing as overseas pharmacies. In addition to the recreational use of anabolic steroids, users in Great Britain have been shown to consume illicit drugs as well, such as cannabis, and cocaine.[39][43][44]

History

Comments on professional athletes in ancient Greece suggest that a wide variety of natural steroidal substances were used to promote androgenic and anabolic growth. These may have ranged from testicular extracts to plant materials. Traditional medicine in general, in the West as well as in contemporary Asian medicine, has a wide pharmacopeia of substances intended to promote virility and masculine traits, though not entirely oriented towards muscle growth and athletic ability so much as sexual performance. In Chinese traditional medicine, substances such as deer antler, tiger bone, bear gall bladder, ginseng and other roots and much more are all primarily consumed and were thought to bolster the male organism. There is no science behind these claims.

Modern pharmaceutical anabolic steroids are believed to have been inadvertently discovered by German scientists in the early 1930s, but at the time the discovery was not considered significant enough to warrant further study. The first known reference to an anabolic steroid in a US weightlifting/bodybuilding magazine is testosterone propinate in a

letter to the editor in Strength and Health magazine in 1938. In the 1950s, scientific interest was rekindled, and methandrostenolone (Dianabol) was approved for use in the United States by the federal Food and Drug Administration in 1958 after promising trials had been conducted in other countries.

Throughout the '50s, '60s, '70s and even '80s there was doubt Anabolic Steroids even had a real effect. In a 1972 study,[45] participants were informed they would receive injections of anabolic steroids on a daily basis, but instead had actually been give placebo. They reportedly could not tell the difference, and the perceived performance enhancement was similar to that of subjects taking the real anabolic compounds. This study had many flaws including inconsistent controls and insignificant doses. According to Geraline Lin, a researcher for the National Institute on Drug Abuse, at the time of the books' publishing in 1996, the results of the study remained unchallenged for 18 years.[46]

In the 1996 study mentioned above which was founded by the NIH it examined the effect of high doses of testosterone enanthate (600 mg/week intramuscularly for 10 weeks). The results showed a clear increase in muscle mass and decrease in fat mass in those who took the testosterone opposed to the placebo. No adverse reactions were noted.[33]

The U.S. Congress in the Anabolic Steroid Control Act of 1990 placed anabolic steroids into Schedule III of the Controlled Substances Act (CSA). The CSA defines anabolic steroids as any drug or hormonal substance chemically and pharmacologically related to testosterone (other than estrogens, progestins, and corticosteroids) that promotes muscle growth.

By the early 1990s after anabolic steroids were scheduled in the United States several pharmaceutical companies stopped manufacturing or marketing the products in the United States, including Ciba, Searle, Syntex and others.

In addition, an entire market for counterfeit drugs emerged at this time. Never seen in the previous 30 years of their availability on the U.S. market, computers and scanning technology made the ease of counterfeiting legitimate products by utilizing their original label design, and the market was flooded with products that contained everything from mere vegetable oil to toxic substances which unsuspecting users injected into themselves, of which some died as a result of blood poisoning, methanol poisoning or subcutaneous abscess.

On January 20, 2005, the Anabolic Steroid Control Act of 2004 took effect, amending the Controlled Substance Act to place both anabolic steroids and prohormones on a list of controlled substances, making possession of the banned substances without a prescription a federal crime.[47]

Movement for decriminalization

Anabolic steroids are Schedule III controlled substances in the United States and are strictly regulated in some other countries. (It is perhaps worth noting that anabolic steroids are readily available without a prescription in some other countries such as Mexico, Germany, and Thailand.) However, since the U.S. Congress passed the Anabolic Steroid Control Act of 1990, a small movement has arisen that is highly critical of current laws concerning anabolic steroids. On June 21, 2005 Real Sports aired a segment discussing the legality and prohibition of anabolic steroids in America.[48] The show featured Dr. Gary Wadler, chairman of the U.S. Anti- Doping Agency and a prominent anti-steroid activist. When pressed for scientific evidence by correspondent Armen Keteyian that anabolic

steroids are as 'highly fatal' as he claims, Wadler admitted there was no evidence. Gumbel concluded the 'hoopla' concerning the dangers of anabolic steroids in the media was 'all smoke and no fire.' The show also featured John Romano, a pro-steroid activist who authors 'The Romano Factor,' a pro-steroid column for bodybuilding magazine Muscular Development.[49]

In July 2005 Philip Sweitzer, an Attorney and Author, published an open letter to the Members of the House Committee on Government Reform, and the Senate Committee on Commerce et al. In it he criticized lawmakers' actions in scheduling anabolic steroids, as well as criticized their 'disregard of scientific reality for symbolic effect.' He also pleaded for the consideration of the decriminalization of anabolic steroids and asked for a new policy direction.[50] The U.S. government's position since the late 1980's has been and continues to be that the risks of steroid use are too great to allow them to be decriminalized or unregulated.

List of anabolic compounds commonly used as ergogenic aids

- Testosterone (attached to various esters enanthate, cypionate, propinate or suspended in oil or water)

Methandrostenolone / methandienone (Dianabol)
Nandrolone Decanoate (Deca-durabolin)
Nandrolone Phenylpropionate (Durabolin)
Boldenone Undecylenate (Equipoise)
Stanozolol (Winstrol)
Oxymetholone (Anadrol-50)
Oxandrolone (Anavar)
Fluoxymesterone (Halotestin)
Trenbolone (Fina)
Methenolone Enanthate (Primobolan)
4-chlordehydromethyltestosterone (Turinabol)
Mesterolone (Proviron)
Mibolerone (Cheque Drops)

NB: many of these products are no longer available from the original manufacturers and are now manufactured by "underground" laboratories in the United States, Mexico, and Canada, but are still widely available in certain countries, in most cases from a subsidiary of the original manufacturer (e.g. Schering, Organon).

Gestrinone

Systematic (IUPAC) name

13-ethyl-17alpha-hydroxy-18,19 dinorpregna-4,9,11-trien-20-yn-3-one

Identifiers

CAS number rn=1" href="http://www.nlm.nih.gov/cgi/mesh/2006/MB_cgi?term=16320-04-0&rn=1"> 16320-04-0

ATC code G03**XA02**

PubChem 27812

Chemical data

Formula $C_{21}H_{24}O_2$

Mol. weight 308.4 g/mol

Pharmacokinetic data

Metabolism Hepatic

Excretion Renal, fecal

Therapeutic considerations

Pregnancy cat. X

Gestrinone is a synthetic steroid hormone that acts as an anti-progestin and also has some androgenic activity. It is marketed under the names *Dimetriose*, *Dimetrose*, and *Nemestran*, as a treatment for endometriosis. Gestrinone is available in many countries, but not in the USA. As it has anabolic effects, its use in competition has been banned by the International Olympic Committee.[1]

Method of action

Its mechanism of action consists of suppression of the release of pituitary gonadotropins. Gestrinone also interacts with the endometrium, inhibiting its growth. The inhibition is the result of gestrinone's interaction with the androgen receptor; this is also the reason for androgenic side effects. Gestrinone has been shown to interact with the estrogen receptor, the androgen receptor, and the progesterone receptor.[2]

Metabolism

The drug is well absorbed via the oral route, passed through the liver, and has a half-life of about 24 hours. It is metabolized by the liver and excreted by urine and feces.

Contraindications and side effects

The drug is contraindicated in pregnancy, during lactation, and in patients with severe cardiac, renal or hepatic insufficiency. It is also contraindicated in patients who experienced metabolic and/or vascular disorders during previous estrogen or progestogen therapy, or who are allergic to the medication. The drug is contraindicated in children.

Side effects include vaginal spotting, and, in susceptible individuals, signs of increased androgen activity such as acne, oily skin, fluid retention, weight gain, hirsutism, voice change, or hair loss.

Other uses

The drug has also been investigated for use as a prospective contraceptive agent and as a postcoital contraceptive.[3] It also has been used to shrink uterine fibroids and to reduce menorrhagia[4][5]

Its androgenic properties are more exploited in a "designer steroid", the derivative tetrahydrogestrinone. THG was banned by the Food and Drug Administration (FDA) in 2003.

Routes Oral

Dehydroepiandrosterone (*DHEA*), is a natural steroid hormone produced from cholesterol by the adrenal glands, the gonads, adipose tissue and the brain. DHEA is the precursor of,

androstenedione, testosterone and estrogen. It is the most abundant hormone in the human body.

Synonyms and brand names

Synonyms for Dehydroepiandrosterone are: Dehydroisoandrosterone; 3^2-Hydroxy-5-androsten-17-one; 3^2-Hydroxyandrost-5-en-17-one; Androstenol; Androstenolone; Dehydroisoandrosterone; Hydroxyandrost-5-en-17-one; Prasterone; trans-Dehydroandrosterone.

Brand names for DHEA include Prastera® and Fidelin®.

DHEAS (Dehydroepiandrosterone sulfate)

Dehydroepiandrosterone sulfate (*DHEAS*, PubChem 12594) is the sulfated version of DHEA, - this conversion is reversibly catalyzed by sulfotransferase (SULT2A1) primarily in the adrenals, the liver, and small intestines. In blood, most DHEA is found as DHEAS with levels that are about 300 times higher than free DHEA. Orally ingested DHEA is converted to its sulfate when passing through intestines and liver. While DHEA levels reach their peak in the early morning hours, DHEAS levels show no diurnal variation.

From a practical point measurement of DHEAS is preferable to DHEA as levels are more stable.

Production

DHEA is produced from cholesterol through two cytochrome P450 enzymes. Cholesterol is converted to pregnenolone by the enzyme P450 scc (side chain cleavage) and then another enzyme CYP17A1 converts pregnenolone to 17±-Hydroxypregnenolone and then to DHEA. In humans DHEA is the dominant steroid hormone and precursor of all sex steroids. Humans produce DHEA in greater quantity than any other species. Even non-human primates have not much more than 10% the relative serum level of DHEA seen in humans. The fact that rodents produce so little DHEA makes the results of experiments conducted with these laboratory animals very controversial.

DHEA production is very high during fetal life by the fetal adrenal glands, declines after birth and remains low during childhood. Production begins around 6 years of age, increasing in quantity until peaking in early adulthood, around the age of 25, and declines afterwards to approximately 10% of peak levels by age 80. It is theorized by some that this decline may be due to reduced oxygen and glucose supply to the adrenal glands as a result of age-related atherosclerosis.

Role

In a simple view DHEA can be understood as a prohormone for the sex steroids. Its DHEAS variation may be looked at as buffer and reservoir. Its production in the brain suggests that is also has a role as a neurosteroid. As most DHEA is produced by the zona

reticularis of the adrenal, it is argued that there is a role in the immune and stress response. DHEA may have more biologic roles.

As almost all DHEA is derived from the adrenal glands, blood measurements of DHEAS/DHEA are useful to detect excess adrenal activity as seen in adrenal cancer or hyperplasia, including certain forms of congenital adrenal hyperplasia. Women with polycystic ovary syndrome tend to have normal or mildly elevated levels of DHEAS.

Effects

Studies have shown that DHEA is useful in patients with systemic lupus erythematosus. An application of the evidence was reviewed by the FDA in 2001 and is available online.[1] This review also shows that cholesterol and other serum lipids decrease with the use of DHEA.

Supplementation with DHEA has been shown to decrease insulin resistance.[2]

Long term supplementation has been shown to improve mood and relieve depression.[3]

Disputed effects

The significance of the hormone in health and disease is not fully established. It is postulated that DHEA supplements are beneficial in alleviating:

- cardiovascular disease
diabetes
hypercholesterolemia
obesity
multiple sclerosis

- Parkinson's disease

- Alzheimer's disease
disorders of the immune system
depression
osteoporosis
decreased libido
decreased orgasmic intensity

It is also commercially advertised that DHEA:

- helps decrease insulin resistance
- improves fat metabolism
- increases immune system function
- has anti-aging properties
- increases lean muscle mass

7-Keto™ DHEA, a recently identified natural metabolite of dehydroepiandrosterone (DHEA) is claimed to be both more effective and safer than DHEA because it does not convert itself into testosterone or estrogens in the body.

DHEA and DHEAS are readily available in the United States, but not in many other countries.

Precautions

Some assert that DHEA should not be supplemented outside specialist centres under careful observation of experts in the field of endocrinology.

Side effects may include:

- Palpitations and other arrhythmias
extensive growth of body hair, or hirsutism
Hair loss, especially male pattern baldness
acne

Contraindication

As DHEAS and DHEA are converted to sex steroids, their use is contraindicated in patients with any cancer that is estrogen or testosterone dependent.

Increasing endogenous production

Regular exercise is known to increase DHEA production in the body.[4][5][6] Caloric restriction has also been shown to increase DHEA in primates.[7]

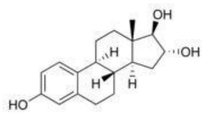
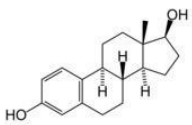
Estrogens



Estriol. Note two hydroxyl (-OH) groups attached to the D ring (rightmost ring).



Estradiol. Note one hydroxyl group attached to the D ring. The 'di' refers both to this hydroxyl and the one on the A ring (leftmost).

Estrogens (also *oestrogens*) are a group of steroid compounds, named for their importance in the oestrus cycle, and functioning as the primary female sex hormone. While estrogens are present in both men and women, they are usually present at significantly higher levels in women of reproductive age. They promote the development of female secondary sex characteristics, such as breasts, and are also involved in the thickening of the endometrium and other aspects of regulating the menstrual cycle.

Explanation

The three major naturally occurring estrogens in women are estradiol, estriol and estrone. From menarche to menopause the primary estrogen is estradiol 17beta. In the body these are all produced from androgens through enzyme action. Estradiol is produced from testosterone and estrone from androstenedione. Estrone is weaker than estradiol, and in post-menopausal women more estrone is present than estradiol.

Estrogens are used as part of some oral contraceptives and also in estrogen replacement therapy of post-menopausal women.

Like all steroid hormones, estrogens readily diffuse across the cell membrane. Inside the cell, they interact with estrogen receptors.[1] A range of synthetic and natural substances have been identified that also possess estrogenic activity.[2] Synthetic substances of this kind are known as xenoestrogens, while natural plant products with estrogenic activity are called phytoestrogens.

Estrogen production

Estrogen is produced primarily by developing follicles in the ovaries, the corpus luteum and the placenta. Follicle stimulating hormone (FSH) and luteinizing hormone (LH) stimulate the production of estrogen in the ovaries. Some estrogens are also produced in smaller amounts by other tissues such as the liver, adrenal glands and the breasts. These secondary sources of estrogen are especially important in post-menopausal women.

Synthesis of estrogens starts in theca interna cells in the ovary, by the synthesis of androstenedione from cholesterol. Androstenedione is a substance of moderate androgenic activity. This compound crosses the basal membrane into the surrounding granulosa cells, where it is converted to estrone or estradiol, either immediately or through testosterone.

The conversion of testosterone to estradiol, and of androstenedione to estrone, is catalyzed by the enzyme aromatase.

Estradiol levels vary through the menstrual cycle, with levels highest just before ovulation.

Functions of estrogens

- structural
  - promote formation of female secondary sex characteristics
  - stimulate endometrial growth
  - increase uterine growth
  - maintenance of vessel and skin
  - reduce bone resorption, increase bone formation
- protein synthesis
  - increase hepatic production of binding proteins
- coagulation
  - increase circulating level of factors 2,7,9,10, antithrombin III, plasminogen
  - increase platelet adhesiveness
- lipid
  - increase HDL, triglyceride, fat deposit
  - decrease LDL
- fluid balance
  - salt and water retention
- gastro-intestinal tract
  - reduce bowel motility
  - increase cholesterol in bile

Studies have found better correlation between sexual desire and androgen levels than for estrogen levels.[3]

In studies involving mice and rats, it was found that lung function may be improved by estrogen. In one study involving 16 animals, female mice that had their ovaries removed to deprive them of estrogen lost 45 percent of their working alveoli from their lungs. Upon receiving estrogen, the mice recovered full lung function. Two proteins that are activated by estrogen play distinct roles in breathing. One protein builds new alveoli, the other stimulates the alveoli to expel carbon dioxide. Loss of estrogen hampered both functions in the test mice.[4]

Medical applications

Since estrogen circulating in the blood can feedback to reduce circulating levels of FSH and LH, most oral contraceptives contain a synthetic estrogen, along with a synthetic progestin.

In hormone replacement therapy, estrogen and other hormones are given to postmenopausal women in order to prevent osteoporosis as well as treat the symptoms of

menopause such as hot flashes, vaginal dryness, urinary stress incontinence, chilly sensations, dizziness, fatigue, irritability, and sweating. Fractures of the spine, wrist, and hips decrease by 50-70% and spinal bone density increases by ~5% in those women treated with estrogen within 3 years of the onset of menopause and for 5-10 years thereafter. Standard therapy is 0.625 mg/day of conjugated estrogens (such as is in Premarin), but the dose can range from 0.3 mg/day to 1.25 mg/day. Estrogen replacement therapy also has favorable effects on serum cholesterol levels and is claimed to dramatically reduce the incidence of cardiovascular disease. There are, however, risks associated with estrogen therapy. Among the older postmenopausal women studied as part of the Women's Health Initiative (WHI), an orally-administered estrogen supplement has been associated with an increased risk of dangerous blood clotting. The WHI studies used one type of estrogen supplement, a high oral dose of conjugated equine estrogens (Premarin alone and with Provera as Prempro)[1]. Research is underway to determine if risks of estrogen supplement use are the same for all estrogen supplement types. In particular, topically-applied estrogen may have a different spectrum of side-effects than does estrogen administered by the oral route[2].

Estrogen is also used in the therapy of vaginal atrophy, hypoestrogenism (as a result of hypogonadism, castration, or primary ovarian failure), amenorrhea, dysmenorrhea, and oligomenorrhea. Estrogens can also be used to suppress lactation after child birth.

Health risks and warning labels

The labeling of estrogen-only products includes a boxed warning that unopposed estrogen (without progestogen) therapy increases the risk of endometrial cancer.

Based on a review of data from the WHI, on January 8, 2003 the FDA changed the labeling of all estrogen and estrogen with progestin products for use by postmenopausal women to include a new boxed warning about cardiovascular and other risks. The estrogen-alone substudy of the WHI reported an increased risk of stroke and deep vein thrombosis (DVT) in postmenopausal women 50 years of age or older and an increased risk of dementia in postmenopausal women 65 years of age or older using 0.625 mg of Premarin conjugated equine estrogens (CEE). The estrogen-plus-progestin substudy of the WHI reported an increased risk of myocardial infarction, stroke, invasive breast cancer, pulmonary emboli and DVT in postmenopausal women 50 years of age or older and an increased risk of dementia in postmenopausal women 65 years of age or older using 0.625 mg of CEE with 2.5 mg of the progestin medroxyprogesterone acetate (MPA).[5][6][7]

Estrogens in cosmetics

Some hair shampoos on the market include estrogens and placental extracts; others contain phytoestrogens. There are case reports of young children developing breasts after exposure to these shampoos. The FDA is aware of these reports but does not consider them of concern to consumers.[8] These products are especially popular with African-American consumers.[9][10]

On September 9, 1993, the FDA determined that all topically-applied hormone-containing drug products for OTC human use are not generally recognized as safe and

effective and are misbranded. An accompanying proposed rule deals with cosmetics, concluding that any use of natural estrogens in a cosmetic product makes the product an unapproved new drug and that any cosmetic using the term "hormone" in the text of its labeling or in its ingredient statement makes an implied drug claim, subjecting such a product to regulatory action.[11]

In addition to being considered misbranded drugs, products claiming to contain placental extract may also be deemed to be misbranded cosmetics if the extract has been prepared from placentas from which the hormones and other biologically active substances have been removed and the extracted substance consists principally of protein. The FDA recommends that this substance be identified by a name other than "placental extract" and describing its composition more accurately because consumers associate the name "placental extract" with a therapeutic use of some biological activity.[11]

The History of Estrogen

The existence and effects of estrogen were established from 1923 to 1938 in which the formulation was led by a group of scientists instead of pharmaceutical companies. Thereafter, the market for hormonal drug research opened up.

The “first orally effective estrogen”, Emmenin, derived from the late-pregnancy urine of Canadian women was introduced in 1930 by Collip and Ayerst Laboratories. However, scientists continued to search for new sources of estrogen because of the concerns associated with the practicality of introducing the drug into the market. At the same time, a German pharmaceutical drug company, Schering, formulated a similar product as Emmenin that was introduced to German women to treat menopausal symptoms.

In 1938, British scientists obtained a patent on a newly formulated nonsteroidal estrogen, Diethylstilbestrol (DES), that was cheaper and more powerful than the previously manufactured estrogens. Soon after, concerns over the side effects of DES were raised in scientific journals while the drug manufacturers came together to lobby for governmental approval of DES. It was only until 1941 when estrogen therapy was finally approved by the Food and Drug Administration (FDA) for the treatment of menopausal symptoms. [12]

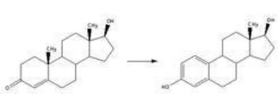
Routes Oral, transdermal

Estradiol (17^2-estradiol) (also *oestradiol*) is a sex hormone. Labelled the "female" hormone but also present in males it represents the major estrogen in humans. Estradiol has not only a critical impact on reproductive and sexual functioning, but also affects other organs including bone structure.

Synthesis



Conversion of testosterone to estradiol

Estradiol, like other sex steroids, is derived from cholesterol. After side chain cleavage and utilizing the delta-5 pathway or the delta-4 pathway androstenedione is the key intermediary. Androstenedione is either converted to testosterone which in turn undergoes aromatization to estradiol, or, alternatively, androstenedione is aromatized to estrone which is converted to estradiol.

Production

During the reproductive years most estradiol in women is produced by the granulosa cells of the ovaries by aromatization of testosterone from the theca cells, or conversion of estrone to estradiol. Smaller amounts of estradiol are also produced by the adrenal cortex. In men, the testes produce estradiol.

Estradiol is not only produced in the gonads. In both sexes precursor hormones, specifically testosterone, are converted by aromatization to estradiol. Particularly fat cells are active to convert precursors to estradiol, and will continue to do so even after the menopause. Estradiol is thus produced also in the brain and in the wall of arterial blood vessels.

Mechanism of action

Estradiol enters cells freely and interacts with a cytoplasmic target cell receptor. When the estrogen receptor has bound its ligand it can enter the nucleus of the target cell, and regulate gene transcription which leads to formation of messenger RNA. The mRNA interacts with ribosomes to produce specific proteins that express the effect of estradiol upon the target cell.

Estradiol binds well to both estrogen receptors, ER± and ER^2, in contrast to certain other estrogens, notably medications that preferentially act on one of these receptors. These medications are called selective estrogen receptor modulators, or SERMs.

Recently there has been speculation about a membrane estrogen receptor, ERX.

Metabolism

In plasma estradiol is largely bound to sex hormone binding globulin, also to albumin, - only a fraction is free and biologically active. Deactivation includes conversion to less active estrogens such as estrone and estriol. Estriol is the major urinary metabolite. Estradiol is conjugated in the liver by sulfate and glucuronide formation and as such excreted via the kidneys. Some of the watersoluble conjugates are excreted via the bile duct, and partly reabsorbed after hydrolysis from the intestinal tract. This enterohepatic circulation contributes to maintaining estradiol levels.

Measurement

Serum estradiol measurement in women reflect primarily the activity of the ovaries. As such they are useful the detect baseline estrogen in women with amenorrhea or menstrual dysfunction and to detect state of hypoestrogenicity and menopause. Furthermore estrogen

monitoring during fertility therapy assesses follicular growth and useful to monitor the treatment. Estrogen-producing tumors will demonstrate persistent high levels of estradiol and other estrogens. In precocious puberty estradiol levels are inappropriately increased.

In the normal menstrual cycle estradiol levels measure typically <50 ng/ml at menstruation, rise with follicular development, drop briefly at ovulation, and rise again during the luteal phase for a second peak. At the end of the luteal phase estradiol levels drop to their menstrual levels unless there is a pregnancy.

During pregnancy estrogen levels including estradiol rise steadily towards term. The source of these estrogens is the placenta that aromatizes prehormones produced in the fetal adrenal gland.

Effects

Female reproduction

In the female, estradiol acts as a growth hormone for tissue of the reproductive organs, supporting the lining of the vagina, the cervical glands, the endometrium and the lining of the fallopian tubes. It enhances growth of the myometrium. Estradiol appears necessary to maintain oocytes in the ovary. During the menstrual cycle, estradiol that is produced by the growing follicle triggers via a positive feedback system the hypothalamic-pituitary events that lead to the luteinizing hormone surge, inducing ovulation. In the luteal phase estradiol , in conjunction with progesterone, prepares the endometrium for implantation. During pregnancy estradiol increases due to placental production. In baboons, blocking of estrogen production leads to pregnancy loss suggesting that estradiol has a role in the maintenance of pregnancy. Research is investigating the role of estrogens in the process of initiation of labor.

Sexual development

The development of secondary sex characteristics in women is driven by estrogens, specifically estradiol. These changes are initiated at the time of puberty, most enhanced during the reproductive years, and become less pronounced with declining estradiol support after the menopause. Thus, estradiol enhances breast development, and is responsible for changes in the body contour affecting bones, joints, fat deposition. Fat structure and skin composition are modified by estradiol.

Male reproduction

The effect of estradiol (and estrogens) upon male reproduction is complex. Estradiol is produced in the Leydig cell of the testes. There is evidence that estradiol is to prevent apoptosis of male germ cells.[1]

Several studies have noted that sperm counts have been declining in many parts of the world and it has been postulated that this may be related to estrogen exposure in the environment. [2] Suppression of estradiol production in a subpopulation of subfertile men may improve the semen analysis.[3]

Males with sex chromosome genetic conditions such as Klinefelters Syndrome will have a higher level of estradiol.

Bone

There is ample evidence that estradiol has a profound effect on bone. Individuals without estradiol (or other estrogens) will become tall and eunuchoid as epiphysieal closure is delayed or may not take place. Bone structure is affected resulting in early osteopenia and

osteoporosis. [4] Also, women past menopause experience an accelerated loss of bone mass due to a relative estrogen deficiency.

Liver

Estradiol has complex affects on the liver. It can lead to cholestasis. It affects the production of multiple proteins including lipoproteins, binding proteins, and proteins responsible for blood clotting.

Brain

Estrogens can be produced in the brain from steroid precursors. As an antioxidant, they have been found to have neuroprotective function.[5]

The positive and negative feedback loop of the menstrual cycle involve ovarian estradiol as the link to the hypothalamic-pituitary system to regulate gonadotropins.

Blood vessels

Estrogen affects certain blood vessels. Improvement in arterial blood flow has demonstrated in coronary arteries.[6]

Oncogene

Estrogen is considered an oncogene as its supports certain cancers, notably breast cancer and cancer of the uterine lining. In addition there are several benign gynecologic conditions that are dependent on estrogen such as endometriosis, leiomyomata uteri, and uterine bleeding.

Pregnancy

The effect of estradiol, together with estrone and estriol, in pregnancy is less clear. They may promote uterine blood flow, myometrial growth, sitmulate breast growth and at term, promote cervical softening and expression of myometrial oxytocin receptors.

Role in sexual differentiation

One of the fascinating twists to mammalian sexual differentiation is that estradiol is one of the two active metabolites of testosterone in males (the other being dihydrotestosterone). Estradiol cannot be transferred readily from the circulation into the brain. Since fetuses of both sexes are exposed to similarly high levels of maternal estradiol, it can play little role in prenatal sexual differentiation. However, testosterone enters the central nervous system more freely and significant amounts are aromatized to estradiol within the brain of most male mammals, including humans. There is now much evidence that the programming of

adult male sexual behavior in "lower mammals," (such as mounting rather than lordosis behavior), is largely dependent on estradiol produced in the central nervous system during prenatal life and early infancy from testosterone. We do not yet know whether this process plays a minimal or significant part in human sexual behaviors.

Estradiol medication

Estrogen is marketed in a number of ways to address issues of hypoestrogenism. Thus there are oral, transdermal, topical, injectable, and vaginal preparations. Furthermore, the estradiol molecule may be linked to an alkyl group at C3 position to facilitate the administration. Such modifications give rise to *estradiol acetate* (oral and vaginal applications) and to *estradiol cyprionate* (injectable).

Oral preparations are not necessarily predictably absorbed and subject to a first pass through the liver where they can be metabolized and also initiate unwanted side effects. Thus, alternative routes of administration have been developed that bypass the liver before primary target organs are hit. Transdermal and transvaginal routes are not subject to the initial liver passage.

A more profound alteration is ethinylestradiol, the most common estrogen ingredient in oral contraceptive medication.

Therapy

Hormone replacement therapy

In the event that levels of estradiol in a woman's blood are low (possibly due to menopause or oophorectomy), a hormone replacement therapy may be prescribed. Often such therapy is combined with a progestin.

Estrogen therapy may be used in fertility therapy when there is a need to develop cervical mucus or an appropriate uterine lining.

Estrogen therapy is also used to maintain female hormone levels in male-to-female transsexuals.

Blocking estrogens

Inducing a state of hypoestrogenism may be beneficial in certain situations where estrogens are contributing to unwanted effects, e.g, certain forms of breast cancer, gynecomastia, and premature closure of epiphyses. Estrogen levels can be reduced by inhibiting production using gonadotropin- releasing factor agonists (GnRH agonists) or blocking the aromatase enzyme using an aromatase inhibitor, or estrogen effects can be reduced with estrogen antagonists such as Tamoxifen. Flaxseed is known to reduce estradiol.[7]

Hormonal contraception

A synthetic form of estradiol, called ethinylestradiol is a major component of hormonal contraceptive devices. Combined oral contraceptives contain ethinylestradiol and a progestin, which both contribute to the inhibition of GnRH, LH, and FSH. The inhibition of these hormones accounts for the ability of combined oral contraceptives or birth control pills to prevent ovulation and thus prevent pregnancy. Other types of hormonal birth control contain only progestins and no ethinylestradiol.

List of estradiol medications

The following are marketed versions of estradiol:

- Oral versions: Estrace®, Activella® (also contains a progestin), estradiol acetate, Progynova®, estrofem®
- Transdermal preparation: Alora®, Climara®, Vivelle®, Menostar®, Estraderm TTS®
- Ointments: Estrasorb Topical®, Estrogel®
- Injection: Estradiol cyprionate: Lunelle® monthly injection, Estradiol valerate
- Vaginal ointment: Estrace Vaginal Cream®, Premarin Cream®
- Vaginal ring: Estring® (estradiol acetate)

Estradiol is also part of conjugated estrogen preparations, including Premarin®.

Contraindications

Estradiol should not be given to women who are pregnant or are breastfeeding, women with unexplained uterine bleeding, certain forms of cancer, or prone to blood clotting disorders. The medication is to be kept away from children. Detailed prescription information is available [8]

Side effects

Side effects of estradiol therapy may include uterine bleeding, breast tenderness, nausea and vomiting, chloasma, cholestasis, and migraine headaches.

Progestagens

Progestagens (also spelled progestogens or gestagens) are hormones which produce effects similar to Progesterone, the only natural progestagen. All other progestogens are synthetic and are often referred to as progestins.

All progestagens have antiestrogenic (counteracting the effects of estrogens on the body) and antigonadotropic (inhibiting the production of sex steroids by gonads) properties.

Progestogens differ in their potency (affinity for progesterone receptors) and side effects. Such side effects may be androgenic (medroxyprogesterone and most C19 progestagens), antiandrogenic (cyproterone acetate), estrogenic, glucocorticoid (some C21 progestogens) or antimineralocorticoid (progesterone).

There is a difference between natural Progesterone and all other synthetic progestagens. Because natural progesterone cannot be patented drug companies have slightly altered the natural progesterone or attached various side groups to the the basic natural progesterone molecule in order to allow them to patent their version.

Numerous studies on HRT were completed prior to the Women's Health Initiative (see external links) and some demonstrated that estrogens plus progestagens, while reducing the risk of endometrial cancer, actually increased the incidence of breast cancers.

There is substantial controversy regarding the safety and effectiveness of artificial intake of hormones. While the synthetic versions of progesterone that are marketed by drug

companies have all been tested over many years by the FDA and other world-wide government bodies and are acceptably safe, recent events with drugs such as Bextra, Celebrex and Vioxx have shown that some drugs may need to be withdrawn after the FDA has become aware of doubts about their safety. This has not been the case with synthetic progestagens, which billions of women have taken for many decades in various forms. Some interested parties have threatened legal action against those individuals who claim otherwise.

Uses

- Birth control
    - Most progestogens are used for their antiestrogenic properties in oral contraceptives to avoid overstimulation of the endometrium which could lead to endometriosis and cancer.
    - Medroxyprogesterone acetate (brand name Depo Provera) is used by depot injection.
    - Etonogestrol is released by subcutaneous implants (Implanon®). Similar products (Norplant® and Jadelle® contain levonogestrol.
- Antiandrogen
    - E.g. Cyproterone.

Melt. point 126 °C (259 °F)

Spec. rot [±]***D***

Pharmacokinetic data

Bioavailability prolonged absorption, half-life approx 25-50 hours

Protein binding 96%-99%

Metabolism hepatic to pregnanediols and pregnanolones

Half life 34.8-55.13 hours

Excretion renal

Therapeutic considerations

Pregnancy cat. B (USA)

Routes oral, implant

Progesterone is a C-21 steroid hormone involved in the female menstrual cycle, pregnancy (supports gestation) and embryogenesis of humans and other species. Progesterone belongs to a class of hormones called progestogens, and is the major naturally occurring human progestogen.

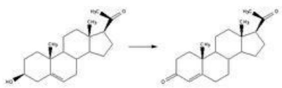
Progesterone should not be confused with progestins, which are synthetically produced progestogens.

Chemistry

Like other steroids, progesterone consists of four interconnected cyclic hydrocarbons. Progesterone contains ketone and oxygenated functional groups, as well as two methyl branches. Like all steroid hormones, it is hydrophobic. This is mostly due to its lack of very polar functional groups.

Synthesis

Progesterone, like all other steroid hormones, is synthesized from pregnenolone, a derivative of cholesterol. This conversion takes place in two steps. The 3-hydroxyl group is converted to a keto group and the double bond is moved to C-4, from C-5.



Conversion of Pregnenolone to Progesterone

Progesterone is the precursor of the mineralocorticoid aldosterone, and after conversion to 17-hydroxyprogesterone (another natural progestogen) of cortisol and androstenedione. Androstenedione can be converted to testosterone, estrone and estradiol.

Sources

Progesterone is produced in the adrenal glands, the gonads (specifically after ovulation in the corpus luteum), the brain, and, during pregnancy, in the placenta. In humans, increasing amounts of progesterone are produced during pregnancy, initially the source is the corpus luteum that has been "rescued" by the presence of human chorionic gonadotropins (hCG) from the conceptus, but after the 8th week production of progesterone shifts over to the placenta. The placenta utilizes maternal cholesterol as the initial substrate, and most of the produced progesterone enters the maternal circulation, but some is picked up by the fetal circulation and is used as substrate for fetal corticosteroids. At term the placenta produces about 250 mg progesterone per day.

Levels

In women, progesterone levels are relatively low during the preovulatory phase of themenstrual cycle, rise after ovulation, and are elevated during the luteal phase. In women progesterone levels tend to be < 2 ng/ml prior to ovulation, and > 5 ng/ml after ovulation. If pregnancy occurs, progesterone levels are maintained at luteal levels initially. With the onset of the luteal-placental shift in progesterone support of the pregnancy levels start to rise further and may reach 100-200 ng/ml at term. Whether a decrease in progesterone levels is critical for the initiation of labor has been argued and may be species-specific. After delivery of the placenta and during lactation, progesterone levels are very low.

Progesterone levels are relatively low in children and postmenopausal women. Adult males have levels similar to those in women during the follicular phase of the menstrual cycle.

Effects

Progesterone exerts its action primarily through the intracellular progesterone receptor though a distinct, membrane bound progesterone receptor has recently been discovered. It has a number of physiological effects, often regulatory, not least of the effects of estrogen. Estrogen often induces a multiplication of progesterone receptors.

Reproduction

Progesterone converts the endometrium to its secretory stage to prepare the uterus for implantation. At the same time progesterone affects the vaginal epithelium and cervical mucus. If pregnancy does not occur, progesterone levels will decrease, leading, in the human, to menstruation. Normal menstrual bleeding is progesterone withdrawal bleeding.

During implantation and gestation, progesterone appears to decrease the maternal immune response to allow for the acceptance of the pregnancy. Progesterone decreases contractility of the uterine smooth muscle. The fetus metabolizes placental progesterone in the production of adrenal mineralo- and glucosteroids. A drop in progesterone levels is possibly one step that facilitates the onset of labor. In addition progesterone inhibits lactation during pregnancy. The fall in progesterone levels following delivery is one of the triggers for milk production .

Neurosteroid

Progesterone, like pregnenolone and dehydroepiandrosterone, belongs to the group of neurosteroids that are found in high concentrations in certain areas in the brain and are synthesized there. Neurosteroids affect synaptic functioning, are neuroprotective, and affect myelinization.[1] They are investigated for their potential to improve memory and cognitive ability. Progesterone as a neuroprotectant affects regulation of apoptotic genes. Its effect as a neurosteroid works predominantly through the GSK-3 beta pathway, as an inhibitor. Other GSK-3 beta inhibitors include bipolar mood stabilizers, lithium and valproic acid. It also raises epidermal growth factor-1 levels, a factor often used to induce proliferation, and used to sustain cultures of stem cells.

Other systems

Progesterone has multiple effects outside of the reproductive system. Progesterone is thermogenic, raising the core temperature. It reduces spasm and relaxes smooth muscle. Bronchi are widened and mucus regulated. Progesterone receptors are widely present in submucosal tissue. Progesterone acts as an antiinflammatory agent and regulates the immune response. Gall-bladder activity is reduced. Other effects include normalizing blood clotting and vascular tone, zinc and copper levels, cell oxygen levels, and use of fat stores for energy. Progesterone also assists in thyroid function, in bone building by osteoblasts, in bone, teeth, gums, joint, tendon, ligament and skin resilience and in some cases healing by regulating various types of collagen, and in nerve function and healing by regulating myelin. Progesterone appears to prevent endometrial cancer (involving the uterine lining) by regulating the effects of estrogen.

Medical Applications

Progesterone is poorly absorbed by oral ingestion unless micronised and in oil, or with fatty foods; it does not dissolve in water. Products such as Prometrium, Utrogestan and

Microgest are therefore capsules containing micronised progesterone in oil - in all three mentioned that is peanut oil, which may cause serious allergic reactions in some people, but compounding pharmacies, which have the facilities and licenses to make their own products, can use alternatives. Vaginal and rectal application is also effective, with products such as Cyclogest, which is progesterone in cocoa butter in the form of pessaries. Progesterone can be given by injection, but because it has a short half-life they need to be daily. Implants, for a longer period, are also available. Marketing of progesterone phamaceutical products, country to country, varies considerably, with many countries having no oral progesterone products marketed, but they can usually be specially imported by pharmacies through international wholesalers.

"Natural progesterone" products derived from yams, do not require a prescription. Wild yams contain a plant steroid called diosgenin, which the human body cannot metabolize into progesterone. Diogenin can only be chemically processed into progesterone in labs.

Progesterone is used to control anovulatory bleeding. It is also used to prepare uterine lining in infertility therapy and to support early pregnancy. Patients with recurrent pregnancy loss due to inadequate progesterone production may receive progesterone.

Progesterone is being investigated as potentially beneficial in Multiple Sclerosis, since the characteristic deterioration of the Myelin insulation of nerves halts during pregnancy, when progesterone levels are raised, but commences again when the levels drop.

Since most progesterone in males is produced in the process of testicular production of testosterone, and most in females by the ovaries, the shutting down (whether by natural or chemical means), or removal, of those inevitably causes a considerable reduction in progesterone levels. Previous concentration upon the role of Progestagen in female reproduction, when progesterone was simply considered a "female hormone" obscured the significance of progesterone elsewhere in both sexes.

The tendency for progesterone to have a regulatory effect, and the presence of progesterone receptors in many types of body tissue, and the pattern of deterioration (or tumour formation) in many of those increasing in later years when progesterone levels have dropped, is prompting widespread research into the potential value of maintaining progesterone levels in both males and females.

Progesterone is used in hormone therapy for transsexual women, and some Intersex women - especially when synthetic progestins have been ineffective or caused side-effects - since normal breast tissue cannot develop except in the presence of both progestogen and estrogen. Mammary glandular tissue is otherwise fibrotic, the breast shape conical and the areola immature, Progesterone can correct those even after years of inadequate hormonal treatment. Research usually cited against such value was conducted using Provera, a synthetic progestin. Progesterone also has a role in skin elasticity and bone strength, in respiration, in nerve tissue and in female sexuality, and the presence of progesterone receptors in certain muscle and fat tissue may hint at a role in sexually-dimorphic proportions of those.

These roles of progesterone may not be fulfilled by synthetic progestins which were designed solely to mimic progesterone's uterine effects.

Progesterone receptor antagonists, or selective progesterone receptor modulators (SPRM)s, such as RU-486 (Mifepristone), can be used to prevent conception or induce medical abortions.

Oral birth control pills do not contain progesterone but a progestin.

Hypolipidemic agents

Hypolipidemic agents, or *antihyperlipidemic agents*, are a diverse group of pharmaceuticals that are used in the treatment of hyperlipidemias. They are called *lipid-lowering drugs* (LLD) or agents.

Classes of hypolipidemic drugs

There are several classes of hypolipidemic drugs. They may differ in both their impact on the cholesterol profile and adverse effects. For example, some may lower the "bad cholesterol" low density lipoprotein (LDL) more so than others, while others may preferentially increase high density lipoprotein (HDL), "the good cholesterol". Clinically, the choice of an agent will depend on the patient's cholesterol profile, cardiovascular risk, and the liver and kidney functions of the patient, evaluated against the balancing of risks and benefits of the medications. In the United States, this is guided by the evidence-based guideline from the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATPIII).

- statins are particularly well-suited for lowering LDL, the cholesterol with the strongest links to cardiovascular diseases. In studies using standard doses, statins have been found to lower LDL-C by 18% to 55%, depending on the specific statin being used. There is a risk of severe muscle damage (myopathy & rhabdomyolysis) with statins.
- fibrates are indicated for hypertriglyceridemia. Fibrates typically lower triglycerides by 20% to 50%. Level of the good cholesterol HDL is also increased. Fibrates may decrease LDL, though generally to a lesser degree than statins. Similar to statins, there is a risk of severe muscle damage (myopathy & rhabdomyolysis) with fibrates.
- nicotinic acid, like fibrates, is also well-suited for lowering triglycerides by 20-50%. It may also lower LDL by 5-25% and increase HDL by 15-35%. Nicotinic acid may cause hyperglycemia, and may also cause liver damage.
- bile acid sequestrants (resins) are particularly effective for lowering LDL-C by sequestering the cholesterol-containing bile acids released into the gut and preventing their reabsorption from the gut. It decreases LDL by 15-30% and raises HDL by 3-5%. It has little effect on triglycerides. Bile acid sequestrants may cause gastrointestinal problems, and may also reduce the absorption of other drugs and vitamins from the gut.
- ezetimibe (Zetia) is a selective inhibitor of dietary cholesterol absorption.
- phytosterols may be found naturally in plants. Similar to ezetimibe, phytosterols reduce the absorption of cholesterol in the gut. Hence, they are most effective when consumed with meals. However, the precise mechanism of action of phytosterols differs from ezetimibe.

Investigational classes of hypolipidemic agents:

- CETP Inhibitors (cholesteryl ester transfer protein inhibitors) are still under development. It is expected that these drugs will mainly increase HDL while lowering LDL.
- squalene synthase inhibitor

Fibrates

In pharmacology, the *fibrates* are a class of amphipathic carboxylic acids. They are used for a range of metabolic disorders, mainly hypercholesterolemia (high cholesterol), and are therefore hypolipidemic agents.

Members

Fibrates prescribed commonly are:

- Bezafibrate (e.g. Bezalip®)

Ciprofibrate (e.g. Modalim®)
Clofibrate (largely obsolete due to side-effect profile, e.g. gallstones)
Gemfibrozil (e.g. Lopid®)
Fenofibrate (e.g. TriCor®)

Indications

Fibrates are used as accessory therapy in many forms of hypercholesterolemia, usually in combination with statins. Trials do support its use as monotherapy.

Although less effective in lowering LDL, fibrates improve HDL and triglyceride levels, and seem to improve insulin resistance when the dyslipidemia is associated with other features of Syndrome X (hypertension and diabetes mellitus type 2).

Side effects

Most fibrates can cause mild stomach upset and myopathy (muscle pain with CPK elevations).

In combination with statin drugs, fibrates cause an increased risk of rhabdomyolysis (idiosyncratic destruction of muscle tissue, leading to renal failure). A powerful statin drug, cerivastatin (Lipobay®), was withdrawn because of this complication. The less lipophilic statins are less prone to cause this reaction, and are probably safer when combined with fibrates.

Pharmacology

Although used clinically since the early 1970s, the mechanism of action of fibrates remained unelucidated until, in the 1990s, it was discovered that fibrates activate PPAR (peroxisome proliferator-activated receptors), especially PPAR±. The PPARs are a class of

intracellular receptors that modulate carbohydrate, fat metabolism and adipose tissue differentiation.

Activation of PPARs causes transcription of a number of genes on the DNA that facilitate lipid metabolism.

Fibrates are structurally and pharmacologically related to the thiazolidinediones, a novel class of anti-diabetic drugs that also act on PPARs (more specifically PPAR[3])

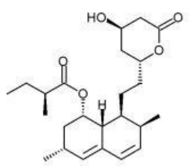
Statins



Lovastatin, the first statin to be marketed

The *statins* (or *HMG-CoA reductase inhibitors*) form a class of hypolipidemic agents, used as pharmaceuticals to lower cholesterol levels in people with or at risk for cardiovascular disease. They work by inhibiting the enzyme HMG-CoA reductase, the enzyme that determines the speed of cholesterol synthesis. Inhibition of this enzyme in the liver stimulates the LDL-receptors, which results in an increased clearance of LDL from the bloodstream and a decrease in blood cholesterol levels. The first results can be seen after one week of use and the effect is maximal after four to six weeks.

Members

The statins are divided into two groups: Fermentation-derived and Synthetic. Fermentation-derived statins appear more effective in reducing LDL, but no clear explanation has accounted for this phenomenon[1].

The statins include, in alphabetical order (brand names vary in different countries):

Statin = Brand name = Derivation

Atorvastatin = Lipitor, Torvast = Synthetic

Cerivastatin = Lipobay, Baycol. (Withdrawn from the market in 2001 due to risk of serious adverse effects) = Synthetic

Fluvastatin = Lescol = Synthetic

Lovastatin = Mevacor, Altocor = Fermentation-derived

Mevastatin = - = Naturally-occurring compound. Found in red yeast rice.

Pitavastatin = Livalo, Pitava = Synthetic

Pravastatin = Pravachol, Selektine, Lipostat = Fermentation-derived

Rosuvastatin = Crestor = Synthetic

Simvastatin = Zocor, Lipex = Fermentation-derived. (Simvastatin is a synthetic derivate of a fermentation product)

LDL-lowering potency varies between agents. Cerivastatin is the most potent, followed by (in order of decreasing potency) rosuvastatin, atorvastatin, simvastatin, lovastatin, pravastatin, and fluvastatin. The relative potency of pitavastatin has not yet been fully established.

Mode of action

Cholesterol lowering

Most circulating cholesterol is manufactured internally, typically about 1000 mg/24 hours, out of the carbohydrate metabolism, by the HMG-CoA reductase pathway. Cholesterol, both from dietary intake and secreted into the duodenum as bile from the liver, is typically absorbed at a rate of 50% by the small intestines. The typical diet in the United States and many other Western countries, is estimated as adding about 200-300 mg/day to intestinal intake; much smaller than that secreted into the intestine in the bile. Thus internal production is an important factor.

Cholesterol is not water-soluble, and is therefore carried in the blood in the form of lipoproteins, the type being determined by the apoprotein, a protein coating that acts as an emulsifier. The relative balance between these lipoproteins is determined by various factors, including genetics, diet, insulin resistance. Low density lipoprotein (LDL) and very low density lipoprotein (VLDL) carry cholesterol towards tissues, and elevated levels of these lipoproteins are associated with atheroma formation (fat-containing deposits in the arterial wall) and cardiovascular disease. High density lipoprotein, in contrast, carries cholesterol back to the liver and is associated with protection against cardiovascular disease.

Statins act by competitively inhibiting HMG-CoA reductase, the first committed enzyme of the HMG-CoA reductase pathway. By reducing intracellular cholesterol levels, they cause liver cells to upregulate expression of the LDL receptor, leading to increased clearance of low-density lipoprotein from the bloodstream.[2]

Direct evidence of the action of statin-based cholesterol lowering on atherosclerosis was presented in the ASTEROID trial, which demonstrated regression of atheroma employing intravascular ultrasound.[3]

Non-cholesterol related actions

Statins exhibit action beyond lipid-lowering activity in the prevention of atherosclerosis. Researchers believe that statins prevent cardiovascular disease via four proposed mechanisms (all subjects of a large body of biomedical research):[1]

- Improving endothelial function

Modulate inflammatory responses
Maintain plaque stability
Prevent thrombus formation

Indications and uses

Statins, the most potent cholesterol-lowering agents, lower LDL-cholesterol (so-called "bad cholesterol") by 30–50%.[citation needed] However, they have less effect than the fibrates or niacin in reducing triglycerides and raising HDL-cholesterol ("good cholesterol"). Professional guidelines generally require that the patient has tried a cholesterol-lowering diet before statin use is considered. In practice, however, a cholesterol reduction of more than 10% is unusual, and many patients do not achieve their targets through dietary approaches.

The indications for the prescription of statins have broadened over the years. Initial studies, such as the Scandinavian Simvastatin Survival Study (4S), supported the use of statins in secondary prevention for cardiovascular disease, or as primary prevention only when the risk for cardiovascular disease was significantly raised (as indicated by e.g. the Framingham risk score[4]). Indications were broadened considerably by studies such as the heart protection study (HPS), which showed preventative effects of statin use in specific risk groups, such as diabetics. The ASTEROID trial published in 2006, using only a statin at high dose, and achieving lower than usual target calculated LDL values, showed disease regression within the heart arteries using IVUS.[5]

Based on clinical trials, the National Cholesterol Education Program guidelines, and the increasing focus on aggressively lowering LDL-cholesterol, the statins continue to play an important, indeed dominant and increasing role in both the primary and secondary prevention coronary heart disease, myocardial infarction, stroke and peripheral artery disease.

Research continues into other areas where statins also appear to have a favorable effect: inflammation, dementia, neoplastic conditions and pulmonary hypertension.

Pharmacogenomics

A 2004 study showed that patients with one of two common single nucleotide polymorphisms (small genetic variations) in the HMG-CoA reductase gene were less responsive to statins[6].

Safety

Adverse effects

While some patients on statin therapy report myalgias, muscle cramps, or far less-frequent gastrointestinal or other symptoms, similar symptoms are also reported with placebo use in all the large statin safety/efficacy trials and usually resolve, either on their own or on temporarily lowering/stopping the dose. Liver enzyme derangements may also occur, typically in about 0.5%, are also seen at similar rates with placebo use and repeated enzyme testing, and generally return to normal either without discontinuance over time or after briefly discontinuing the drug. Multiple other side-effects occur rarely; typically also at similar rates with only placebo in the large statin safety/efficacy trials.

A clearer major safety concern, myositis, myopathy, rarely with rhabdomyolysis (the pathological breakdown of skeletal muscle) may lead to acute renal failure when muscle breakdown products damage the kidney. Co-Enzyme Q-10 (ubiquinone) has shown promise in reducing statin-associated myalgias (statins block production of ubiquinone in addition to cholesterol). One 2004 study found that of 10,000 patients treated for one year, 0.44 will develop this side-effect. Cerivastatin, which was withdrawn by its manufacturer for this reason in 2001, had a much higher incidence (more than 10x)[7]. All commonly used statins show somewhat similar results, however the newer statins, characterized by longer pharmacological half-lifes and more cellular specificity, have had a better ratio of efficacy to lower adverse effect rates.The risk of myopathy is lowest with pravastatin and fluvastatin probably because they are more hydrophillic and as a result have less muscle penetration.

Despite initial concerns that statins might increase the risk of cancer, various studies concluded later that statins have no influence on cancer risk (including the heart protection study and a 2006 meta-analysis[8]). Indeed, a 2005 trial showed that patients taking statins for over 5 years reduced their risk of colorectal cancer by 50%; this effect was not exhibited by fibrates. The trialists warn that the number needed to treat would approximate 5000, making statins unlikely tools for primary prevention[9].

Drug interactions

Combining any statin with a fibrate, another category of lipid-lowering drugs, increases the risks for rhabdomyolysis to almost 6.0 per 10,000 person-years[7]. Most physicians have now abandoned routine monitoring of liver enzymes and creatine kinase, although they still consider this prudent in those on high-dose statins or in those on statin/fibrate combinations, and mandatory in the case of muscle cramps or of deterioration in renal function.

Consumption of grapefruit or grapefruit juice inhibits the metabolism of statins—furanocoumarins in grapefruit juice inhibit the cytochrome P450 enzyme CYP3A4, which is involved in the metabolism of most statins and some other medications[10] (it had been thought that flavonoids were responsible). This increases the levels of the statin, increasing the risk of dose-related adverse effects (including myopathy/rhabdomyolysis). Consequently, consumption of grapefruit juice is not recommended in patients undergoing

therapy with most statins. An alternative, somewhat risky, approach is that some users take grapefruit juice to enhance the effect of lower (hence cheaper) doses of statins. This is not recommended as a result of the increased risk and potential for statin toxicity.

History

Akira Endo and Masao Kuroda of Tokyo, Japan commenced research into inhibitors of HMG-CoA reductase in 1971 (Endo 1992). This team reasoned that certain microorganisms may produce inhibitors of the enzyme to defend themselves against other organisms, as mevalonate is a precursor of many substances required by organisms for the maintenance of their cell wall (ergosterol) or cytoskeleton (isoprenoids)[11].

The first agent isolated was mevastatin (ML-236B), a molecule produced by Penicillium citrinum. The pharmaceutical company Merck & Co. showed an interest in the Japanese research in 1976, and isolated lovastatin (mevinolin, MK803), the first commercially marketed statin, from the mold Aspergillus terreus. Dr Endo was awarded the 2006 Japan Prize for his work on the development of statins.

Routes oral

Atorvastatin (INN) (IPA: [YÈtTvYÌstætn]) is a member of the drug class known as statins, used for lowering cholesterol and thereby reducing cardiovascular disease. Atorvastatin inhibits a rate-determining enzyme located in hepatic tissue used in cholesterol synthesis, which lowers the amount of cholesterol produced. This also has the effect of lowering the total amount of LDL cholesterol.

With 2005 sales of US$12.2 billion under the brand name Lipitor, it is the largest selling drug in the world.

Pharmacology

Main article: Statin

As with other statins, atorvastatin is a competitive inhibitor of HMG-CoA reductase. Unlike most others, however, it is a completely synthetic compound. HMG-CoA reductase catalyzes the reduction of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) to mevalonate, which is the rate-limiting step in hepatic cholesterol biosynthesis. Inhibition of the enzyme decreases de novo cholesterol synthesis, increasing expression of low-density lipoprotein receptors (LDL receptors) on hepatocytes. This increases the LDL uptake by the hepatocytes, decreasing the amount of LDL in the blood.

Clinical use

Indications

Atorvastatin is indicated as an adjunct to diet for the treatment of dyslipidaemia, specifically hypercholesterolaemia. It has also been used in the treatment of combined hyperlipidemia.[1]

Available forms

Atorvastatin calcium tablets are currently marketed by Pfizer under the trade name *Lipitor*, in tablets (10, 20, 40 or 80 mg) for oral administration. Tablets are white, elliptical,

and film coated. In some countries it may also be known as: *Sortis*, *Torvast*, *Totalip*, *Tulip*, *Xarator* or *Liprimar*.

Adverse effects

Common adverse drug reactions (e1% of patients) associated with atorvastatin therapy include: myalgia, mild transient gastrointestinal symptoms, elevated hepatic transaminase concentrations, headache, insomnia, and/or dizziness.[1]

Myopathy and rhabdomyolysis occur in <0.1% of patients. Risk is increased in patients with renal impairment, serious concurrent illness; and/or concomitant use of drugs which inhibit CYP3A4.[1]

Routes Oral

Simvastatin (INN) (IPA: [ÈsjmvYÌstætYn]) is a hypolipidemic drug belonging to the class of pharmaceuticals called "statins". It is used to control hypercholesterolemia (elevated cholesterol levels) and to prevent cardiovascular disease. Simvastatin is a synthetic derivate of a fermentation product of Aspergillus terreus.

History

The development of simvastatin was closely linked with the research and development of lovastatin. Biochemist Jesse Huff and his colleagues at Merck began researching the biosynthesis of cholesterol in the early 1950s. In 1956, mevalonic acid was isolated from a yeast extract by Karl Folkers, Carl Hoffman, and others at Merck; while Huff and his associates confirmed that mevalonic acid was an intermediate in cholesterol biosynthesis. In 1959, the HMG-CoA reductase enzyme (a major contributor of internal cholesterol production) was discovered by researchers at the Max Planck Institute. This discovery encouraged scientists worldwide to find an effective inhibitor of this enzyme.

By 1976, Akira Endo had isolated the first inhibitor (compactin ML-236B) from the fungus, Penicillium citrinium in Sankyo, Japan[1]. In 1979, Hoffman and colleagues isolated lovastatin from a strain of the fungus Aspergillus terreus. While developing and researching lovastatin, Merck scientists synthetically derived a more potent HMG-CoA reductase

inhibitor from a fermentation product of Aspergillus terreus, which was designated MK-733 (later to be named simvastatin).[2]

Uses

Simvastatin is a powerful lipid-lowering drug that can decrease low density lipoprotein (LDL) levels by up to 50%. It is used in doses of 5 mg up to 80 mg. Higher doses (160 mg) have been found to be too toxic, while giving only minimal benefit in terms of lipid lowering. There is no real effect on HDL and triglyceride levels.

From recent research it has become apparent that simvastatin and other statins inhibit the progression of atherosclerosis beyond their effects on LDL. A large number of explanations has been proposed, for example its inhibitory effect on macrophages in the atherosclerotic plaque lesions.

Rationing

Since its introduction, there has been a large debate surrounding the price for lipid-lowering treatment and its benefits on atherosclerosis. Although this has affected the other statins as well, simvastatin was the first statin drug to be used extensively in clinical practice.

A number of large epidemiological studies were conducted to discover which patients would benefit most from statin drugs; most studies involve simvastatin as the study drug. The most influential studies were the Scandinavian Simvastatin Survival Study (4S) and the Heart protection study (HPS).

It has now become apparent that patients with one or more risk factors for cardiovascular disease (such as diabetes mellitus, hypertension or a positive family history) can benefit from statins—even if they do not have substantially elevated cholesterol levels.

Simvastatin was introduced in the late 1980s, and in many countries it is now available as a generic preparation. This has led to a decrease of the price of most statin drugs, and a reappraisal of the health economics of preventive statin treatment.

In the UK, simvastatin (in a dose of 10mg) has recently become available to purchase from pharmacies without prescription.

Pharmacology

Main article: Statin

All statins act by inhibiting HMG-CoA reductase, the rate-limiting enzyme of the HMG-CoA reductase pathway, the metabolic pathway responsible for the endogenous production of cholesterol.

The drug is the form of an inactive lactone that is hydrolized after ingestion to produce the active agent. It is a white, nonhygroscopic, crystalline powder that is practically insoluble in water, and freely soluble in chloroform, methanol and ethanol.

Interactions

Grapefruit contains the flavanones naringenin and bergamottin, which inhibit the liver cytochrome P450 3A4. This in turn slows metabolization of simvastatin and a large number of other drugs. Therefore, patients taking simvastatin should restrict their intake of grapefruit and grapefruit-containing products. [3]

Marketing

Reference: Drug Discovery Today editorial, 2005.[4]

Brand names: Zocor®, Zocor Heart Pro®, marketed by the pharmaceutical company Merck & Co. and Denan (Germany), Liponorm, Sinvacor, Sivastin (Italy), Lipovas (Japan), Lodales (France), Zocord (Austria and Sweden), Zimstat, Simvahexal and Lipex (Australia) and other.

The primary US patent for Zocor expired on June 23, 2006; Ranbaxy Laboratories (at the 80-mg strength) and Teva Pharmaceutical Industries thru its Ivax Pharmaceuticals unit (at all other strengths) were given approval by the FDA to manufacture and sell simvastatin as a generic drug with 180-day exclusivity. Dr. Reddy's Laboratories also has a license from Merck & Co. to sell simvastatin as an authorized generic drug.

Ezetimibe/simvastatin is a combination product to lower lipids and marketed as Vytorin.

Sales

Prior to losing U.S. patent protection, simvastatin was Merck & Co.'s largest selling drug and second largest selling cholesterol lowering drug in the world; it recorded 4.3 billion dollars of sales in 2005.[4] Zocor had an original patent expiration date of January 2006 but was extended by the United States Federal Drug Administration (FDA) o expire on June 23, 2006. The FDA granted the patent extension after Merck & Co, Inc. submitted data from studies of the drug's positive effect on children, a move typically used by drug companies to lengthen exclusivity.[4]

Ordinarily, Merck & Co. would have expected a sharp decrease in sales after the generic versions of simvastatin entered the market; however, Merck has slashed the price of Zocor dramatically in an effort to claim sales that would have otherwise gone to the generic versions. At least two major U.S. health insurers, UnitedHealthcare and WellPoint, are now offering Zocor to their members at generic copays.[5]

In addition, since Merck & Co. itself manufactures at least some versions of Dr. Reddy's authorized generic simvastatin, and since only Dr. Reddy's can supply generic simvastatin in all available strengths (unlike Teva and Ranbaxy), Merck & Co. is also poised to profit from the Dr. Reddy's version. An 80mg, 30-count bottle of Dr. Reddy's simvastatin obtained July 6, 2006, states it is made by Merck Sharp & Dohme (Merck & Co.'s name outside the US to avoid conflicts with Merck KGaA) in the UK, just like 80mg Zocor, and has a Merck & Co. logo on the bottom; except for omitting the "80" on one side, the pills are visually identical to 80mg Zocor, including "543" on the other side which is the key part of the National Drug Code for 80mg Zocor.

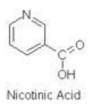
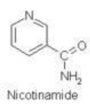
Niacin





Systematic name 3-Pyridinecarboxylic acid

Chemical formula $C_6H_5NO_2$

Molecular mass 123.11 g/mol

Melting point 236.6 °C

CAS number [59-67-6]

Niacin, also known as *nicotinic acid* or *vitamin B3*, is a water-soluble vitamin whose derivatives such as NADH, NAD, NAD+, and NADP play essential roles in energy metabolism in the living cell and DNA repair.[1] The designation vitamin B3 also includes the amide form, *nicotinamide* or *niacinamide*, whose chemical formula is C6H6N2O. Severe lack of niacin causes the deficiency disease pellagra, wherein a mild deficiency slows down the metabolism decreasing cold tolerance. The recommended daily allowance of niacin is 2-12 mg a day for children, 14 mg a day for women, 16 mg a day for men, and 18 mg a day for pregnant or breast-feeding women.[2]

Discovery

Nicotinic acid was first discovered from the oxidation of nicotine. When the properties of nicotinic acid were discovered, it was thought prudent to choose a name to dissociate it from nicotine and to avoid the idea that either smoking provided vitamins or that wholesome food contained a poison. The resulting name 'niacin' was derived from *ni*cotinic *ac*id + vitam*in*.

Vitamin B3 is also referred to as "vitamin PP", a name derived from the obsolete term "pellagra-preventing factor."

Bioavailability

The liver can synthesize niacin from the essential amino acid tryptophan (see below), but the synthesis is extremely slow; 60 mg of tryptophan are required to make one milligram of niacin. Dietary niacin deficiency tends to occur only in areas where people eat corn, the only grain low in niacin, as a staple food, and that don't use lime during maize (corn) meal/flour production. Alkali lime releases the tryptophan from the corn so that it can be absorbed in the gut, and converted to niacin.[3]

Biosynthesis

The 5-membered aromatic heterocycle of the essential amino acid, tryptophan, is cleaved and rearranged with the alpha amino group of tryptophan into the 6-membered aromatic heterocycle of niacin. By the following reaction:

Tryptophan --> Kynurenine --> 3-hydroxy kynurenine* --(B6 enzyme needed)--> Niacin

(*) from this intermediary xanthurenic acid is formed

Food Sources

Animal products:

liver, heart and kidney
chicken
fish: tuna, salmon
milk
eggs

Fruits and vegetables:

leaf vegetables
broccoli
tomatoes
carrots
dates
sweet potatoes
asparagus
avocados

Seeds:

nuts
whole grain products
legumes
saltbush seeds

Fungi:

mushrooms
brewer's yeast

Other uses

Niacin plays an important role in the production of several sex and stress-related hormones, particularly those made by the adrenal gland. It is also plays a role in removing toxic and harmful chemicals from the body.[3] There is evidence that doses of 500-1000mg can terminate a bad trip on LSD, a synthetic indole, or enhance the MDMA experience.

Niacin, when taken in large doses, increases the level of High density lipoprotein (HDL)or "good" cholesterol in blood, and is sometimes prescribed for patients with low HDL, and at high risk of heart attack.[4] Niacin (but not niacinamide) is also used in the treatment of hyperlipidemia because it reduces Very low density lipoprotein (VLDL) secretion, a precursor of Low density lipoprotein (LDL) or "bad" cholesterol, from the liver and inhibits cholesterol synthesis.[5] However, niacin is toxic to the skin and liver in overdose, and high doses of niacin should only be taken when prescribed by a knowledgeable health care provider. Studies in laboratory animals have demonstrated behavioral changes when large doses of niacin are given.[6]

Industrial use

Nicotinic acid reacts with hemoglobin and myoglobin in meat to form a brightly coloured complex, and thus has been used as a food additive, typically to improve the colour of minced (ground) meat. Niacin is licensed as a food colouring agent in some countries. i

Immunosuppressive agents

Immunosuppressive agents are a class of drugs which act to suppress the normal activity of the immune system. They are frequently used to prevent rejection of organs after organ transplant and also in the treatment of autoimmune disorders. Examples include azathioprine, 6-mercaptopurine, Prednisone, infliximab (Remicade), and tetracycline.

See also

- Immunosuppressive drug

Immunosuppressive drugs

Immunosuppressive drugs or *immunosuppressants* are drugs that are used in immunosuppressive therapy to inhibit or prevent activity of the immune system. Clinically they are used to:

- prevent the rejection of transplanted organs and tissues (e.g. bone marrow, heart, kidney, liver)
- treatment of autoimmune diseases or diseases that are most likely of autoimmune origin (e.g. rheumatoid arthritis, myasthenia gravis, systemic lupus erythematosus, Crohn's disease, and ulcerative colitis).
- treatment of some other non-autoimmune inflammatory diseases (eg. long term Allergic Asthma control).

These drugs are not without side effects and risks. Because the majority of them act non-selectively, the immune system loses its ability to successfully resist infections and spreading of malignant cells. There are also other side effects, like hypertension, dyslipidemia, hyperglycemia, peptic ulcers, liver and kidney injury. The immunosuppressive drugs also interact with other medicines and affect their metabolism and action.

Immunosuppressive drugs can be classified into four groups:

- glucocorticoids
- cytostatics
- antibodies
- drugs acting on immunophilins
- other drugs

Glucocorticoids

General information: Glucocorticoid.

In pharmacologic (supraphysiologic) doses, glucocorticoids are used to suppress various allergic, inflammatory, and autoimmune disorders. They are also administered as

posttransplantory immunosuppressants to prevent the acute transplant rejection and graft-versus-host disease. Nevertheless, they do not prevent an infection and also inhibit later reparative processes.

Immunosuppressive mechanism

Glucocorticoids suppress the cell-mediated immunity. They act by inhibiting genes that code for the cytokines IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8 and TNF-[3], the most important of which is the IL-2. Smaller cytokine production reduces the T cell proliferation.

Glucocorticoids also suppress the humoral immunity, causing B cells to express smaller amounts of IL-2 and of IL-2 receptors. This diminishes both B cell clone expansion and antibody synthesis.

Antiinflammatory effects

Glucocorticoids influence all types of inflammatory events, no matter what their cause. They induce the lipocortin-1 (annexin-1) synthesis, which then binds to cell membranes preventing the phospholipase A2 from coming into contact with its substrate arachidonic acid. This leads to diminished eicosanoid production. The cyclooxygenase (both COX-1 and COX-2) expression is also suppressed, potentiating the effect.

Glucocorticoids also stimulate the lipocortin-1 escaping to the extracellular space, where it binds to the leukocyte membrane receptors and inhibits various inflammatory events: epithelial adhesion, emigration, chemotaxis, phagocytosis, respiratory burst and the release of various inflammatory mediators (lysosomal enzymes, cytokines, tissue plasminogen activator, chemokines etc.) from neutrophils, macrophages and mastocytes.

Cytostatics

General information: Chemotherapy

Cytostatics inhibit cell division. In immunotherapy, they are used in smaller doses than in the treatment of malignant diseases. They affect the proliferation of both T cells and B cells. Due to their highest effectiveness, purine analogs are most frequently administered.

Alkylating agents

The alkylating agents used in immunotherapy are nitrogen mustards (cyclophosphamide), nitrosoureas, platinum compounds and others. Cyclophosphamide is probably the most potent immunosuppressive compound. In small doses, it is very efficient in the therapy of systemic lupus erythematosus, autoimmune hemolytic anemias, Wegener's granulomatosis and other immune diseases. High doses cause pancytopenia and hemorrhagic cystitis.

Antimetabolites

Antimetabolites interfere with the synthesis of nucleic acids. These include:

- folic acid analogues, such as methotrexate
- purine analogues such as azathioprine and mercaptopurine
- pyrimidine analogues
- protein synthesis inhibitors.

Methotrexate

Methotrexate is a folic acid analogue. It binds dihydrofolate reductase and prevents synthesis of tetrahydrofolate. It is used in the treatment of autoimmune diseases (for example rheumatoid arthritis) and in transplantations.

Azathioprine and Mercaptopurine

Azathioprine, is the main immunosuppressive cytotoxic substance. It is extensively used to control transplant rejection reactions. It is nonenzymatically cleaved to mercaptopurine, that acts as a purine analogue and an inhibitor of DNA synthesis. Mercaptopurine itself can also be administered directly.

By preventing the clonal expansion of lymphocytes in the induction phase of the immune response, it affects both the cell and the humoral immunity. It is also efficient in the treatment of autoimmune diseases.

Cytotoxic antibiotics

Among these, dactinomycin is the most important. It is used in kidney transplantations. Other cytotoxic antibiotics are anthracyclines, mitomycin C, bleomycin, mitramycin.

Antibodies

Antibodies are used as a quick and potent immunosuppression method to prevent the acute rejection reaction.

Polyclonal antibodies

Heterologous polyclonal antibodies are obtained from the serum of animals (e.g. rabbit, horse) and injected with the patient's thymocytes or lymphocytes. The antilymphocyte (ALG) and antithymocyte antigens (ATG) are being used. They are part of the steroid-resistant acute rejection reaction and grave aplastic anemia treatment. However, they are primarily added to other immunosuppressives to diminish their dosage and toxicity. They also allow transition to cyclosporine therapy.

Polyclonal antibodies inhibit T lymphocytes and cause their lysis, which is both complement mediated cytolysis and cell-mediated opsonization followed by removal of reticuloendothelial cells from the circulation in the spleen and liver]]. In this way, polyclonal antibodies inhibit cell-mediated immune reactions, including graft rejection, delayed

hypersensitivity (i.e. tuberculin skin reaction), and the graft-versus-host disease (GVHD), but influence thymus-dependent antibody production.

Currently (March 2005) there are two preparations available to the market: Atgam (R), obtained from horse serum, and Thymoglobuline (R), obtained from rabbit serum.Polyclonal antibodies affect all lymphocytes and cause general immunosuppression possibly leading to post-transplant lymphoproliferative disorders (PTLD) or serious infections, especially by cytomegalovirus. To reduce these risks, treatment is provided in a hospital where adequate isolation from infection is available. They are usually administered for five days intravenously in the appropriate quantity. Patients stay in the hospital as long as three weeks to give the immune system time to recover to a point where there is no longer a risk of serum sickness.

Because of a high immunogenicity of polyclonal antibodies, almost all patients have an acute reaction to the treatment. It is characterized by fever, rigor episodes and even anaphylaxis. Later during the treatment, some patients develop serum sickness or immune complex glomerulonephritis. Serum sickness arises seven to fourteen days after the therapy has begun. The patient suffers from fever, joint pain and erythema that can be soothed with the use of steroids and analgesics. Urticaria (hives) can also be present. It is possible to diminish their toxicity by using highly purified serum fractions and intravenous administration in the combination with other immunosuppressants, for example calcineurin inhibitors, cytostatics and cortisteroids. The most frequent combination is to simultaneously use antibodies and cyclosporine. Patients gradually develop a strong immune response to these drugs, reducing or eliminating their effectiveness.

Monoclonal antibodies

Monoclonal antibodies are directed towards exactly defined antigens. Therefore, they cause fewer side effects. Especially significant are the IL-2 receptor (CD25) and CD3 directed antibodies. They are used to prevent the rejection of transplanted organs, but also to track changes in the lymphocyte subpopulations. It is reasonable to expect similar new drugs in the future.

T-cell receptor directed antibodies

OKT3 (R) is presently the only approved anti-CD3 antibody. It is a mouse anti-CD3 monoclonal antibody of the IgG2a type that prevents T-cell activation and proliferation by binding the T-cell receptor complex present on all differentiated T cells. As such, it is one of the most potent immunosuppressive substances and is clinically used to control the steroid and/or polyclonal antibodies resistant acute rejection episodes. For acting more specifically than polyclonal antibodies, it is also used preventively in transplantations.

Presently, the OKT3's action mechanism is not yet sufficiently understood. It is known that the molecule binds TCR/CD3, the T-cell receptor complex. During the first few administrations, this binding non-specifically activates T cells, leading to a serious syndrome 30 to 60 minutes later. It is characterized by fever, myalgia, headache and artralgia. In some cases, it progresses to a life-threatening reaction of the cardiovascular system and the central

nervous system needing a lengthy therapy. Past this period, CD3 (R) blocks the TCR - antigen binding and causes conformation change or the removal of the entire TCR3/CD3 from the T-cell surface. This lowers the number of T cells, perhaps by sensitising them for the uptake by the reticular epithelial cells. The cross-binding of CD3 molecules also activates an intracellular signal, causing the T cells' anergy or apoptosis, unless they receive another signal through a costimulatory molecule. CD3 antibodies also shift the balance from Th1 to Th2 cells.

Deciding whether to use OKT3(R) in the treatment, it is therefore necessary not only to consider its great effectiveness, but also its toxic side effects: the risk of excessive immunosuppression and the risk that the patient develops neutralizing antibodies against the drug, making it inefficacious. Although CD3(R) antibodies act more specifically than polyclonal antibodies, they lower the cell-mediated immunity significantly, predisposing the patient to opportunistic infections and malignancies.

IL-2 receptor directed antibodies

Interleukin-2 is an important immune system regulator necessary for the clone expansion and survival of activated lymphocytes T. Its effects are mediated by the trimer cell surface receptor IL-2a, consisting of the ±, ^{2} and ^{3} chains. The IL-2a (CD25, T-cell activation antigen, TAC) is expressed only by the already activated T lymphocytes. Therefore, it is of special significance to the selective immunosuppressive treatment and the research has been focused on the development of effective and safe anti-IL-2 antibodies. By the use of the recombinant gene technology, the mouse anti-Tac antibodies have been modified leading to the presentation of two himeric mouse/human anti-Tac antibodies in the year 1998: basiliximab (Simulect (R)) and daclizumab (Zenapax (R)). These drugs act by binding the IL-2a receptor's ± chain, preventing the IL-2 induced clonal expansion of activated lymphocytes and shortening their survival. They are used in the profilaxis of the acute organ rejection after the bilateral kidney transplantation, both being similarly effective and with only few side effects.

Drugs acting on immunophilins

Cyclosporin

Together with tacrolimus, cyclosporin is a calcineurin inhibitor. It has been in use since 1983 and is one of the most widely used immunosuppressive drugs. It is a fungal peptide, composed of 11 amino acids.

Cyclosporin is thought to bind to the cytosolic protein cyclophilin (an immunophilin) of immunocompetent lymphocytes, especially T-lymphocytes. This complex of ciclosporin and cyclophilin inhibits calcineurin, which under normal circumstances induces the transcription of interleukin-2. The drug also inhibits lymphokine production and interleukin release, leading to a reduced function of effector T-cells.

Cyclosporin is used in the treatment of acute rejection reactions, but has been increasingly substituted with newer immunosuppressants, as it is nephrotoxic.

Tacrolimus (Prograf(TM), FK506)

Tacrolimus is a bacterial product (Streptomyces tsukubaensis). It is a macrolide lactone and acts by inhibiting calcineurin.

The drug is used particularly in the liver and kidney transplantations, although in some clinics it is used in heart, lung and heart/lung transplants. It binds to an immunophilin, followed by the binding of the complex to calcineurin and the inhibition of its phosphatase activity. In this way, it prevents the passage of G0 into G1 phase. Tacrolimus is more potent than cyclosporin and has less pronounced side effects.

Sirolimus (Rapamune (Tm), Rapamicin)

Sirolimus is a macrolide lactone, produced by the actinomycetes Streptomyces hygroscopicus. It is used to prevent rejection reactions. Although it is a structural analogue of tacrolimus, it acts somewhat differently and has different side effects.

Contrary to cyclosporine and tacrolimus that affect the first phase of the T lymphocyte activation, sirolimus affects the second one, namely the signal transduction and their clonal proliferation. It binds to the same receptor (immunophilin) as tacrolimus, however the produced complex does not inhibit calcineurin, but another protein. Therefore, sirolimus acts synergistically with cyclosporine and, in combination with other immunosuppressants, has few side effects. Indirectly it inhibits several T lympohocyte kinases and phosphatases, preventing the transmission of signal into their activity and the transition of the cell cycle from G1 to S phase. Similarly, it prevents the B cell differentiation to the plasma cells, which lowers the quantity of IgM, IgG and IgA antibodies produced. It acts immunoregulatory.

Other drugs

Interferons

General information:Interferon.

IFN-^{2} suppresses the production of Th1 cytokines and the activation of monocytes. It is used to slow down the progression of multiple sclerosis. IFN-^{3} is able to trigger lymphocytic apoptosis.

Opioids

Prolonged use of opioids may cause immunosuppression by inhibiting the migration of leukocytes.

TNF binding proteins

A TNF-± (tumor necrosis factor alpha) binding protein is a monoclonal antibody or a circulating receptor such as infliximab (Remicade®), etanercept (Enbrel®), or adalimumab (Humira®) that binds to TNF-± and prevent it from inducing the synthesis of IL-1 and IL-6 and the adhesion of lymphocyte activating molecules. They are used in the treatment of rheumatoid arthritis, ankylosing spondylitis, Crohn's disease and psoriasis.

TNF or the effects of TNF are also suppressed by various natural compounds, including curcumin (an ingredient in turmeric) and catechins (in green tea).

These drugs may raise the risk of contracting tuberculosis or inducing a latent infection to become active. Infliximab and adalimumab have label warnings stating that patients should be evaluated for latent TB infection and treatment should be initiated prior to starting therapy with them.

Mycophenolate

Mycophenolic acid acts as a non-competitive, selective and reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), which is a key enzyme in the de novo guanosine nucleotide synthesis. In contrast to other human cell types, lymphocytes B and T are very dependent on this process.

Small biological agents

FTY720 is a new synthetic immunosuppressant, currently in phase 3 of clinical trials. It increases the expression or changes the function of certain adhesion molecules (±4/^{2}7 integrin) in lymphocytes, so they accumulate in the lymphatic tissue (lymphatic nodes) and their number in the circulation is diminished. In this respect, it differs from all other known immunosuppressants.

Inotropic agents

An *inotrope* (IPA: [ÈajnYtrop]) is an agent which increases or decreases the force or energy of muscular contractions. Negatively inotropic agents weaken the force of muscular contractions. Positively inotropic agents increase the strength of muscular contraction.

Most commonly, the term is used in reference to various drugs that affect the strength of contraction of heart muscle (myocardial contractility). Both positive and negative inotropes are used in the management of various cardiovascular conditions. The choice of agent largely depends on specific pharmacological effects of individual agents with respect to the condition.

Positive inotropic agents

Positive inotropic agents increase myocardial contractility, and are used to support cardiac function in conditions such as decompensated congestive heart failure, cardiogenic shock, septic shock, myocardial infarction, cardiomyopathy, etc.

Examples of positive inotropic agents include:

- Calcium sensitisers
  - Levosimendan

- Cardiac glycosides
  - Digoxin

- Catecholamines
  - Dopamine
  - Dobutamine
  - Dopexamine
  - Isoprenaline (isoproterenol)
  - Norepinephrine (noradrenaline)

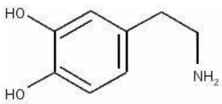
Negative inotropic agents

Negative inotropic agents decrease myocardial contractility, and are used to decrease cardiac workload in conditions such as angina. While negative inotropism may precipitate or exacerbate heart failure, certain beta blockers (e.g. carvedilol) have been shown to reduce morbidity and mortality in congestive heart failure.

- Beta blockers

- Diltiazem
- Verapamil

Dopamine



Systematic name 4-(2-aminoethyl)benzene-1,2-diol

Other names 2-(3,4-dihydroxyphenyl)ethylamine; 3,4-dihydroxyphenethylamine; 3-hydroxytyramine; DA; Intropin Revivan; Oxytyramine

Molecular formula C***8***H***11***NO***2***

SMILES C1=CC(=C(C=C1CCN)O)O

Molar mass 153.178 g/mol

Appearance white powder with distinctive smell

CAS number [51-61-6]

Properties

Solubility in water 60.0 g/100 ml (? °C), solid

Melting point 128 °C (401 K)

Hazards

R/S statement R: 36/37/38 S: 26-36

RTECS number UX1088000

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Dopamine is a chemical naturally produced in the body. In the brain, dopamine functions as a neurotransmitter, activating dopamine receptors. Dopamine is also a neurohormone released by the hypothalamus. Its main function as a hormone is to inhibit the release of prolactin from the anterior lobe of the pituitary.

Dopamine can be supplied as a medication that acts on the sympathetic nervous system, producing effects such as increased heart rate and blood pressure. However, since dopamine cannot cross the blood-brain barrier, dopamine given as a drug does not directly affect the central nervous system. To increase the amount of dopamine in the brains of patients with

diseases such as Parkinson's disease and Dopa-Responsive Dystonia, a synthetic precursor to dopamine such as L-DOPA can be given, since this will cross the blood-brain barrier.

Biochemistry

Dopamine has the chemical formula ($C_6H_3(OH)_2$-CH_2-CH_2-NH_2). Its chemical name is 4-(2-aminoethyl)benzene-1,2-diol and it is abbreviated "DA."

As a member of the catecholamine family, dopamine is a precursor to epinephrine (adrenaline) and norepinephrine (noradrenaline) in the biosynthetic pathways for these neurotransmitters. Arvid Carlsson won a share of the 2000 Nobel Prize in Physiology or Medicine for showing that dopamine is not just a precursor to these, but a neurotransmitter as well.

Dopamine is synthesized in the body (mainly by nervous tissue and adrenal glands) first by the hydration of the amino acid tyrosine to DOPA by tyrosine hydroxylase and then by the decarboxylation of DOPA by aromatic-L-amino-acid decarboxylase. In neurons, dopamine is packaged after synthesis into vesicles, which are then released in response to the presynaptic action potential. The inactivation mechanism of neurotransmission are 1) uptake via a specific transporter; 2) enzymatic breakdown; and 3) diffusion. Uptake back to the presynaptic neuron via the dopamine transporter is the major role in the inactivation of dopamine neurotransmission. The recycled dopamine will face either breakdown by an enzyme or be re-packaged into vesicles and reused.

Functions in the brain

Dopamine has many functions in the brain. Most importantly, dopamine is central to the reward system[1]. Dopamine neurons may have the role to emit a teaching signal for prioritizing and learning of reward-directed behaviour and to code reward information relative to established predictions.

Movement

Dopamine affects the basal ganglia motor loop which in turn affects the way the brain controls our movements. Shortage of dopamine, particularly the death of dopamine neurons in the nigrostriatal pathway, causes Parkinson's disease, in which a person loses the ability to execute smooth, controlled movements.

Cognition and frontal cortex

In the frontal lobes, dopamine controls the flow of information from other areas of the brain. Dopamine disorders in this region of the brain can cause a decline in neurocognitive functions, especially memory, attention and problem-solving. Reduced dopamine concentrations in the prefrontal cortex are thought to contribute to attention deficit disorder and negative schizophrenia. Conversely, anti-psychotic medications rely on their inhibition of dopamine uptake and are used in the treatment of positive symptoms in schizophrenia.

Regulating prolactin secretion

Dopamine is the primary neuroendocrine regulator of the secretion of prolactin from the anterior pituitary gland. Dopamine produced by neurons in the arcuate nucleus of the hypothalamus is secreted into the hypothalamo-hypophysial blood vessels of the median eminence, which supply the pituitary gland. The lactotrope cells that produce prolactin, in the absence of dopamine, secrete prolactin continuously; dopamine inhibits this secretion.

Motivation and pleasure

Dopamine is commonly associated with the pleasure system of the brain, providing feelings of enjoyment and reinforcement to motivate a person proactively to perform certain activities. Dopamine is released (particularly in areas such as the nucleus accumbens and striatum) by naturally rewarding experiences such as food, sex, use of certain drugs and neutral stimuli that become associated with them. This theory is often discussed in terms of drugs (such as cocaine and amphetamines), which seem to be directly or indirectly related to the increase of dopamine in these areas, and in relation to neurobiological theories of chemical addiction, arguing that these dopamine pathways are pathologically altered in addicted persons. However, cocaine and amphetamine influence separate mechanisms of action.

Cocaine is a dopamine transporter blocker that competitively inhibits dopamine uptake to increase the lifetime of dopamine and augments an overabundance of dopamine (an increase of up to 150%) within the parameters of the dopamine neurotransmitters. Like cocaine, amphetamines increase the concentration of dopamine in the synaptic gap, but by a different mechanism. Amphetamines are similar in structure to dopamine, and so can enter the terminal button of the presynaptic neuron via its dopamine transporters as well as by diffusing through the neural membrane directly. When entering inside the presynaptic neuron, amphetamines force the dopamine molecules out of their storage vesicles and expel them into the synaptic gap by making the dopamine transporters work in reverse. Dopamine's role in experiencing pleasure has been questioned by several researchers. It has been argued that dopamine is more associated with anticipatory desire and motivation (commonly referred to as "wanting") as opposed to actual consummatory pleasure (commonly referred to as "liking"). Dopamine is released when unpleasant or aversive stimuli are encountered, and so motivates towards the pleasure of avoiding or removing the unpleasant stimuli.

Recent research suggests that the firing of dopamine neurons is a motivational chemical as a result of reward-anticipation. This is based on evidence that, when a reward is perceived to be greater than expected, the firing of certain dopamine neurons increases, which correspondingly increases desire or motivation toward the reward.

Clues to dopamine's role in motivation, desire and pleasure have come from studies performed on animals. In one such study rats were depleted of dopamine by up to 99% in the nucleus accumbens and neostriatum using 6-hydroxydopamine.[1] With this large reduction in dopamine, the rats would no longer eat by their own volition. The researchers then force fed the rats food and noted whether they had the proper facial expressions

indicating whether they liked or disliked it. The researchers of this study concluded that the reduction in dopamine did not reduce the rat's consummatory pleasure, only the desire to actually eat. In another study, mutant hyperdopaminergic (increased dopamine) mice show higher "wanting" but not "liking" of sweet rewards.[2]

In humans, though, drugs that reduce dopamine activity (e.g., antipsychotics) have been shown to reduce motivation as well as cause anhedonia (the inability to experience pleasure).[3] Conversely the selective D2/D3 agonists pramipexole and ropinirole have anti-anhedonic properties as measured by the Snaith-Hamilton Pleasure Scale.[4] (The Snaith-Hamilton-Pleasure-Scale (SHAPS), introduced in English in 1995, assesses self-reported anhedonia in psychiatric patients.)

Opioid and cannabinoid transmission instead of dopamine may modulate consummatory pleasure and food palatability(liking).[5] This could explain why animals "liking" of food is independent of brain dopamine concentration. Other consummatory pleasures, however, may be more associated with dopamine. One study found that both anticipatory and consummatory measures of sexual behavior (male rats) were disrupted by DA receptor antagonists.[6] Libido can be increased by drugs that affect dopamine but not by drugs that affect opioid peptides or other neurotransmitters.

Sociability is also closely tied to dopamine neurotransmission. Low D2 receptor binding is found in people with social anxiety. Traits common to negative schizophrenia (social withdrawal, apathy, anhedonia) are thought to be related to a hypodopaminergic state in certain areas of the brain. In instances of bipolar, manic subjects can become hypersocial as well as hypersexual. This is also credited to an increase in dopamine, because mania alleviates from dopamine blocking antipsychotics.

Other theories reinforce that the crucial role of dopamine may be in desire, or anticipating pleasurable activity. Related theories [7] argue that dopamine function may be involved in the salience ('noticeableness') of perceived objects and events, with potentially important stimuli such as: 1) rewarding things or 2) dangerous or threatening things seeming more noticeable or important. This hypothesis argues that dopamine assists decision-making by influencing the priority, or level of desire, of such stimuli to the person concerned.

Pharmacological blockade of brain dopamine receptors increases rather than decreases drug-taking behavior. Since blocking dopamine decreases desire, the increase in drug taking behavior may be seen as not a chemical desire but as a deeply psychological desire to just 'feel something'.

Deficits in dopamine levels are implicated as one of several possible causes for Adult attention-deficit disorder (AADD), and some types of medications used to treat Attention-deficit hyperactivity disorder (ADHD/ADD) will help to stimulate dopaminergic systems, leading to potentially heightened sensation, for those afflicted by it and receiving treatment for it.

Links to psychosis

Disruption to the dopamine system has also been strongly linked to psychosis and schizophrenia.[8] Dopamine neurons in the mesolimbic pathway are particularly associated with these conditions. This is partly due to the discovery of a class of drugs called the

phenothiazines (which block D2 dopamine receptors) that can reduce psychotic symptoms, and partly due to the finding that drugs such as amphetamine and cocaine (which are known to greatly increase dopamine levels) can cause psychosis. Because of this, most modern antipsychotic medication is designed to block dopamine function to varying degrees.

Depression

Dopamine is a neurotransmitter that is involved in depression. Amphetamines and dopamine reuptake blockers have potent anti-depressant effects but these drugs quickly lose their benefit after they deplete dopamine levels in the brain. Antidepressants appear to primarily enhance serotonergic neurotransmission during preliminary drug administration but it takes several weeks for the antidepressant effect to be noticed. The late effect of antidepressants is thought to involve the indirect serotonergic modulation of dopaminergic neurotransmission. Blocking the D***2*** dopamine receptor is known to cause relapse in patients that have achieved remission from depression, and such blocking also counteracts the effectiveness of SSRI medication.

Therapeutic use

Levodopa is a dopamine precursor used to treat Parkinson's disease. It is typically co-administered with an inhibitor of peripheral decarboxylation (DDC, dopa decarboxylase), such as carbidopa or benserazide. Inhibitors of alternative metabolic route for dopamine by catechol-O-methyl transferase are also used. These include entacapone and tolcapone.

Dopamine is also used as an inotropic drug in patients with shock to increase cardiac output and blood pressure.

Intravenous fluids

Intravenous therapy or *IV therapy* is the administration of liquid substances directly into a vein. It can be intermittent or continuous; continuous administration is called an *intravenous drip*. The word *intravenous* simply means "within a vein", but is most commonly used to refer to IV therapy. Therapies administered intravenously are often called *specialty pharmaceuticals*.

Compared with other routes of administration, the intravenous route is the fastest way to deliver fluids and medications throughout the body. Some medications, as well as blood transfusions and lethal injections, can only be given intravenously.

Intravenous access devices

Needle and syringe

The simplest form of intravenous access is a syringe with an attached hollow needle. The needle is inserted through the skin into a vein, and the contents of the syringe are injected through the needle into the bloodstream. This is most easily done with an arm vein, especially one of the metacarpal veins. Usually it is necessary to use a tourniquet first to make the vein bulge; once the needle is in place, it is common to draw back slightly on the syringe to aspirate blood, thus verifying that the needle is really in a vein; then the tourniquet is removed before injecting.

This is the most common method of intravenous drug use for euphoriants such as heroin, or in any case where a person must self-administer intravenous medication at home. It is also a convenient way to deliver life-saving medications in an emergency. However, in a controlled health-care setting, direct injection is rarely used since it only allows delivery of a single dose of medication.

Peripheral IV lines

This is the most common intravenous access method in both hospitals and paramedic services. A *peripheral IV line* consists of a short catheter (a few centimeters long) inserted through the skin into a peripheral vein. A peripheral vein is any vein that is not in the chest or abdomen. Arm and hand veins are typically used although leg and foot veins are occasionally used. On infants the scalp veins are sometimes used. Part of the catheter remains outside the skin, with a hub that can be connected to a syringe or an intravenous infusion line, or capped with a bung between treatments. The caliber of cannulae is commonly indicated in gauge, with 14 being a very large cannula (used in resuscitation settings) and 24-26 the smallest. The most common sizes are 16-gauge (midsize line used for blood donation and transfusion), 18- and 20-gauge (all-purpose line for infusions and blood draws), and 22-gauge (all-purpose pediatric line). 12 and 14-gauge peripheral lines actually deliver equivalent volumes of fluid faster than central lines, accounting for their

popularity in emergency medicine; these lines are frequently called "widebores" or "trauma lines." For illustration, please view IV Catheter pictures here.

Blood can be drawn from a peripheral IV if necessary, but only if it is in a relatively large vein and only if the IV is newly inserted. Blood draws are typically taken with specialized IV access sets known as phlebotomy kits, and once the draw is complete, the needle is removed and the site is not used again. If a patient needs frequent venous access, the veins may scar and narrow, making any future access extremely difficult or impossible; this situation is known as a "blown vein," and the person attempting to obtain the access must find a new access site proximal to the "blown" area.

Originally, a peripheral IV was simply a needle that was taped in place and connected to tubing rather than to a syringe; this system is still used for blood donation sets, as the IV access will only be needed for a few minutes and the donor may not move while the needle is in place. Today, hospitals use a safer system in which the catheter is a flexible plastic tube that originally contains a needle to allow it to pierce the skin; the needle is then removed and discarded, while the soft catheter stays in the vein. The external portion of the catheter, which is usually taped in place or secured with a self-adhesive dressing, consists of an inch or so of flexible tubing and a locking hub. Many sets contain a small amount of the anticoagulant heparin to keep the line from clotting off, and frequently are called "heparin locks" or "hep-locks."

A peripheral IV cannot be left in the vein indefinitely, because of the risk of insertion-site infection leading to phlebitis, cellulitis and bacteremia. Hospital policies usually dictate that every peripheral IV be replaced (at a different location) every three to four days to avoid this complication.

Central IV lines

Central IV lines flow through a catheter with its tip within a large vein, usually the superior vena cava or inferior vena cava, or within the right atrium of the heart. This has several advantages over a peripheral IV:

- It can deliver fluids and medications that would be overly irritating to peripheral veins because of their concentration or chemical composition. These include some chemotherapy drugs and total parenteral nutrition.
- Medications reach the heart immediately, and are quickly distributed to the rest of the body.
- There is room for multiple parallel compartments (lumens) within the catheter, so that multiple medications can be delivered at once even if they would not be chemically compatible within a single tube.
- Caregivers can measure central venous pressure and other physiological variables through the line.

Central IV lines carry higher risks of bleeding, bacteremia, and gas embolism (see Risks below).

There are several types of central IVs, depending on the route that the catheter takes from the outside of the body to the vein.

Peripherally inserted central catheter (PICC)

PICC lines are used when intravenous access is required over a prolonged period of time, as in the case of long chemotherapy regimens, extended antibiotic therapy, or total parenteral nutrition.

The PICC line is inserted into a peripheral vein, usually in the arm, and then carefully advanced upward until the catheter is in the superior vena cava or the right atrium. This is usually done by feel and estimation; an X-ray then verifies that the tip is in the right place.

A PICC may have two parallel compartments, each with its own external connector (double-lumen), or a single tube and connector (single-lumen). From the outside, a single-lumen PICC resembles a peripheral IV, except that the tubing is slightly wider.

The insertion site must be covered by a larger sterile dressing than would be required for a peripheral IV, due to the higher risk of infection if bacteria travel up the catheter. However, a PICC poses less of a systemic infection risk than other central IVs, because bacteria would have to travel up the entire length of the narrow catheter before spreading through the bloodstream.

The chief advantage of a PICC over other types of central lines is that it is easy to insert, poses a relatively low risk of bleeding, is externally unobtrusive, and can be left in place for months to years for patients who require extended treatment. The chief disadvantage is that it must travel through a relatively small peripheral vein and is therefore limited in diameter, and also somewhat vulnerable to occlusion or damage from movement or squeezing of the arm.

Central venous lines

There are several types of catheters that take a more direct route into central veins. These are collectively called central venous lines.

In the simplest type of central venous access, a catheter is inserted into a subclavian, internal jugular, or (less commonly) a femoral vein and advanced toward the heart until it reaches the superior vena cava or right atrium. Because all of these veins are larger than peripheral veins, central lines can deliver a higher volume of fluid and can have multiple lumens.

Another type of central line, called a Hickman line or Broviac catheter, is inserted into the target vein and then "tunneled" under the skin to emerge a short distance away. This reduces the risk of infection, since bacteria from the skin surface are not able to travel directly into the vein; these catheters are also made of materials that resist infection and clotting.

Implantable ports

A port (often referred to by brand names such as Port-a-Cath or MediPort) is a central venous line that does not have an external connector; instead, it has a small reservoir implanted under the skin. Medication is administered intermittently by placing a small needle through the skin into the reservoir. Ports cause less inconvenience and have a lower

risk of infection than PICCs, and are therefore commonly used for patients on long-term intermittent treatment.

Forms of intravenous therapy

Intravenous drip

An *intravenous drip* is the continuous infusion of fluids, with or without medications, through an IV access device. This may be to correct dehydration or an electrolyte imbalance, to deliver medications, or for blood transfusion.

IV fluids

There are two types of fluids that are used for intravenous drips; crystalloids and colloids. Crystalloids are aqueous solutions of mineral salts or other water-soluble molecules. Colloids contain larger insoluble molecules, such as gelatin; blood itself is a colloid.

The most commonly used crystalloid fluid is normal saline, a solution of sodium chloride at 0.9% concentration, which is close to the concentration in the blood (isotonic). Ringer's lactate or Ringer's acetate (ASERING) is another isotonic solution often used for large-volume fluid replacement. A solution of 5% dextrose in water, sometimes called D5W, is often used instead if the patient is at risk for having low blood sugar or high sodium. The choice of fluids may also depend on the chemical properties of the medications being given.

Intravenous fluids must always be sterile.

Composition of Common Crystalloid Solutions

Solution	Other Name	$[Na^+]$	$[Cl^-]$	[Glucose]
D5W	5% Dextrose	0	0	252
2/3D & 1/3S	3.3% Dextrose / 0.3% saline	51	51	168
Half-normal saline	0.45% NaCl	77	77	0
Normal saline	0.9% NaCl	154	154	0
Ringer's lactate	Lactated Ringer	130	109	0

Ringer's lactate also has 28 mmol/L lactate, 4 mmol/L K^+ and 3 mmol/L Ca^{2+}. Ringer's acetate (ASERING) also has 28 mmol/L acetate, 4 mmol/L K^+ and 3 mmol/L Ca^{2+}.

Effect of Adding One Litre

Solution	Change in ECF	Change in ICF
D5W	333 mL	667 mL
2/3D & 1/3S	556 mL	444 mL
Half-normal saline	667 mL	333 mL
Normal saline	1000 mL	0 mL
Ringer's lactate	900 mL	100 mL

Infusion equipment

A standard IV infusion set consists of a pre-filled, sterile container (glass bottle, plastic bottle or plastic bag) of fluids with an attached drip chamber which allows the fluid to flow one drop at a time, making it easy to see the flow rate (and also reducing air bubbles); a long sterile tube with a clamp to regulate or stop the flow; a connector to attach to the access device; and connectors to allow "piggybacking" of another infusion set onto the same line, e.g., adding a dose of antibiotics to a continuous fluid drip.

An infusion pump allows precise control over the flow rate and total amount delivered, but in cases where a change in the flow rate would not have serious consequences, or if pumps are not available, the drip is often left to flow simply by placing the bag above the level of the patient and using the clamp to regulate the rate; this is a gravity drip.

A rapid infuser can be used if the patient requires a high flow rate and the IV access device is of a large enough diameter to accommodate it. This is either an inflatable cuff placed around the fluid bag to force the fluid into the patient or a similar electrical device that may also heat the fluid being infused.

Intermittent infusion

Intermittent infusion is used when a patient requires medications only at certain times, and does not require additional fluid. It can use the same techniques as an intravenous drip (pump or gravity drip), but after the complete dose of medication has been given, the tubing is disconnected from the IV access device. Some medications are also given by *IV push*, meaning that a syringe is connected to the IV access device and the medication is injected directly (slowly, if it might irritate the vein or cause a too-rapid effect). Once a medicine has been injected into the fluid stream of the IV tubing there must be some means of ensuring that it gets from the tubing to the patient. Usually this is accomplished by allowing the fluid stream to flow normally and therby carry the medicine into the bloodstream; however, a

second fluid injection is sometimes used, a "flush", following the injection to push the medicine into the bloodstream more quickly.

Risks of intravenous therapy

Intravenous therapy has many risks and should therefore only be performed by trained personnel under medical supervision, using proper equipment.

Infection

Any break in the skin carries a risk of infection. Although IV insertion is a sterile procedure, skin-dwelling organisms such as Coagulase-negative Staphylococcus or Candida albicans may enter through the insertion site around the catheter, or bacteria may be accidentally introduced inside the catheter from contaminated equipment.

Infection of IV sites is usually local, causing easily visible swelling, redness, and fever. If bacteria do not remain in one area but spread through the bloodstream, the infection is called septicemia and can be rapid and life-threatening. An infected central IV poses a higher risk of septicemia, as it can deliver bacteria directly into the central circulation.

Phlebitis

Phlebitis is irritation of a vein that is not caused by infection, but from the mere presence of a foreign body (the IV catheter) or the fluids or medication being given. Symptoms are swelling, pain, and redness around the vein. It does not necessarily mean the IV device must be removed; warmth, elevation of the affected limb, or a change in the rate of flow may resolve the symptoms.

Due to frequent injections and recurring phlebitis, the peripheral veins of intravenous drug addicts, and of cancer patients undergoing chemotherapy, become hardened and difficult to access over time.

Infiltration

This occurs when the tip of the IV catheter withdraws from the vein or pokes through the vein into surrounding tissue, or when the vein's wall becomes permeable and leaks fluid (in this instance it is said that the cannula has 'tissued'). It occurs frequently with peripheral IVs, and requires replacement of the IV at a different location. The symptoms of pain and swelling are temporary and not dangerous, unless giving a highly irritating medication, such intravenous contrast or amiodarone. Additionally it can become dangerous if the person monitoring the IV site fails to recognize that an infiltration has occurred and fluid continues to drip in the tissue under the skin. It can cause a compression injury. This known as an infiltration injury.

Fluid overload

This occurs when fluids are given at a higher rate or in a larger volume than the system can absorb or excrete. Possible consequences include hypertension, heart failure, and pulmonary edema.

Electrolyte imbalance

Administering a too-dilute or too-concentrated solution can disrupt the patient's balance of sodium, potassium, magnesium, and other electrolytes. Hospital patients usually receive blood tests to monitor these levels.

Embolism

A blood clot or other solid mass, or an air bubble, can be delivered into the circulation through an IV and end up blocking a vessel; this is called embolism. Peripheral IVs have a low risk of embolism, since large solid masses cannot travel through a narrow catheter, and it is nearly impossible to inject air through a peripheral IV at a dangerous rate. The risk is greater with a central IV.

Air bubbles of less than 30 milliliters generally dissolve into the circulation harmlessly. A larger amount of air, if delivered all at once, can cause life-threatening damage to pulmonary circulation, or, if extremely large (3-8 milliliters per kilogram of body weight), can stop the heart.

One reason veins are preferred over arteries for intravascular administration is because the flow will pass through the lungs before passing through the body. Air bubbles can leave the blood through the lungs. A patient with a heart defect causing a right-to-left shunt is vulnerable to embolism from smaller amounts of air.

Fatality by air embolism is vanishingly rare, in part because it is also difficult to diagnose.

Saline

In medicine, *saline* is a solution of sodium chloride in sterile water, used commonly for intravenous infusion, rinsing contact lenses, and nasal irrigation or jala neti. Sodium chloride (NaCl) is ordinary salt. Saline solutions are available in various concentrations for different purposes.

Normal saline is the solution of 0.9% w/v of NaCl. It contains 154 mEq/L of Na+ and Cl. It has a slightly higher degree of osmolality (i.e. more solute per liter) compared to blood (hence, though it is referred to as being isotonic with blood in clinical contexts, this is a technical inaccuracy), about 300 mOsm/L. Normal saline (NS) is therefore used frequently in intravenous drips (IVs) for patients who cannot take fluids orally and have developed severe dehydration. Normal saline is typically the first fluid used when dehydration is severe

enough to threaten the adequacy of blood circulation and is the safest fluid to give quickly in large volumes.

Other concentrations of saline are frequently used for other purposes, such as supplying extra water to a dehydrated patient or supplying the daily water and salt needs ("maintenance" needs) of a patient who is unable to take them by mouth. Because infusing a solution of low osmolality can cause problems, intravenous solutions with reduced saline concentrations typically have dextrose (glucose) added to maintain a safe osmolality while providing less sodium chloride. As the molecular weight (MW) of dextrose is greater, this has the same osmolality as normal saline but contributes less sodium to the circulation. Because dextrose monohydrate (MW 198 in contrast to MW 180 for glucose) is the commercial form of dextrose used in these preparations, 5% dextrose actually contains only 4.5 g/dL of glucose.

Concentrations commonly used include

1. Half-normal saline (0.45% NaCl), often with "D5" (5% dextrose), contains 77 mEq/L of Na and Cl and 4.5 g/L glucose.
2. Quarter-normal saline (0.22% NaCl) has 39 mEq/L of Na and Cl and always contains 5% dextrose for osmolality reasons.
3. Dextrose (glucose) 4% in 0.18% saline is used sometimes for maintenance replacement.

The amount of normal saline infused depends largely on the needs of the patient (e.g. ongoing diarrhoea or heart failure) but is typically between 1.5 and 3 litres a day for an adult.

Rinsing with a saline solution is also a common remedy for a toothache or mouth pain.

Essential oil

Macerated

Uses

Drying oil - Oil paint, Cooking oil, Fuel - Biodiesel, Aromatherapy

Components

Saturated fat, Monounsaturated fat, Polyunsaturated fat, Trans fat

An *essential oil* is a concentrated, hydrophobic liquid containing volatile aromatic compounds from plants. It is produced by distillation. Other extraction processes to obtain aromatic plant compounds include expression, or solvent extraction. Essential oils are used in perfumery, aromatherapy, cosmetics, incense, for flavoring food and drink, and to a lesser extent, in medicine and household cleaning products. They are valuable commodities to the fragrance and flavorant industries.

Essential oil is also known as *volatile oil* and *ethereal oil*. It may also be referred to as "oil of" the raw plant material from which it was extracted, such as oil of clove. The term *essential* is intended to indicate that the oil is the fragrant essence of the plant from which it is extracted and not in the more common sense of being indispensable. It is not to be confused with essential fatty acids.

Medical use of vegetable oils has a long and distinguished history. Many oils that are use medicinally are *essential oils*, which are distilled rather than pressed or otherwise extracted. Medical properties claimed by those who sell medicinal oils vary from skin treatments to remedies for cancer, and are often based on historical use of these oils for these purposes. Such claims are now subject to regulation in most countries, and have grown correspondingly more vague, to stay within these regulations.

Interest in such uses of essential oils has enjoyed a revival in recent decades, with the popularity of aromatherapy, in which oils are heated and volatilized.

Production

Distillation

Today, most common essential oils, such as lavender, peppermint, and eucalyptus, are distilled. Raw plant material, consisting of the flowers, leaves, wood, bark, roots, seeds, or peel, is put into an alembic (distillation apparatus) over water, As the water is heated the steam passes through the plant material, vaporizing the volatile compounds. The vapors flow through a coil where they condense back to liquid, which is then collected in the receiving vessel.

Most oils are distilled in a single process. One exception is Ylang-ylang (Cananga odorata), which takes 22 hours to complete through a Fractional distillation.

The water recondensed from the distillation process is referred to as a hydrosol, hydrolat, herbal distillate or plant water essence, which may be sold as another fragrant product. Popular hydrosols are rose water, lavender water, lemon balm, clary sage and orange blossom water. The use of herbal distillates in cosmetics is increasing. Some plant hydrosols have unpleasant smells and are therefore not sold.

Expression

Most citrus peel oils are usually expressed mechanically, or cold-pressed. Due to the large quantities of oil in citrus peel and the relatively low cost to grow and harvest the raw materials, citrus-fruit oils are cheaper than most other essential oils. Lemon or sweet orange oils that are obtained as by-products of the commercial citrus industry are even cheaper.

Prior to the discovery of distillation, essential oils (EO) were extracted by pressing.

Solvent extraction

Most flowers contain very little volatile oil to undergo expression and their chemical components are too delicate and easily denatured by the high heat used in steam distillation. Instead, a solvent such as hexane or supercritical carbon dioxide is used to extract the oils. Extracts from hexane and other hydrophobic solvent are called concretes, which is mixture of essential oil, waxes, resins, and other lipophilic (oil soluble) plant material.

Although highly fragrant, concretes contain large quantities of non-fragrant waxes and resins. As such another solvent, often ethyl alcohol, which only dissolves the fragrant low-molecular weight compounds is used to extract the fragrant oil from the concrete. The alcohol is removed by a second distillation, leaving behind the absolute.

In supercritical fluid extraction, supercritical carbon dioxide is used as a solvent. This method has many benefits, including avoiding petrochemical residues in the product. It does not obtain an absolute directly. The supercritical carbon dioxide will extract both the waxes and the essential oils that make up the concrete. Subsequent processing with liquid carbon

dioxide, achieved in the same extractor by merely lowering the extraction temperature, will separate the waxes from the essential oils. This lower temperature process prevents the decomposition and denaturing of compounds and provides for a superior product. When the extraction is complete, the pressure is reduced to ambient and the carbon dioxide reverts back to a gas, leaving no residue. Although supercritical carbon dioxide is also used for making decaffeinated coffee, the actual process is different.

Production quantities

Estimates of total production of essential oils are difficult to obtain. One estimate, compiled from data in 1989. 1990 and 1994 from various sources gives the following total production, in tonnes, of essential oils for which more than 1,000 tonnes were produced.[1]

Oil, Tonnes

- Sweet orange 12,000
- Mentha arvensis 4,800
- Peppermint **3,200**
- Cedarwood 2,600
- Lemon 2,300
- Eucalyptus globulus 2,070
- Litsea cubeba 2,000
- Clove (leaf) 2,000
- Spearmint 1,300

Essential oil use in aromatherapy

Aromatherapy is a form of herbal medicine, in which healing effects are ascribed to the aromatic compounds in essential oils and other plant extracts. Many common essential oils have medicinal properties that have been applied in folk medicine since ancient times and are still widely used today. For example, many essential oils have antiseptic properties, though some are stronger than others. In addition, many have an uplifting effect on the mind, though different essential oils have different properties.

Solvents

Essential oils are usually lipophilic compounds. It thus has been found that alcohols, such as methanol and ethanol (primarily 100% concentrations), or organic solvents, such as acetone, are the best diluents to be used for dilution. Water is not recommended as water and fats do not dissolve in one another, although oil dilution in water can be achieved at extremely low concentrations of oil, and depending on the viscosity of the oil.

Raw Materials

Essential oils are derived from various parts of plants. Some, like orange oil, are derived from any of several parts of the plant.

Rose oil

The most well-known essential oil is probably Rose oil, produced from Rosa damascena and Rosa centifolia. Steam-distilled rose oil is known as "rose otto" or "attar of roses" while oil which is solvent-extracted is known as "rose absolute".

Dangers

Because of their concentrated nature, EO's generally should not be applied directly to the skin in their undiluted or "neat" form. Some can cause severe irritation or provoke an allergic reaction. Instead, essential oil should be applied with a plants oils or other fats (carrier oil), such as olive, hazelnut, or any other "soft" oil. Common ratio of essential oil disbursed in a carrier oil is 0.5–3% (most less than 10%) and depends on its purpose. Some EO's including many of the citrus peel oils, are photosensitizers, increasing the skin's reaction to sunlight and making it more likely to burn.

Industrial users of essential oils should consult the material safety data sheets (MSDS) to determine the hazards and handling requirements of particular oils.

Pesticide residues

There is some concern about pesticide residues in EO's, particularly those used therapeutically. For this reason, many practitioners of aromatherapy choose to buy organically produced oils.

Ingestion

While some advocate the ingestion of essential oils for therapeutic purposes, this should never be done except under the supervision of a professional who is licensed to prescribe such treatment. Some very common EO's such as Eucalyptus are extremely toxic internally. Pharmacopoeia standards for medicinal oils should be heeded. EO's should always be kept out of the reach of children. Some oils can be toxic to some domestic animals, cats in particular. Owners must ensure that their pets do not come into contact with potentially harmful essential oils.[2]

Smoke

The smoke from burning essential oils may contain potential carcinogens, such as polycyclic aromatic hydrocarbons (PAHs). Essential oils are naturally high in volatile organic compounds (VOCs). The internal use of essential oils should be fully avoided during pregnancy without consulting with a licensed professional, as some can be abortifacients in dose 0.5–10 ml.

Toxicology

LD50 of most EO or their main components are 0.5-10 g/kg (orally or skin test).

Herbal and fungal hallucinogens

Agaricales | Amanita muscaria | Ayahuasca | Ergot | Morning glory | **Nicotiana rustica** | Peyote | Psychedelic mushroom | Soma | Tobacco

Agaricales

Scientific classification

Kingdom: Fungi
Division: Basidiomycota
Class: Homobasidiomycetes
Order: *Agaricales*

Families

Agaricaceae
Amanitaceae
Bolbitiaceae
Cortinariaceae
Crepidotaceae
Entolomataceae
Fistulinaceae
Hygrophoraceae
Omphalotaceae
Pleurotaceae
Pluteaceae
Podaxaceae
Psathyrellaceae
Schizophyllaceae
Strophariaceae
Tricholomataceae

The order *Agaricales*, also known as *gilled mushrooms* (for their distinctive gills), or *euagarics*, contains some of the most familiar types of mushrooms. The order has about 4,000 species, or one quarter of all known homobasidiomycetes. They range from the ubiquitous button mushroom to the deadly destroying angel and the hallucinogenic fly agaric to the bioluminescent jack-o-lantern mushroom.

Classification

Some notable fungi with gill-like structures, such as chanterelles, have long been recognised as being substantially different to usual Agaricales. Interestingly, molecular studies are showing other groups as being more divergent than previously thought, such as

the genera Russula and Lactarius belonging to a separate order Russulales, and other gilled fungi, including such species as Paxillus involutus and Hygrophoropsis aurantiaca showing a closer affinity with Boletes in the order Boletales.

Also, some other quite distinctive fungi, the puffballs and the Beefsteak fungus have been recently been shown lie within the Agaricales.

Distribution and habitat

Agarics are ubiquitous, being found across all continents except Antarctica. Although all are terrestrial, their habitats include all types of woodland and grassland, varying largely from one species to another.

Characteristics

Basidiocarps of the agarics are typically fleshy, with a stipe, often called a stem or stalkm a pileus (or cap) and lamellae (or gills), where basidiospores are stored. This is indeed the stereotyped structure of what we would call a mushroom or toadstool.

Life cycle

The agarics' life cycle is very much representative of the basiodiomycetes. Clamp connections are present in the dikaryons of several species, but that is not always the case.

Propagation

The agarics always have their basiodiospores ejected from the basidium into the area between gill edges. The spores are then let fall to the ground or carried by the wind.

Amanita muscaria

Amanita muscaria
Conservation status: Secure

Scientific classification

Kingdom: Fungi
Division: Basidiomycota
Class: Homobasidiomycetae
Subclass: Hymenomycetes
Order: Agaricales
Family: Amanitaceae
Genus: Amanita
Species: *A. muscaria*

Binomial name

Amanita muscaria

(Linnaeus) Hook.

Amanita muscaria, commonly called *fly agaric* or less often *fly mushroom*, is a basidiomycete mushroom of the genus Amanita. The original white-spotted red toadstool, it is one of the most recognizable mushrooms and is widely used in popular culture. Though it is generally considered poisonous, Amanita muscaria is otherwise famed for its hallucinogenic properties.

The common names in English, "fly agaric", and German, "Fliegenpilz", come from its European use as an insecticide, sprinkled in milk. This was known to Linnaeus who gave it the name *"Agaricus muscarius"*, the specific name deriving from Latin musca meaning "fly". The flykilling agent is now known to be ibotenic acid[1].

A mushroom that is native to both Europe and North America, Amanita muscaria has been unintentionally conveyed to many countries in the southern hemisphere, generally as a symbiont with pine plantations, and is now a true cosmopolitan species.

Description

Amanita muscaria is a large distinctive mushroom, generally common and numerous where it grows, often being found in groups with basidiocarps in all stages of development. Fully grown, the bright red cap is usually around 8-20 cm (3-8 in) in diameter, though sometimes larger ones are found, and is covered with numerous small white to yellow flecks (warts). It is worth noting that the red colour may fade after rain and in older mushrooms. The warts are remnants of the universal veil, a membrane that encloses the entire mushroom when it is still very young. The gills are white, as is the sporeprint. The stem is white, 5-20 cm high (approximately 2-8 inches), with a basal bulb that bears universal veil remnants, in the form of a ragged collar or group of more or less distinct rings or ruffs that circles the base of the stalk (or stipe). The white ring can be quite wide and flaccid. There is generally no associated smell.[2]

Fly agaric fruiting bodies emerge from the soil looking like a white egg, covered in the white warty material of the universal veil. As the fungus grows, the red colour appears through the broken veil, and the cap changes from bell-shaped to hemispherical and finally flattening in mature specimens[3].

Though very distinctive, the fly agaric has been mistaken for other yellow to red species in the Americas such as Armillaria cf. mellea and the edible Amanita basii, a Mexican species similar to A. caesarea of Europe. Poison control centers in the U.S. and Canada are aware that "amarillo" is a common name of caesarea-like species in Mexico, not just the Spanish for 'yellow'.

Amanita caesarea can be distinguished as it has an entire orange red cap, lacking the numerous white warty spots of the fly agaric. Furthermore the stem, gills and ring are bright yellow, not white[4]. Finally the volva is a distinct white bag, not broken into scales[5].

In Australia, the introduced fly agaric may be confused with the local Amanita xanthocephala, which grows in association with Eucalypts. This species also generally lacks the white warts of A. muscaria and bears no ring.

Classification

Amanita muscaria is a member of the large genus Amanita, of which there are many deadly poisonous as well as some edible species. The highly poisonous Panther Cap (Amanita pantherina) is somewhat similar in appearance though brown rather than red. Other red Amanitas include the previously mentioned edible Caesar's mushroom (Amanita caesarea).

Two recent molecular studies show that Amanita muscaria's close relatives in the genus appear to be Amanita gemmata, A. farinosa and A. roseitincta.[6][7]

Varieties

Other varieties have similar appearance to var. muscaria, but differ most conspicuously in cap colour:

- Var. *alba*, an uncommon fungus, has a white to silvery white cap with white warts but otherwise similar to the usual form. Fruiting in August and September, it is restricted to mixed coniferous and deciduous forests in northern North America.[8]
- Var. *americana* has a yellow or yellow-orange cap
- Var. *aureola* is found in southern Europe, and has an orange cap.
- Var. *flavivolvata* is red, with yellow warts, and occurs in the western regions of the North American continent, from southern Alaska down through the Rocky Mountains, Costa Rica to at least Andean Colombia. It contains similar poisons to var. muscaria.
- Var. *formosa*, found in Europe, has an orange-yellow cap with yellowish or tan warts and stem.
- Var. *guessowii* is yellow to orange, with center of cap more orange or reddish orange than the outer part, apparently restricted to northeastern North America, from Newfoundland and Quebec down to Tennessee.
- Var. *persicina* is pinkish to orangish "melon" colored with poorly formed or absent remnants of universal veil on the stem and vasal bulb, known from the Southeastern Coastal areas of the U.S.A, described in 1977[9].
- Var. *regalis*, from Scandinavia and Alaska[10], is liver-brown and has yellow warts. It appears to be uniformly distinctive and some authorities treat it as a separate species (A. regalis) though at least one DNA study does not support this.[11]

Distribution and habitat

Amanita muscaria is a cosmopolitan mushroom, found naturally in birch, pine, spruce and fir woodlands across the northern hemisphere from the British Isles to Siberia, and North America. It has been widely transported into the southern hemisphere, including Australia,[12] New Zealand, South Africa[13] and South America, where it usually occurs under introduced pine trees.

In Australia it appears to have formed new associations with southern beech (Nothofagus) in Tasmania and Victoria and invading native rainforest.[14]

When imported to a new country, A. muscaria can jump to native species (for example, Eucalyptus in Australia). It can then be exported with its new symbiont (for example, from Australia to Argentina).

A recent molecular study proposes an ancestral origin in the Siberian–Beringian region in the Tertiary period before radiating outwards across Asia, Europe and North America.[11]

Toxicity

Consuming more than about one gram of Amanita muscaria can cause nausea and a number of other effects, depending on dosage, ranging from twitching to drowsiness, cholinergic effects (lower blood pressure, increase sweat and saliva), visual distortions, mood changes, euphoria, relaxation, and hallucinations.

In near-fatal doses it causes swollen features and delirium, characterised by bouts of marked agitation followed by periods of quiet hallucination. Effects appear after around 60 minutes and typically peak within three hours, but certain effects can last for up to ten hours. The effect is highly variable and individuals can react quite differently to the same dose.

Deaths from A. muscaria are extremely rare. Fatal doses have occurred in North America (var. guessowii). The amount and ratio of chemical compounds per mushroom varies widely from region to region, season to season, further confusing the issue. Many older books list it as deadly, giving the impression that it is far more toxic than it really is. The vast majority of mushroom poisoning fatalities (90% or more) are from having eaten either the greenish to yellowish to brownish mottled death cap (Amanita phalloides) or one of the destroying angels (Amanita virosa), several overall white Amanita species.

The toxic substances of A. muscaria are water soluble and susceptible to heat. The mushroom can be at least partly de-toxified by thoroughly parboiling or leaching it in boiling water. According to some sources[1], once detoxified, the mushroom becomes edible.

Chemistry

The mushroom contains a number of psychoactive agents: ibotenic acid, muscimol, muscazone and muscarine, of which muscimol (3hydroxy-5-aminomethy-1 isoxazole, an unsaturated cyclic hydroxamic acid) is the most significant. Muscarine, discovered in 1869, was long thought to be the active hallucinogenic agent in A. muscaria until late 1960s, when scientists recognized it as ibotenic acid and muscimol. Some users cook the mushroom before ingestion, because it is said that the ibotenic acid turns into muscimol under this heat.

This supposedly removes several unpleasant side effects due to the conversion of the much more toxic ibotenic acid into muscimol.

Muscarine binds with Muscarinic acetylcholine receptor and lead to the excitation of the neurons bearing these receptors.

Psychoactive properties

Although the fly agaric is not related to other psychoactive fungi such as the Psilocybe species, it has been used as an entheogen in rituals to communicate to the spirit world, largely in Siberia, with some reported incidents elsewhere in the northern hemisphere. Mesoamericans never consumed fly agaric for religion, but instead use Psilocybe. Psilocybe and Amanita are not chemically related with regard to their psychoactive properties and therefore produce markedly different psychoactive effects.[15]

The active ingredient is excreted in the urine of those consuming the mushrooms, and it has sometimes been the practice for a shaman to consume the mushrooms, and the rest of the tribe to drink his urine: the shaman, in effect, partially detoxifying the drug (the sweat- and twitch-causing muscarine is absent in the urine)[16]. This was also not an uncommon practice in Siberia, where the poor would consume the urine of the wealthy, who could afford to buy the mushrooms. If a fly agaric is eaten, it is usually not fresh, but in its sun-dried form, where the hallucinogenic chemicals are more concentrated (ibotenic acid converted to the more stable and far less poisonous muscimol).

The notion that Nordic Vikings used Amanita muscaria to produce their berserker rages was first suggested by the Swedish professor Samuel Ödman in 1784.[17] Ödman based his theories on reports about the use of fly agaric among Siberian shamans. The notion has become widespread since the 19th century, but no contemporary sources mention this use or anything similar in their description of berserkers. Today, it is generally considered an urban legend or at best speculation that cannot be proven.

Mythology and religion

Koryak Siberians have a story about the fly agaric (wapaq) which enabled Big Raven to carry a whale to its home. In the story, the deity Vahiyinin ("Existence") spat onto earth, and his spittle became the wapaq, and his saliva becomes the warts. After experiencing the power of the wapaq, Raven was so exhilarated that he told it to grow forever on earth so his children, the people, can learn from it.Finno-Ugric peoples have traditionally used Amanita muscaria as entheogen.

Amanita muscaria is widely thought to be the Soma talked about in Rig Veda of India,[15] and is less often also thought to be the amrita talked about in Buddhist scriptures.[18]

John Marco Allegro argues in The Sacred Mushroom and the Cross that the Christian religion is derived from a sex and psychedelic mushroom cult.[19]

Ethnobotanist and ethnomycologist Giorgio Samorini suggests in his book "Animals and Psychedelics" a symbiotic relationship between toads, flies and fly agaric. Flies, after a lick of Amanita Muscaria become inebriated and delirious prey for hungry toads that may have learned this, therefore hanging out around toadstools. This relationship within nature

illuminates an etymological keystone and example of zoopharmacognosy. This would also provide further biosemiotic insight into the ancient mystery of toads, flies and mushrooms appearing together in popular mythology and fairy lore.

The British writer Robert Graves theorizes in a preface to his book, The Greek Myths, that the Dionysian saturnalias were conducted under the influence of this mushroom.[20]

Legality

Amanita muscaria is un-scheduled in the United States. Any sales of Amanita muscaria for human ingestion are regulated by the FDA.

In the United Kingdom, the sale of Amanita muscaria is illegal.

Popular culture

The red-and-white spotted toadstool is a common image in popular culture; a partly grown Amanita muscaria, as shown left, is clearly the fungus which this icon is based on.

Children's culture

Garden ornaments, and children's picture books depicting gnomes and fairies very often show fly agaric mushrooms used as seats, or homes; it is rather uncommon for any other mushroom to be shown in this role. How this artistic convention arose is not known.

Art

The mushroom is mentioned in the song "The Flowers of Guatemala" by the American band R.E.M., providing the song's central image.

Santa Claus

The ethnobotanist Jonathan Ott has suggested that the idea of Santa Claus and the tradition of hanging stockings over the fireplace is based centrally upon the fly agaric mushroom itself.[21] With its generally red and white color scheme, he argues that Santa Claus's suit is related to the mushroom. He also draws parallels with flying reindeer: reindeer are said to enjoy the mushroom because of its euphoric results, and therefore prance around in a hallucinogenic after-effect.[22] A direct connection to Santa Claus is not very likely, as until the 20th century, the red-and-white Santa suit familiar today was not especially common (see also: Origins of Santa Claus). One scholar researching possible links between religious myths and the red mushroom notes, "If Santa Claus had but one eye [like Odin], or if magic urine had been a part of his legend, his connection to the Amanita muscaria would be much easier to believe."[23]

Ott also speculates about Santa's bag of toys. According to historians, ancient Siberia was one of the first civilizations to use fly agaric in practice. The Siberian hut, or yurt, is equipped with a smokehole at the top. Ott suggests that a shaman entered the yurt through the

smokehole with a sack of mushrooms in his hand, to be placed in stockings over the fireplace where they could be dried for celebratory use.

Ayahuasca

The widely used Quechua name *ayahuasca* (pronounced [a.ja.Èwa.ska]) has two highly interrelated yet distinct meanings and referents: 1) an Amazonian giant vine native to the rainforest containing various harmala alkaloids, generally Banisteriopsis caapi, and, by extension, 2) pharmacologically complex psychoactive infusions prepared from it for shamanic, folk-medicinal, and religious purposes. Sections of vine are macerated and boiled alone or with leaves from any of a large number of other plants, including Psychotria viridis (chakruna in Quechua) or Diplopterys cabrerana (also known as chacropanga). The resulting brew contains MAO inhibiting harmala alkaloids and the powerful hallucinogenic alkaloid N,N-dimethyltryptamine (DMT), a psychedelic which is active orally only when combined with an MAOI. Harmala alkaloids in Banisteriopsis caapi serve as MAOIs in Ayahuasca. Western brews sometimes substitute plant sources such as Syrian Rue or other harmala containing plants in lieu of the Banisteriopsis caapi vine, but the vine itself is always central to traditional usage.

Brews are also made with no DMT-containing plants; sometimes they are made with plants such as Justicia pectoralis, Brugmansia and sometimes made with no plants other than the ayahuasca vine itself. Tobacco is a common additive in traditional brews. The potency of this brew varies radically from one batch to the next, both in strength and psychoactive effect, based mainly on the skill of the shaman or brewer, as well as other admixtures sometimes added. Natural variations in plant alkaloid content and profiles also affect the

final concentration of alkaloids in the brew, and the physical act of cooking may also serve to modify the alkaloid profile of harmala alkaloids.[1][2]

Individual polymorphisms in the cytochrome P450-2D6 enzyme affects the ability of individuals to metabolize harmine.[3] Some natural tolerance to the regular use of Ayahuasca (e.g. once weekly) may be seen as an upregulation of the serotonergic system.[4] A phase 1 pharmacokinetic study on Ayahuasca (as Hoasca) with 15 volunteers was conducted in 1993, during the Hoasca Project.[5] A review of the Hoasca Project has been published.[6]

Names

- "ayahuasca" or "daime" in Brazil

"yagé" or "yajé" (both pronounced [ja.'he]) in Colombia; popularized in English by the beat generation writers William S. Burroughs and Allen Ginsberg in The Yage Letters.

"ayahuasca" or "ayawaska" in Ecuador, Bolivia and Peru, also to a lesser extent in Brazil ("vine of the dead" or "vine of souls": in Quechua, aya means "spirit," "ancestor," or "dead person," while waska means "vine" or "rope"). The name is properly that of the plant B. caapi, one of the primary sources of beta-carbolines for the brew.

"natem" amongst the indigenous Shuar people of Peru.

It should be noted that the spelling ayahuasca is the hispanicized version of the name; many Quechua or Aymara speakers would prefer the spelling ayawaska. In the central andeans of Perú Ayacwasca means :"Ayac" (spirit or dead) and "Wasca" (vine, cord or rope)

Usage

Ayahuasca is used in largely as a religious sacrament, no matter which culture it is associated with. Those who use ayahuasca in non-traditional contexts often align themselves with the philosophies and cosmolgies associated with ayahuasca shamanism, as practiced among indigenous peoples like the Urarina of Peruvian Amazonia.

While non-native users know of the spiritual applications of ayahuasca, a less well-known traditional usage focuses on the medicinal properties of ayahuasca. Its purgative properties are highly important (many refer to it as la Purga, "the purge"). The intense vomiting and occasional diarrhea it induces can clear the body of worms and other tropical parasites, and harmala alkaloids themselves have been shown to be anthelmintic[7]. Thus, this action is two-fold; a direct action on the parasites by these harmala alkaloids (particularly harmine in ayahuasca) works to kill the parasites, and parasites are expelled through the increased intestinal motility that is caused by these alkaloids.

Dietary taboos are almost always associated with the use of Ayahuasca; in the rainforest, these tend towards the purification of one's self- abstaining from spicy and heavily seasoned foods, fat, salt, caffeine, acidic foods (such as citrus) and sex before, after, or both before and after a ceremony. A diet low in foods containing tyramine is recommended, as the interaction of tyramine and MAOIs can lead to a hypertensive crisis. This extreme dietary specificity is largely a modern one, as most tyramine is produced as food ages, and is therefore not usually

a problem in traditional South American cultures. These dietary restrictions have developed as a means of making ayahuasca ingestion easier on the body, as well as having strong traditional and spiritual significance

Today, the name 'ayahuasca' can mean a variety of botanical concoctions containing one or more MAOIs and DMT or one of its chemical analogues. The synthetic pharmahuasca is sometimes called ayahuasca as well. In this usage, the DMT is generally considered the main psychoactive active ingredient, while the MAOI merely activates orally ingested DMT. However, most ayahuasqueros and others working with the brew claim the B. caapi vine to be the defining ingredient; according to them, it is not ayahuasca unless B. caapi is in the brew. The vine is considered to be the "spirit" of ayahuasca, the gatekeeper and guide to the otherworldly realms.

In some areas, it is even said that the chacruna or chaliponga admixtures are added only to make the brew taste sweeter. This is a strong indicator of the often wildly divergent intentions and cultural differences between the native ayahuasca-using cultures and psychedelics enthusiasts in other countries.

In modern Europe and North America, ayahuasca analogues are often prepared using non-traditional plants which contain the same alkaloids. For example, seeds of the Syrian rue plant are often used as a substitute for the ayawaska vine, and the DMT-rich Mimosa hostilis is used in place of chakruna. Australia has several indigenous plants which are popular among modern ayahuasqueros there, such as various DMT-rich species of Acacia.

In modern Western culture, entheogen users sometimes base concoctions off of Ayahuasca. When doing so, most often Rue or B. caapi are used with an alternative form of the DMT molecule, such as psilocin, or a non-DMT based hallucinogen such as mescaline. Nicknames such as Psilohuasca, Mush-rue-asca, or 'Shroom-a-huasca, for mushroom based mixtures, or Pedrohuasca (from the San Pedro Cactus, which contains mescaline) are often given to such brews. Such nicknames are by many considered innapropriate and culturally insensitive seeing as "huasca" means "vine" and none of the above are vines, nor do the psychedelic experimentalist trappings of such concoctions bear any resemblance to the medicinal use of Ayahuasca in its original cultural context. This is usually only done by experienced entheogen users who are more familiar with the chemicals and plants being used, as the uninformed combination of various neuro-chemicals can be dangerous.

It seems unlikely that Ayahuasca could ever emerge as a "street-drug", given the difficulty of making the tea and the intense experience it provides. Most Western users employ it almost exclusively for spiritual purposes, in line with both traditional, animist usage and organized churches such as the the Uniao do Vegetal (or UDV). A diet is almost always followed before use, including a day of fasting, to rid the body of tyramines and other contraindicated chemicals; a "dieta" is often followed as well, to spiritually cleanse the body before and after the experience. Most recreational drug users have never even heard of Ayahuasca, DMT or MAOIs, or the possibility of alterations to the shamanic brew.

Introduction to the West

Ayahuasca is mentioned in the writings of some of the earliest missionaries to South America, but it wasn't for some time that it became commonly known in the West. The early

missionary reports generally claim it as demonic, and great efforts were made by the Roman Catholic Church to stamp it out.

When originally researched in the 20th century, the active chemical constituent of Caapi was called telepathine, but it was found to be identical to a chemical already isolated from Peganum harmala and given the name harmaline.

William Burroughs sought yagé (still considered to be "telepathine") in the 1950s while traveling through South America, in the hopes that it could relieve or cure opiate addiction. The Yage Letters, written between Burroughs and Allen Ginsberg were probably the first major introduction of Ayahuasca to the West.

Ayahuasca was made more widely known by Terence and Dennis McKenna's experiences with Amazonian tribes as detailed in the book Invisible Landscape, which they co-authored. Their journey to the rainforest to search for Ayahuasca was spurred by their reading of Burroughs and Ginsberg. Dennis later extensively studied the pharmacology, botany, and chemistry of ayahuasca and oo-koo-he, which were the subjects of his master's thesis.

In Brazil, a number of modern religious movements based on the use of ayahuasca have emerged, the most famous of them being Santo Daime and the União do Vegetal (or UDV), usually in an animistic context that may be shamanistic or, more often, (as with Santo Daime and the UDV,) integrated with Christian. Both Santo Daime and União do Vegetal now have members and churches throughout the world.

Similarly, the US and Europe has started to see new religious groups born of experiences with ayahuasca. In the US a Wicca group, PaDeva, has become the first incorporated legal church with which ayahuasca is central to their beliefs.

Several notable celebrities have publicly discussed their use of ayahuasca, including Sting, Tori Amos, and Paul Simon (who wrote the song Spirit Voices about his experience with the brew in the Amazon).

Some "Westerners" have teamed up with "shamans" in the amazon rainforest regions and forming Ayahuasca "healing retreats" claiming that it can cure mental and physical illness and allow communication with the spirit world. This is not to say that all organizations catering to ayahuasca tourists are inherently bad, but one should be cautious. Though both anecdotal reporting and scientific studies affirm that ritualized use of ayahuasca can lead to the betterment of human mental and physical health, the monoamine oxidase inhibitor (MAOI) component of the brew is a powerful compound that interacts with many foods that some Westerners would not consider dangerous, from liver to Vegemite.

Wade Davis most notably acredited with the writting of The Serpent and The Rainbow wrote in addition to that book one entitled One River. Many examples of ayahuasca as used traditionally by the indigenous jungle tribes of the Amazon Basin are detailed through the book. "The smell and acrid taste was that of the entire jungle ground up and mixed with bile." [p.194]

Plant constituents

Traditional

Traditional Ayahuasca brews are always made with B. caapi as an MAOI, although DMT sources and other admixtures vary from region to region. There are several varieties of caapi, often known as different "colors", with varying effects, potencies, and uses.

DMT admixtures:

- Psychotria viridis (Chakruna) - leaves
- Diplopterys cabrerana (Chaliponga, Banisteriopsis rusbyana) - leaves
- Psychotria carthagensis (Amyruca) - leaves

Other common admixtures:

- Justicia pectoralis
- Brugmansia (Toé)
- Nicotiana rustica (Mapacho)
- Ilex guayusa, a relative of yerba mate

Western

Although traditional plant materials are often used, sources with similar chemical constituents are often substituted for the traditional ingredients.

MAOI:

- Harmal (Peganum harmala, Syrian Rue) - seeds
- Passion flower

DMT admixture sources:

- Acacia maidenii (Maiden's Wattle), Acacia phlebophylla, and other Acacias, most commonly employed in Australia - bark
- Anadenanthera peregrina, A. colubrina, A. excelsa, A. macrocarpa
- Mimosa hostilis (Jurema) - root bark - not traditionally employed with ayahuasca by any existing cultures, though likely it was in the past. Popular in Europe and North America.

Legal status

Internationally, DMT is a Schedule I drug under the Convention on Psychotropic Substances. The Commentary on the Convention on Psychotropic Substances notes, however, that the plant itself is excluded from international control[1]:

The cultivation of plants from which psychotropic substances are obtained is not controlled by the Vienna Convention. . . . Neither the crown (fruit, mescal button) of the Peyote cactus nor the roots of the plant Mimosa hostilis nor Psilocybe mushrooms themselves are included in Schedule 1, but only their respective principles, mescaline, DMT and psilocin.

A fax from the Secretary of the International Narcotics Control Board to the Netherlands Ministry of Public Health sent in 2001 goes on to state that "Consequently, preparations (e.g.decoctions) made of these plants, including ayahuasca are not under international control and, therefore, not subject to any of the articles of the 1971 Convention." [2]

The legal status of these plants in the United States is somewhat questionable. Ayahuasca plants and preparations are legal as they contain no scheduled chemicals. However, brews made using DMT containing plants are illegal since DMT is a Schedule I drug. That said, some

people are challenging this, using arguments similar to those used by peyotist religious sects, such as the Native American Church. A court case allowing Uniao do Vegetal to use the tea for religious purposes in the United States, Gonzales v. O Centro Espírita Beneficente União do Vegetal, was heard by the U.S. Supreme Court on November 1, 2005; the decision, released February 21st, 2006, allows the UDV to use the tea in its ceremonies persuant to the Religious Freedom Restoration Act.

Religious use in Brazil was legalized after two official inquiries into the tea in the mid-1980s, which concluded that ayahuasca is not a recreational drug and has valid spiritual uses. (more on the legal status of ayahuasca can be found in the Erowid vault on the legality of ayahuasca).

In France, Santo Daime won a court case allowing them to use the tea in early 2005; however, they were not allowed an exception for religious purposes, but rather for the simple reason that they did not perform chemical extractions to end up with pure DMT and harmala and the plants used were not scheduled. Four months after the court victory, the common ingredients of Ayahuasca as well as harmala were declared stupéfiants, or narcotic schedule I substances, making the tea and its ingredients illegal to use or possess. See [3] and [4] ***(French)*** for more information.

Dimethyltryptamine

Chemical name 2-(1H-indol-3-yl)-N,N-dimethylethanamine

Chemical formula C***12***H***16***N***2***

Molar mass 188.27 g/mol

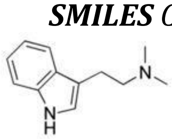
Density 1.099 g/ml

Melting point 49 °C and 74 °C (two different crystal structures)

Boiling point 160 °C at 0.8 hPa (reduced pressure)

CAS number 61-50-7

SMILES *CN(C)CCC1=CNC2=C1C=CC=C2*



Dimethyltryptamine(DMT), also known as Dimitri, and *N,N-dimethyltryptamine*, not to be confused with 5-MeO-DMT, is a psychedelic tryptamine, similar in structure to the neurotransmitter serotonin. DMT is created in small amounts by the human body during normal metabolism[1] by the enzyme Tryptamine-N-methyltransferase. Pure DMT at room temperature is a light pink, orange, or yellow waxy or crystalline solid. DMT was first chemically synthesized in 1931. It also occurs naturally in many species of plants. DMT-containing plants are used in several South American shamanic practices. It is one of the main active constituents of snuffs like yopo and of the drink ayahuasca.

DMT is not orally active unless it is combined with a monoamine oxidase inhibitor (MAOI), such as harmaline. Without an MAOI, the body quickly metabolizes orally-administered DMT, and it therefore has no hallucinogenic effect. Other means of ingestion such as smoking or injecting the drug, however, can produce powerful hallucinations and entheogenic activity for a short time (usually less than half an hour).

Hallucinogenic properties

DMT is a powerful psychoactive substance. If DMT is smoked, injected, or orally ingested with an MAOI, it can produce powerful entheogenic experiences including true hallucinations (perceived extensions of reality). A trip sitter is often employed to assist the drug user in staying physically and mentally healthy, and, in the case of smoked DMT, to catch the pipe when the user loses awareness of it.

Smoked: If DMT is smoked, the maximal effects last for a short period of time (5 - 30 minutes +). The onset after inhalation is very fast (less than 45 seconds) and maximal effects are reached within about a minute.

Insufflation: If DMT is insufflated (snorted through the nostrils) it will last slightly longer than if smoked and has less powerful effects.

Injection: Injected DMT produces an experience similar to inhalation in duration, intensity, and characteristics, although by some accounts it is more emotionally clinical (versus spiritual).

Oral ingestion: DMT, which is broken down by the digestive enzyme monoamine oxidase, is inactive if taken orally, unless combined with a monoamine oxidase inhibitor (MAOI). The traditional South American ayahuasca, or yage, is a decocted tea-like mixture containing DMT. There are a number of admixtures to this brew, but most commonly it is simply the leaves of Psychotria viridis (containing DMT), and the vine Banisteriopsis caapi (the MAOI). Other DMT containing plants, including Diplopterys cabrerana, are sometimes used in ayahuasca in different areas of South America. A common source in the western US is Reed canary grass or Phalaris arundinacea, and Harding grass or Phalaris aquatica. This invasive grass contains high levels of DMT and other alkaloids . Taken orally with an appropriate MAOI, DMT produces a long lasting (over 1 hour), slow onset experience. MAOIs should be used with extreme caution as they can have lethal complications with some prescription drugs, such as SSRI antidepressants, and some over-the-counter drugs.[2]

Induced DMT experiences can include profound time-dilation, visual and audio hallucinations, and other experiences that, by most firsthand accounts, defy verbal or visual description. Some users report intense erotic imagery and sensations and utilize the drug in

a ritual sexual context. Professor Alan Watts described the effects of DMT as "Load universe into cannon. Aim at brain. Fire."

In a 1988 study conducted at UNM, psychiatrist Rick Strassman found that approximately 20% of volunteers injected with high doses of DMT had experiences with a perceived alien entity. At least one subject reported sexual contact with these beings, and many others reported erotic experiences.

Excretion Urine

Legal status US: I CA: III UK: 1/A

Delivery Vaporized, injected, or orally in combination with MAO inhibitors

Recreational uses:
Euphoria
Psychedelic effects
Other uses:
Mystical Experience
Shamanic
spiritual/Religious
Contraindications:
Potentially fatal if currently taking an MAO-Inhibitor, such as many common anti-depressants
Do not use if suffering from Schizophrenia or similar conditions, or if such runs in your family.

Side Effects

When DMT is vaporized, the vapor produced is often felt to be very harsh on the lungs, especially if the dose contains impurities (commonly residue of sodium hydroxide or yellow/orange tannins from the plant sources), in extreme cases this can lead to retching and vomiting.

Chemistry

DMT is a derivative of tryptamine with two additional methyl groups at the amine nitrogen atom. DMT is often synthesized by the Speeter-Anthony synthesis from indole using oxalyl chloride, dimethylamine, and lithium aluminium hydride as reagents. DMT is usually used in its base form, but it is more stable as a salt, e.g. as a fumarate. In contrast to DMT's base, its salts are water-soluble. DMT in solution degrades relatively fast and should be stored protected from air and light in a freezer.

When solvents containing N,N-DMT are evaporated different purities of alkaloid and rates of evaporation produce different crystalline patterns. Depending upon purity, the formations produced can vary from small white raised bumps which may or may not appear to have a crystalline pattern within them to a fine pointed array of delicate crystalline

needled formations. Due to confinement in an evaporation container the extract shown in these photos became irregular tile-like shapes instead of the more common spoked circles at this purity. Ninety plus percent purity extract, when evaporated out of a solvent and depositing upon glass often produce small but highly defined white crystalline needles which when viewed under intense light will sparkle and upon close examination at high magnification can be seen to actually be without color and completely clear, if pure.

DMT which is in the form of a salt in dried Mimosa hostilis root bark is exceptionally free of plant fats which allows this substance to be extracted or isolated from the plant material by simply mixing powdered root bark into basified water which has had a base chemical such as NaOH dissolved into it to raise the pH of the watery mix to close to a pH of 13.5 and thereby converting the DMT salt into an alkaloid which can then be absorbed by a solvent. Once the root bark has been placed in basified water and stirred for a few minutes naphtha can be poured into the aqueous room temperature soup and stirred for twenty minutes or more which will allow the solvent to fairly selectively pull out a large portion of the alkaloid. Multiple half hour extractions are typical, stirring and extracting several times over until most of the alkaloid has been depleted through absorption into the solvent, combining the multiple fractions of solvent which have been separated from the aqueous mix each time by simply pouring the lower specific gravity solvent which is floating on top of the basified mix into a collection container and evaporated to net the alkaloid.

Speculations

Several speculative and as yet untested hypotheses suggest that endogenous DMT, produced in the human brain, is involved in certain psychological and neurological states. As DMT is naturally produced in small amounts in the brains and other tissues of humans, and other mammals[4], some believe it plays a role in promoting the visual effects of natural dreaming, near-death experiences and other mystical states. A biochemical mechanism for this was proposed by the medical researcher JC Callaway, who suggested in 1988 that DMT might be connected with visual dream phenomena, where brain DMT levels are periodically elevated to induce visual dreaming and possibly other natural states of mind.[3]

Dr. Rick Strassman, while conducting DMT research in the 1990's at the University of New Mexico, advanced the theory that a massive release of DMT from the pineal gland prior to death or near death was the cause of the near death experience phenomenon. Only two of his test subjects reported NDE-like audio or video hallucinations. His explanation for this was the possible lack of panic involved in the clinical setting and possible dosage differences between those administered and those encountered in actual NDE cases.

Several subjects also reported contact with 'other beings', alien like, insectoid and reptillian in nature, in technological environments[4] where the subjects were 'probed', 'tested' and sometimes even 'manipulated' by these 'beings', anyone is, regardless of interest for the subject, tempted to draw similarities between these experiences and the tales of alien encounters.

In the 1950s, the endogenous production of psychoactive agents was considered to be a potential explanation for the hallucinatory symptoms of some psychiatric diseases as the transmethylation hypothesis.[5]. Unfortunately, this hypothesis does not account for the natural presence of endogenous DMT in otherwise normal humans, not to mention rats and

other laboratory animals. The proposal by Dr. Callaway was the first to suggest a useful function for the endogenous production of DMT; i.e. to facilitate the visual phenomenon of normal dreaming.

Ethical concerns do not allow for the testing of this hypothesis in humans, as the biological samples must come from the living human brain. It is unknown if other animals actually do dream, as it is quite impossible to know this without their ability to tell us that they have had a dream, although REM sleep is highly correlated with dream sleep.

Writers on DMT include Terence McKenna and Jeremy Narby, though most scientists who study psychedelic drugs treat their writings with skepticism. McKenna writes of his experiences with DMT in which he encounters entities he describes as "Self-Transforming Machine Elves". McKenna believed DMT to be a tool that could be used to enhance communication and allow for communication with other-worldly entities. Other users report visitation from external intelligences attempting to impart information. These Machine Elf experiences are said to be shared by many DMT users. From a researcher's perspective, perhaps best known is Rick Strassman's DMT: The Spirit Molecule (ISBN 0-89281-927-8); Strassman also proposed that DMT is made in the pineal gland, although this is only speculation.

Legal status

DMT is classified in the United States as a Schedule I drug. In December of 2004, the Supreme Court lifted a stay thereby allowing the Brazil-based União do Vegetal (UDV) church to use a decoction containing DMT in their Christmas services that year. This decoction is a "tea" made from boiled leaves and vines, known as hoasca within the UDV, and ayahuasca in different cultures. In Gonzales v. O Centro Espírita Beneficente União do Vegetal, the Supreme Court heard arguments on November 1st, 2005 and unanimously ruled in February 2006 that the U.S. federal government must allow the UDV to import and consume the tea for religious ceremonies under the 1993 Religious Freedom Restoration Act.

DMT is classified in Canada as a Schedule III drug.

DMT, *along with most of its plant sources*, is classified in France as a stupéfiant.

DMT is classified in the United Kingdom as a Class A drug.

DMT creates legal dilemmas in many countries because possession is illegal but at the same time the drug is naturally present in the human body.

Culture

In Brazil there are a number of religious movements based on the use of Ayahuasca, usually in an animistic context that may be shamanistic, sometimes mixed with Christian imagery.

There are four main branches using DMT-MAOI based sacraments in Brasil:

1) Indigenous people - they are the oldest culture in the whole South America to use ayahuasca or analogue brews, such as the ones made from Jurema (Mimosa hostilis).

2) Santo Daime (Saint Giveme) and Barquinha (Lil'Boat) - the former was founded by a simple man, called Raimundo Irineu Serra, in the early 30s as an esoteric Christian religion with shamanic tendencies. The Barquinha cult was derived from this one.

3) União do Vegetal (Vegetable's Union) - another Christian ayahuasca religion, with a more Masonic tone. Today it's divided into at least three sects.

4) Neo-shamans - there are some shamanic facilitators in Brasil using ayahuasca and analogue brews in their rituals and séances, mainly in the State of Sao Paulo.

About 50, including:
Claviceps africanum
Claviceps fusiformis
Claviceps paspali
Claviceps purpurea

Ergot is the common name of a fungus in the genus Claviceps. The fungus is parasitic on certain grains and grasses. The form the fungus takes to over-winter is called a sclerotium, and this small structure is what is usually referred to as 'ergot', although referring to the members of the Claviceps genus as 'ergot' is also correct. There are about 50 known species of Claviceps, most of them in the tropical regions. Economically important species are Claviceps purpurea (parasitic on grasses and cereals), C. fusiformis (on pearl millet, buffel grass), C. paspali (on dallis grass), and C. africana[1](on sorghum). C. purpurea can affect a number of cereals including rye (its most common host), triticale, wheat and barley. It affects oats only rarely.

There are three races or varieties of C. purpurea, differing in their host specifity: G1 - land grasses of open meadows and fields; G2 - grasses from moist, forest and mountain habitats; G3 (C. purpurea var. spartinae) - salt marsh grasses (Spartina, Distichlis).

Life cycle of the fungus

An *ergot kernel* called a sclerotium develops when a floret of flowering grass or cereal is infected by a spore of Claviceps fungus. The infection process mimicks a pollen grain growing into an ovary during fertilization. The fungus then destroys the plant ovary and attaches itself to a vascular bundle originally intended for seed nutrition. The first stage of ergot infection manifests itself as a white soft tissue (known as sphacelia) producing sugary honeydew, which often drops out of the grass florets. This honeydew contains millions of asexual spores (conidia) which are dispersed to other florets by insects. Later, the sphacelia convert into a hard dry sclerotium inside the husk of the floret. At this stage, alkaloids and lipids accumulate in the sclerotium.

Claviceps species from tropic and subtropic regions produce macro- and microconidia in their honeydew. Macroconidia differ in shape and size between the species, whereas microconidia are rather uniform, oval to globose (5x3um). Macroconidia are able to produce secondary conidia. A germ tube emerges from a macroconidium through the surface of a honeydew drop and a secondary conidium of the oval to pearlike shape is formed to which the contents of the original macroconidium migrates. Secondary conidia form white frost-like surface on honeydew drops and are spread by wind. No such process occurs in Claviceps purpurea, Claviceps grohii, Claviceps nigricans and Claviceps zizaniae, all from North temperate regions.

When a mature sclerotium drops to the ground, the fungus remains dormant until proper conditions trigger its fruiting phase (onset of spring, rain period, etc.). It germinates, forming one or several fruiting bodies with head and stipe, variously colored (resembling a tiny mushroom). In the head, threadlike sexual spores are formed, which are ejected simultaneously, when suitable grass hosts are flowering. Ergot infection causes a reduction in the yield and quality of grain and hay produced, and if infected grain or hay is fed to livestock it may cause a disease called ergotism.

Black and protruding sclerotia of C. purpurea are well known. However, many tropical ergots have brown or greyish sclerotia, mimicking the shape of the host seed. For this reason, the infection is often overlooked.

Effects on humans and animals

Ergot contains alkaloids of the ergoline group, which have a wide range of activities including effects on circulation and neurotransmission. Ergotism is the name for the collection of symptoms a human or animal has when it has ingested (too much of) this fungus. Ergotism went also under the name "St. Anthony's fire" hinting at burning sensations in the limbs. Another effect of ergot alkaloids is vasoconstriction, therefore ergotism may lead to gangrene and loss of the limbs due to limited blood circulation. This may also cause insanity, convulsions, or death, due to limited circulation to the brain. Other symptoms include strong uterine contractions, nausea, seizures, and unconsciousness. Monks of the order of St. Anthony the Great specialized in treating ergotism victims with balms containing tranquilizing and blood circulation-stimulating plants; they were also skilled in amputations. Entire villages have been known to suffer ergotism after the village bakery used infected grain.

In addition to ergot alkaloids, Claviceps paspali also produces tremorgens (paspalitrem) causing "paspalum staggers" in cattle.

Historically, controlled doses of ergot were used to induce abortions and to stop maternal bleeding after childbirth, but simple ergot extract is no longer used as a pharmaceutical.

Among those who studied ergot and its derivatives was Albert Hofmann, whose experiments led to the discovery of LSD, a powerfully hallucinogenic ergot derivative that affects the serotonin system. Contrary to some rumors, ergot contains no LSD, but there are links between the two substances:

- LSD was first synthesised during research on the active ingredients of ergot.
- Lysergic acid, a raw material used in the synthesis of LSD, was and is still prepared from ergot.

Speculations

The disease cycle of the ergot fungus was first described in the 1800s, but the connection with ergot and epidemics among people and animals was known several hundred years before that.

Human poisoning due to the consumption of rye bread made from ergot-infected grain was common in Europe in the Middle Ages. The phenomenon known as Dancing mania has been blamed on accidental consumption of the fungus.

It has also been posited — though speculatively — that the Salem Witch Trials were initiated by young women who had consumed ergot-tainted rye. The Great Fear in France during the Revolution has also been linked by some historians to the influence of ergot. Most famously, ergot intoxicated a whole French village in 1951, at Pont-Saint-Esprit.

Kykeon, the beverage consumed by participants in the ancient Greek mystery of Eleusinian Mysteries, might have been based on hallucinogens from ergot.

Nowadays, rye grain is infected repeatedly to produce ergot.

Morning glory

Morning glory is a common name for a number of species of flowering plants in the family the Convolvulaceae, belonging to the following genera:

- Calystegia

Convolvulus
Ipomoea
Merremia
Rivea

As the name implies, morning glory flowers, which are funnel-shaped, open at morning time, allowing them to be pollinated by hummingbirds, butterflies, bees and other daytime insects and birds, as well as Hawkmoth at dusk for longer blooming variants. The flower typically lasts for a single morning and dies in the afternoon. New flowers bloom each day. The flowers usually start to fade a couple of hours before the petals start showing visible curling. They prefer full sun throughout the day, and mesic soils. In cultivation, most are treated as perennial plants in tropical areas, and as annual plants in colder climates, but some species tolerate winter cold.

Morning glory is also called *asagao* (in Japanese, a compound of asa "morning" and T kao "face"). A rare brownish-coloured variant known as Danjuro is very popular. It was first known in China for its medicinal uses, due to the laxative properties of its seeds. It was introduced to the Japanese in the 9th century, and they were first to cultivate it as an ornament. During the Edo Period, it became a very popular ornamental flower. Aztec priests in Mexico were also known to use the plant's hallucinogenic properties to commune with their gods.

Ancient Mesoamerican civilizations used it to coagulate rubber latex to produce bouncing rubber balls. The sulphur in the Morning Glory vine served to vulcanize the rubber; a process which pre-dates the Charles Goodyear discovery by over 1000 years.

Because of their fast growth, twining habit, attractive flowers, and tolerance for poor, dry soils, some morning glories are excellent vines for creating summer shade on building walls when trellised, thus keeping the building cooler and reducing air condtioning costs.

Culinary use

Ipomoea aquatica, known as water teeth, water morning-glory, water convolvulus or swamp cabbage, is popularly used as a green vegetable especially in East and Southeast Asian cuisines.

Recreational use

The seeds of many species of morning glory contain d-lysergic acid amide, ergoline alkaloids better known as LSA. Seeds of I. violacea and R. corymbosa are used as hallucinogens. They are about 5% to 10% as potent as LSD. To discourage morning glory's use as hallucinogenic drugs, some commercial seed producers have started treating seeds with a chemical that will not wash off. This chemical has been known to cause vomiting, nausea and abdominal pain. Typically some form of a warning or notice is printed on the package if seeds have been treated.

Peyote

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Caryophyllales
Family: Cactaceae
Genus: Lophophora
Species: *L. williamsii*

Binomial name Lophophora williamsii (Lem.) J. Coult.

Peyote (Lophophora williamsii) is a small, spineless cactus whose native region extends from the southwestern United States (including the states of Texas and New Mexico) through central Mexico. It has been used for centuries for the psychedelic effects experienced when it is ingested.

Plant

The cactus flowers sporadically, producing small pink fruit, similar in appearance to a chili pepper, which can be very delectable and sweet-tasting when eaten. The seeds are small and black, requiring hot and humid conditions to germinate, one of the reasons this tranquil plant is becoming rare in its natural habitat. Numbers are reducing due to harvesting for commercial purposes. Peyote contains a large spectrum of phenethylamine alkaloids, the principal of which is mescaline. All Lophophora species are extremely slow growing, often taking up to thirty years to reach flowering age (at about the size of a golf ball, not including root) in the wild. Human cultivated specimens grow considerably faster, usually taking from

six to ten years to go from seedling to mature flowering adult. Due to this slow growth and over-harvesting by collectors, peyote is considered to be in danger of extinction in the wild.

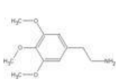
The top of the cactus above ground, also referred to as the crown, consists of disc-shaped buttons that are cut from the roots and dried. When done properly the top of the root will callous over and new buttons will eventually grow. When poor harvesting technique is used, however, the root is damaged and the entire plant dies. These buttons are generally chewed, or boiled in water to produce a psychoactive tea. The resulting infusion is extremely bitter and, in most cases, the user experiences some degree of nausea before the onset of the psychedelic effects. This is considered quite normal according to experienced users and historians.

Medicinal effects

The effective dose for mescaline is about 300 to 500 mg (equivalent to roughly 5 grams of dried peyote) and the effects last about 10 to 12 hours. When combined with appropriate set and setting, peyote is reported to trigger states of deep introspection and insight that have been described as being of a metaphysical or spiritual nature. At times, these can be accompanied by rich visual or auditory effects (see synesthesia). Unless one is embarking on the experience in a ceremonial context conducted by a "Peyotero" with much experience, similar to a shaman or medicine man, it is recommended, for safety reasons, that the user be accompanied at all times by someone who is not likewise intoxicated. This person is referred to by some as a "guide" or "trip sitter". In spite of this, a person who wants to undergo such an experience must observe two points to guarantee a mentally healthy trip: set and setting, i.e., the state of mind and the situation one is living at the session. The works of Timothy Leary explain this further.

History

From earliest recorded time, peyote has been used by indigenous peoples, such as the Huichol peoples of northern Mexico and the Navajo in the southwestern United States, as a part of traditional religious rites. In the late 1800s, the tradition began to spread northward as part of a revival of native spirituality under the auspices of what came to be known as the Native American Church, whose members refer to peyote as "the medicine", and use it to combat alcoholism and other social ills. The Native American Church is one among several religious organizations that use peyote as part of their religious practice.



chemical structure of mescaline

A resurgence of interest in the use of peyote was spawned in the 1970s by accounts of its use in the early works of writer Carlos Castaneda. Don Juan Matus, the pseudonym for Castaneda's instructor in the use of peyote, used the name "Mescalito" to refer to an entity that purportedly can be sensed by those using peyote to gain insight in how to live one's life. Later works of Castaneda asserted that the use of such psychotropic substances was not necessary to achieve heightened awareness and de-emphasized the use of peyote as a

general means to achieve this end. Castaneda's writing has been largely discredited as serious anthropological research and is generally considered to be allegorical fiction.

Legality

USA

United States federal law (and many state laws) protect the harvest, possession and consumption (but not cultivation) of peyote as part of "bonafide religious ceremonies" (the federal regulation is 42 USC §1996a, "Traditional Indian religious use of the peyote sacrament," exempting only Native American use, while most state laws exempt any general "bonafide religious activity"). These laws notwithstanding, religious or therapeutic use not under the aegis of the Native American Church has often been targeted by local law enforcement agencies, and non-natives attempting to establish spiritual centers based on the consumption of peyote as a sacrament or as medicine, such as the Peyote Foundation in Arizona, have been prosecuted.

Canada

Under the Canadian Controlled Drugs and Substances Act mescaline is defined as illegal but peyote is specifically exempt. [Controlled Drugs And Substances Act] "17. Mescaline (3,4,5–trimethoxybenzeneethanamine) and any salt thereof, but not peyote (lophophora)"

International

Article 32 of the Convention on Psychotropic Substances allows nations to exempt certain traditional uses of peyote from prohibition:

> A State on whose territory there are plants growing wild which contain psychotropic substances from among those in Schedule I and which are traditionally used by certain small, clearly determined groups in magical or religious rites, may, at the time of signature, ratification or accession, make reservations concerning these plants, in respect of the provisions of article 7, except for the provisions relating to international trade.

Psychedelic mushroom

Psychedelic mushrooms are fungi that contain psychedelic substances, such as psilocybin, psilocin, or muscimol. The most common colloquial terms for psychedelic mushrooms are *magic mushrooms*, *boomers*,[1] or just '*shrooms*, though there are many more.

Categorization

Psychedelic mushrooms can be divided into two groups: the psilocybin-bearing mushrooms, found primarily in the Psilocybe genus, and the muscimol-containing mushroom Amanita muscaria.

Psilocybe mushrooms contain psilocybin and/or psilocin, psychedelic tryptamines that are structurally similar to serotonin, a strong regulator of mood, state of mind, and consciousness. Several species of Psilocybe also contain the alkaloid baeocystin, which is a demethylated derivative of psilocybin. Other genera that contain psilocybin include Conocybe, Copelandia, Gymnopilus, Inocybe and Panaeolus.

Amanita muscaria, or Fly Agaric, contains many entheogenic elements, most notably muscimol, but also including muscazone, ibotenic acid and muscarine. It produces a much different experience compared to a Psilocybe mushroom. This mushroom is toxic in large doses, as ibotenic acid and muscazone can cause unpleasant side-effects such as nausea or even permanent damage, although there are very few fatalities caused by Amanita muscaria. Recreational users who wish to consume the Amanita muscaria often heat dry or cook the mushrooms, as the high temperature is believed to reduce negative effects by converting ibotenic acid into muscimol.

History

Various cultures throughout the ages have used psychedelic fungi for shamanistic and other purposes; rock paintings in the Sahara of mushroom effigies date back to 7000 BCE.

Mesoamerican mushroom stones of the pre-classic Mayans representing deified mushrooms date back to approximately 500 BCE, Psilocybin mushrooms were a revered tradition in native Central American cultures at the time of the European invasion, and have been in continuous use up to the present. Named teonanácatl ("flesh of the gods") in Nahuatl, they may have been employed for healing, divination and for intercession with spirits. Since the beginning of the Latin American colonial era, their use has been hidden due to persecution by the Christian church, which branded all native religious practices, especially those employing entheogenic sacraments, as "pagan".

Some scholars believe that Soma, the drink mentioned in Vedic literature, was derived from psychedelic mushrooms; R. Gordon Wasson suggests that this was amanita muscaria, which is known to have been used in Siberian shamanism. That Nordic Vikings may have used fly-agaric to produce their berserker rages was first suggested by the Swedish professor Samual Ödman in 1784. Ödman based his theory on reports about the use of fly-agaric among Siberian shamans. The notion has become widespread since the 19th century, but no contemporary sources mention this use or anything similar in their description of berserkers. Today, it is generally considered an unproven speculation.

According to the BBC, the first documented use of psychedelic mushrooms was in the Medical and Physical Journal: In 1799, a man who had been picking mushrooms for breakfast in London's Green Park included them in his harvest, accidentally sending his entire family on a trip. The doctor who treated them later described how the youngest child "was attacked with fits of immoderate laughter, nor could the threats of his father or mother refrain him."

In 1957, amateur mycologist R. Gordon Wasson published an article for Life describing his experiences with psilocybin mushrooms while a guest in the rituals of the Mazatec shaman Maria Sabina in a mountain village in the Mexican state of Oaxaca. His account triggered a wave of experimentation with these mushrooms which resulted in their eventual classification in the United States as a Schedule I drug under the Controlled Substances Act.

The introduction of westerners into the previously secret rites was later rued by Maria Sabina: "From the moment the foreigners arrived, the 'holy children' (a Mazatec euphemism for the mushrooms, which are otherwise not named directly) lost their purity. They lost their force, they ruined them. Henceforth they will no longer work. There is no remedy for it."

Effects

As with many psychoactive substances, the effects of any mushrooms consumed are subjective and unpredictable. Generally speaking, the experience of psilocybin containing mushrooms lasts four to six hours or more. The effect is typically inwardly oriented, with strong visual and auditory components. Visions and revelations may be experienced, and the effect can range from exhilarating to distraught. There can be also a total absence of effects, even with large doses.

The effects of mushrooms are strongly dependent upon set and setting. The Mazatecs purify themselves before a velada (or "vision quest") by abstaining from meat, eggs, alcohol and sex for four days. The veladas are always done in the dark, in a protected and sealed space which no one may enter or leave until all have regained their composure. Modern psychonauts often speak of "packing for the trip", by which is meant a loading of information into the brain prior to "departure", for example, by reading a philosophical writing or watching natural history or science documentaries in the days immediately prior to a planned experience. Experienced users find that there are ways of adjusting their environment to enhance their trip.

There have been calls for medical investigation of the use of psilocybin-containing mushrooms for the treatment of chronic cluster headaches, following numerous anecdotal reports of benefits.[2]

Physical

Physical effects are all related to how many mushrooms are consumed. Low doses exhibit effects along the lines of feelings of relaxation or peace, a feeling of heaviness or lightness, and loss of appetite.[3] Higher doses cause numerous effects like a feeling of coldness in some users, numbness of the mouth and adjacent features, nausea, weakness in the limbs (making locomotion difficult), excessive yawning which usually occurs during the come-up, swollen features, pupil dilation, and stiffness in points of the body, often the result of the users staying in awkward positions because of their inability to accurately judge the flow of time and their level of fatigue.

Sensory

As with many hallucinogens, the sensory effects are often the most dramatic of the experience. Most general doses cause a noticeable enhancement and contrasting of worldly colors, surfaces that seem to ripple, shimmer, or breathe, and some visual hallucinations.[1] Heavy experiences cause complex open and closed eye visuals, objects that warp, morph, or change solid colors (juxtaposed with the free-flowing and changing colors of LSD), a sense of melding into the environment, trails, and auditory hallucinations. Natural and artificial sounds seem to be heard with increased clarity; music, for example, can often take on a profound sense of cadence and depth. Intriguingly, some users speak about the feeling of their senses overlapping or synesthesia, a rather interesting experience wherein it causes, for example, a visualization of color upon hearing a particular sound. Unusual natural designs, such as wood grain, seem to flow like rivers and finer details are noticed more sharply. Interesting textures can be quite stimulating to some users.

Emotional

Feelings of euphoric bliss, relaxation, peace, wonder, anxiety, or fear have all been reported.[4] A childlike sense of intrigue about the world on common doses is contrasted with cosmic revelations and perceptions of a "higher power" on large amounts. Some users may experience intense episodes of hilarity, such as laughing for the duration of the psychedelic experience.[1] Emotions can be experienced with increased sensitivity. Heavier trips carry the increased possibility of a surreal event known as ego death, whereby the user loses the sense of boundaries between their self and the environment, creating a sort of perceived universal unity. Also, anxiety and paranoia are possible and if they become severe enough they could culminate into a bad trip. However, this can be easily offset by being in a comfortable place.

Psychological

Mushrooms cause the mind to conduct itself in an unusual manner. Abstract thoughts develop and are often difficult to explain to others correctly. An intricate thought pattern becomes apparent, climaxing in deep philosophical or introspective silence. Complex personal issues may be taken on full force by more experienced users, helping them arrive at a conclusion and make an appropriate change to their lifestyle. During this process, a user may also gain a new perspective on a thought they've held for years. The mind seems to flow more lucidly from idea to idea, making such things as improvisation easier. The natural filters of the mind are bypassed, causing a large increase in mental stimulation and creativity. Time dilation has been reported, with minutes and seconds taking an unusually large amount of time to pass. There may also be some indecisiveness in deciding what to do or get. Some people find that they experience stimulation of the verbal faculties (such as speech and singing), a phenomenon known as glossolalia, experimenting with phonetics like vowels, consonants, or click consonants

Dosage

Dosage of psilocybin mushrooms depends on the total psilocybin and psilocin content of the mushrooms, which varies significantly both between species and within the same species, but is typically around 0.5-2% of the dried weight of the mushroom. A typical dose of the rather common species, Psilocybe cubensis, is approximately 1 to 3 grams, corresponding with 10 to 30 milligrams psilocybin and psilocin, while about 3 to 5 grams dried material or 30 to 50 milligrams of psilocybin/psilocin is considered a heavy dose. Mushrooms are approximately 90% water, though dosages for fresh mushrooms are not 10 times higher as some of the psilocybin and much of the psilocin are lost from oxidation in the drying process.

Legal status

In many countries, psilocybin and psilocin containing mushrooms are illegal. This is because these substances are controlled by the UN convention on psychotropic substances of 1971. The mushrooms themselves are not listed as a controlled substance. Nonetheless, there is an active international trade both in mushrooms and in spores, which can be grown in sterile medium. Fly Agaric is not a controlled substance in most countries. The new drugs act of 2005 has been changed so that now "magic mushrooms" are a class A drug. Possession can get you a seven year sentence and/or an unlimited fine. Supplying or dealing can get you life in jail and an unlimited fine.

The Netherlands

In the Netherlands, magic mushrooms can be obtained in "smart shops" which specialise in ethnobotanicals. Magic mushrooms, whether dried or fresh were legal until 2001, when the Supreme Court of The Netherlands ruled dry mushrooms to be an illegal preparation of psilocybin and psilocin. The limitation to fresh mushrooms (which go bad quite fast) is severely reducing the export of magic mushrooms. In a series of court cases during 2003-2005 this was challenged by De Sjamaan, a Dutch mushroom wholesaler. The vice president of the International Narcotics Control Board (INCB) of the UN testified to the court that the UN does not see dried or prepared psilocybe mushrooms as a controlled substance. Explanation: Psilocybe mushrooms are not listed as controlled substances, therefore preparations are also not controlled. Preparations of the controlled substances psilocybin and psilocin (i.e. tablets, etc) are controlled. Various mushroom experts have testified that there is no way to see the difference between passively and actively dried mushrooms. The court decided to agree to other viewpoints of De Sjamaan in order not to touch the subject of the UN's stance. The court also decided not to publish the testimony of the vice president of the INCB. The high court ruled that:

- there is no definition in regards to water content, which differentiates between a dry mushroom and a fresh mushroom. - passively dried mushrooms (natural desiccation) are legal. - a police-officer is not skilled to differentiate between a fresh and dry mushroom.

Canada

Mushroom spore kits are legal and are sold openly in stores as the spores themselves are not illegal. However, production, sale and possession of psilocybin mushrooms is illegal.

Japan

Before 2002, psilocybin mushrooms were widely available in Japan, often sold in mail-order shop, online vendor and "smart shops" similar to those of the Netherlands. In June 2002, Japan Health, Labor and Welfare Ministry added psilocybin mushrooms to Schedule Narcotics (similar to U.S. Schedule I of Controlled Substances Act) of Narcotic and Psychotropic Drug Control Law (similar to U.S. Controlled Substances Act). Use, production, trafficking, growing, possession, botanizing of psilocybin mushrooms is now illegal in Japan. However, muscimol-containing mushrooms such as Amanita muscaria are still not controlled in Japan, probably due to its notorious difficulty in obtaining a psychedelic experience.

New Zealand

In New Zealand, psilocybin mushrooms are class A drugs, putting them in the highest class of illicit compounds along with heroin and LSD. They do not have to be prepared in any way for possession to be illegal.

Republic of Ireland

Until 31 January, 2006, unprepared psilocybin mushrooms were legal in the Republic of Ireland. On that date they were made illegal by a ministerial order. This decision was partly based on the death of well-known Dubliner Colm Hodkinson, age 33, at a Halloween party on 30th October 2005, who died after jumping off of a balcony after consuming legally purchased magic mushrooms.[5]

United Kingdom

As of 18 July 2005, both dried and "prepared" (that is, made into a tea) psilocybin mushrooms were made illegal in the United Kingdom. Prior to this date, fresh mushrooms were widely available (even in city centre shops), but Clause 21 of the Drugs Bill 2005 made fresh psychedelic mushrooms ("fungi containing psilocin"), a Class A drug. However, mushrooms spores are not illegal, due to the fact they do not carry psilocin until they are cultivated.

United States of America

In the United States, possession of psilocybin-containing mushrooms is illegal because they contain the Schedule I drugs psilocin and psilocybin. Spores, however, which do not contain psychoactive chemicals, are only explicitly illegal in California, Idaho, and Georgia. In the state of Florida, fresh or unprepared psilocybin mushrooms that grow wild are legal to possess.

In all states, except possibly New Mexico, growing psilocybin-containing mushrooms from spores is considered manufacture of a controlled substance. In New Mexico, on June 15, 2005, the New Mexico appeals court ruled that growing psilocybin mushrooms for personal use is not manufacture of a controlled substance.[6]

Drug trade

Production

It is not difficult to cultivate Psilocybe mushrooms (esp. Psilocybe cubensis). The legal availability of spores and mycelium varies by country and state. Most of the other supplies needed for mushroom cultivation (mason jars, potting supplements, rye, brown rice flour) are easily obtained. One can also purchase kits through the mail or Internet that include everything one needs for personal growing. These grow kits are often used by amateur growers, with varying rates of success and yields; contamination of the supplies is a common problem.

Trafficking

Because mushrooms can be grown indoors (namely Psilocybe cubensis and Panaeolus cyanescens), they are generally grown within the same national borders as they are sold. There have been few high-profile cases of mushroom producers and traffickers being caught or prosecuted.

While mushrooms may be distributed by organized crime, more often they are moved by informal affiliations of acquaintances and fellow users, and do not often travel long distances. They are sold in plastic bags containing either whole dried or powdered, sometimes crushed, fungi, and are generally sold by weight. They are sometimes incorporated into chocolate or baked into brownies, cakes, or muffins. The typical price for an ounce of dried mushrooms can range from as little as 70$ to 400$ depending on the quality of the product, as well as their availability in the area. The quality of the product is generally about the same, varying only as can be expected with a non-synthetic psychedelics. The major factor in the quality of this drug is how well they have been stored, with well dried whole mushrooms kept in cool dark places being ideal. Contaminated grows yield poor quality, possibly toxic mushrooms. One should be extremely cautious of any mushrooms which have unusual growths or mold, as well as any mushrooms which may have been harvested from the same grow as mushrooms with these growths.

The potency of mushrooms can vary greatly depending on the growing conditions, and buyers of this and any other drug run the risk of ingesting a poisonous, mis-identified species, or being cheated by substitutions or cutting of the mushrooms with other, non-psychedelic varieties, or by non-psychedelic varieties laced with other psychedelics, most often LSD.

Identification

While growing psychedelic mushrooms in a controlled environment is generally considered easier and safer than searching for them in the wild, such mushrooms can be found in places like farms, parks, and stables.

Amanita muscaria

Amanita muscaria can be easily confused by the layperson with Amanita pantherina as well as other toxic Amanitas. Misidentified Amanitas are the cause of 95% of fatal mushroom poisonings. For this reason, extreme caution should be used when attempting to identify an Amanita muscaria for ingestion.

Recreational use of these mushrooms is limited in spite of the fact that they are legal to buy/sell in most areas. Most users only eat the mushrooms once or twice due to their unpleasant side effects and the tendency for a recreational user to try too much causing very harsh side effects. Light doses (1 – 3 grams dried) are described to be similar to alcohol and a very 'social buzz'. Higher doses (9+ grams dried) have been described as having the flu along with delirium usually accompanied with vomiting and stomach discomfort.

Soma

Soma (Sanskrit), or *Haoma* (Avestan), from Proto-Indo-Iranian *sauma-, was a ritual drink of importance among the early Indo-Iranians, and the later Vedic and greater Persian cultures. It is frequently mentioned in the Rigveda, which contains many hymns praising its energizing or intoxicating qualities. In the Avesta, Haoma has an entire Yasht dedicated to it.

It is described as prepared by pressing juice from the stalks of a certain mountain plant, which has been variously hypothesized to be a psychedelic mushroom, cannabis, peganum harmala, or ephedra. In both Vedic and Zoroastrian tradition, the drink is identified with the plant, and also personified as a divinity, the three forming a religious or mythological unity.

Etymology

Both Soma and the Avestan Haoma are derived from Proto-Indo-Iranian *sauma-. The name of the Scythian tribe Hauma-varga is related to the word, and probably connected with the ritual. The word is derived from an Indo-Iranian root *sav- (Sanskrit sav-) "to press", i.e. *sav-ma- is the drink prepared by pressing the stalks of a plant (cf. es-presso). The root is probably Proto-Indo-European (*sewh-), and also appears in son (from *suhnu-, "pressed out" i.e. "newly born").

Vedic Soma

In the Vedas, Soma is portrayed as sacred and as a god (deva). The god, the drink and the plant probably referred to the same entity, or at least the differentiation was ambiguous. In this aspect, Soma is similar to the Greek ambrosia (cognate to amrita); it is what the gods drink, and what made them deities. Indra and Agni are portrayed as consuming Soma in copious quantities. In vedic mythology, the eagle Aquila brought soma to Indra during her battle with the serpent Hydra. The consumption of Soma by human beings was probably under the belief that it bestowed divine qualities on them.

In the Rigveda

The Rigveda (8.48.3, tr. Griffith) states,

a ápma sómam amUt abhkmâganma jyótir ávidma devân c kíC nknám asmân k[Gavad árti% kím u dhkrtír am[ta mártyasya We have drunk Soma and become immortal; we have attained the light, the Gods discovered. Now what may foeman's malice do to harm us? What, O Immortal, mortal man's deception?

The Ninth Mandala of the Rigveda is known as the *Soma Mandala*. It consists entirely of hymns addressed to *Soma Pavamana* ("purified Soma"). The drink Soma was kept and distributed by the Gandharvas. The Rigveda associates the Sushoma, Arjikiya and other regions with Soma (e.g. 8.7.29; 8.64.10-11). Sharyanavat was possibly the name of a pond or lake on the banks of which Soma could be found.

The plant is described as growing in the mountains (giristha, cf. Orestes), with long stalks, and of yellow or tawny (hari) colour. The drink is prepared by priests pounding the stalks with stones, an occupation that creates tapas (literally "heat", later referring to "spiritual excitement" in particular). The juice so gathered is mixed with other ingredients (including milk and honey) before it is drunk.

Growing far away, in the mountains, Soma had to be purchased from travelling traders. The plant supposedly grew in the Hindukush and thus it had to be imported to the Punjab region. Later, knowledge of the plant was lost altogether, and Indian ritual reflects this, in expiatory prayers apologizing to the gods for the use of a substitute plant (e.g. rhubarb) because Soma had become unavailable.

In Hinduism

In Hindu art, the god Soma was depicted as a bull or bird, and sometimes as an embryo, but rarely as an adult human. In Hinduism, the god Soma evolved into a lunar deity, and became associated with the underworld. The moon is the cup from which the gods drink Soma, and so Soma became identified with the moon god Chandra. A waxing moon meant Soma was recreating himself, ready to be drunk again. Alternatively, Soma's twenty-seven wives were daughters of Daksha, who felt he paid too much attention to just one of his wives,

Rohini. He cursed him to wither and die, but the wives intervened and the death became periodic and temporary, and is symbolized by the waxing and waning of the moon.

The famous ayurvedic scholar Susruta wrote that the best Soma is found in the upper Indus and Kashmir region (Susruta Samhita: 537-538, SS.CS. 29.28-31).

Avestan Haoma

The continuing importance of Haoma in Zoroastrianism may be glimpsed from the Avesta (particularly in the HMm Yast, Yasna 9.11), and Avestan language *hauma also survived as middle Persian hMm. The plant Haoma yielded the essential ingredient for the ritual drink, parahaoma.

In the HMm yašt of the Avesta, the Yazata (divine) Haoma appears to Zoroaster "at the time of pressing" (havani ratu) in the form of a beautiful man. Yasna 9.1 and 9.2 exhort him to gather and press Haoma plants. Haoma's epitheta include "the Golden-Green One" (zairi-, Sanskrit hari-), "righteous" (ašavan-), "furthering righteousness" (aša-vazah-), and "of good wisdom" (hu.xratu-, Sanskrit sukratu-).

In Yasna 9.22, Haoma grants "speed and strength to warriors, excellent and righteous sons to those giving birth, spiritual power and knowledge to those who apply themselves to the study of the nasks". As the religion's chief cult divinity he came to be perceived as its divine priest. In Yasna 9.26, Ahura Mazda is said to have invested him with the sacred girdle, and in Yasna 10.89, to have installed Haoma as the "swiftly sacrificing zaotar" (Sanskrit hotar) for himself and the Amesha Spenta. Haoma services were celebrated until the 1960s in a strongly conservative village near Yazd.

Candidates for the Soma plant

There has been much speculation as to the original Proto-Indo-Iranian Sauma plant. It was generally assumed to be hallucinogenic, based on RV 8.48 cited above. But note that this is the only evidence of hallucinogenic properties, in a book full of hymns to Soma. The typical description of Soma is associated with excitation and tapas. Soma is associated with the warrior-god Indra, and appears to have been drunk before battle. For these reasons, there are energizing plants as well as hallucinogenic plants among the candidates that have been suggested. Including the mushroom amanita muscaria, which was widely used as a brew of sorts among Siberian shamans for its hallucinogenic and 'religious experience' inducing properties. In fact, several texts like the Atharva Veda extol the medicinal properties of Soma and he is regarded as the king of medicinal herbs (and also of the Brahmana class).

Since the late 1700s, when Anquetil-Duperron and others made portions of the Avesta available to western scholarship, several scholars have sought a representative botanical equivalent of the haoma as described in the texts and as used in living Zoroastrian practice. Most of the proposals concentrated on either linguistic evidence or comparative pharmacology or reflected ritual use. Rarely were all three considered together, which usually resulted in such proposals being quickly rejected.

In the late 19th century, the highly conservative Zoroastrians of Yazd (Iran) were found to use Ephedra (genus Ephedra), which was locally known as hum or homa and which they exported to the Indian Zoroastrians. (Aitchison, 1888) The plant, as Falk also established,

requires a cool and dry climate, i.e. it does not grow in India (which is either too hot or too humid or both) but thrives in central Asia. Later, it was discovered that a number of Iranian languages and Persian dialects have hom or similar terms as the local name for some variant of Ephedra. Considered together, the linguistic and ritual evidence appeared to conclusively establish that haoma was some variant of Ephedra.

In Western Culture

- Soma is mentioned in the well-known Christian hymn "Dear Lord and Father of Mankind", by the American Quaker poet, John Whittier (1807-1892) who saw the drinking of soma as causing a distraction of the mind from the proper worship of God. Verse four of the original is usually omitted, but includes the phrase, "In sensual transports - wild as vain, we brew in many a Christian fane the heathen soma still..."
- In Aldous Huxley's dystopian novel Brave New World, Soma is a popular hallucinogenic drug which is sometimes used in a pseudo-religious capacity.
- In Blake's 7, Soma is used as a tranquiliser and sedative. Frequently imbibed as a green liquid, Soma is used as a social drug almost like alcohol.

Coca

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Malpighiales
Family: Erythroxylaceae
Genus: Erythroxylum
Species: *E. coca*
Binomial name *Erythroxylum coca*

Coca is a plant in the family Erythroxylaceae, native to northwestern South America. The plant plays a significant role in traditional Andean culture, but is best-known in modern times for the stimulant drug cocaine that is extracted from its new fresh leaf tips in a similar fashion to tea bush harvesting.

The plant resembles a blackthorn bush, and grows to a height of 2-3 m (7-10 ft). The branches are straight, and the leaves, which have a green tint, are thin, opaque, oval, more or less tapering at the extremities. A marked characteristic of the leaf is an areolated portion bounded by two longitudinal curved lines, one line on each side of the midrib, and more conspicuous on the under face of the leaf.

The flowers are small, and disposed in little clusters on short stalks; the corolla is composed of five yellowish-white petals, the anthers are heart-shaped, and the pistil consists of three carpels united to form a three-chambered ovary. The flowers mature into red berries.

The leaves are sometimes eaten by the maggots of the moth Eloria noyesi.

Species and classification

There are twelve main species and varieties (Erythroxylum coca). Two subspecies, E. coca var. coca and E. coca var. ipadu, are almost indistinguishable phenotypically; a related high cocaine-bearing species has two subspecies, E. novogranatense var. novogranatense and E. novogranatense var. truxillense that are phenotypically similar, but morphologically distinguishable. Under the older Cronquist system of classifying flowering plants, this was placed in an order Linales; more modern systems place it in the order Malpighiales.

Cultivation and uses

Coca is traditionally cultivated in the lower altitudes of the eastern slopes of the Andes, or the highlands depending on the species grown. Since ancient times, its leaves have been used as a stimulant by some of the indigenous people of Venezuela, Colombia, Ecuador, Peru, Bolivia, Brazil, northern Argentina, and Trinidad. In the highlands, it is used as a breathing aid. It also has religious and symbolic significance. Since the 1980s, the cultivation of coca has become controversial because it is used for the manufacture of the drug cocaine, which is illegal in most countries for recreational use, but legal for medical uses, e.g., nose and throat anaesthesia.

Good fresh samples of the dried leaves are uncurled, are of a deep green on the upper, and a grey-green on the lower surface, and have a strong tea-like odor; when chewed they produce a faint numbness in the mouth, and have a pleasant, pungent taste. They are traditionally chewed with lime to increase the release of cocaine from the leaf. Bad specimens, usually old or stale leaves, have a camphoraceous smell and a brownish colour, and lack the pungent taste.

The seeds are sown from December to January in small plots (almacigas) sheltered from the sun, and the young plants when at 40-60 cm in height are placed in final planting holes (aspi), or, if the ground is level, in furrows (uachos) in carefully weeded soil. The plants thrive best in hot, damp and humid situations, such as the clearings of forests; but the leaves most preferred are obtained in drier localities, on the sides of hills. The leaves are gathered from plants varying in age from one and a half to upwards of forty years, but only the new fresh growth is harvested. They are considered ready for plucking when they break on being bent. The first and most abundant harvest is in March, after the rains; the second is at the end of June, the third in October or November. The green leaves (matu) are spread in thin layers on coarse woollen cloths and dried in the sun; they are then packed in sacks, which must be kept dry in order to preserve the quality of the leaves.

Pharmacological aspects

The pharmacologically active ingredient of coca is the alkaloid cocaine which is found in the amount of about 0.2% in fresh leaves. Besides cocaine, the coca leaf contains a number of other alkaloids, including Methylecgonine cinnamate, Benzoylecgonine, Truxilline, Hydroxytropacocaine, Tropacocaine, Ecgonine, Cuscohygrine, Dihydrocuscohygrine, Nicotine and Hygrine. Some of these non-psychoactive chemicals are still used for the flavouring of Coca-Cola. When chewed, Coca acts as a stimulant to help suppress hunger sensations, thirst, and fatigue. Some anesthetics such as Novocaine are derived from the coca plant. The LD50 of coca extract is 3450 mg/kg, however, the LD50 of the extract based on its cocaine content is 31.4 mg/kg, indicating that the coca leaf contains constituents other than cocaine that may contribute to a toxic effect of the plant

Traditional uses

In the Andes, the indigenous peoples have been chewing the leaves of the coca plant for millennia. They traditionally carried a woven pouch called a chuspa or huallqui in which they kept a day's supply of coca leaves, along with a small amount of ilucta or uipta, which is made from pulverized unslaked lime or from the ashes of the quinoa plant. A tiny quantity of ilucta is chewed together with the coca leaves; it softens their astringent flavor and activates the alkaloids. Other names for this basifying substance are llipta in Peru and the Spanish word lejía, lye in English. Many of these materials are salty in flavor, but there are variations. The most common base in the La Paz area of Bolivia is a product known as lejía dulce (sweet lye) which is made from quinoa ashes mixed with anise and cane sugar, forming a soft black putty with a sweet and pleasing licorice flavor. In some places, baking soda is used under the name bico.

The practice of chewing coca was most likely originally a simple matter of survival. The coca leaf contained many essential nutrients in addition to its more well-known mood-altering alkaloid. It is rich in protein and vitamins, and it grows in regions where other food sources are scarce. The perceived boost in energy and strength provided by the cocaine in coca leaves was also very functional in an area where oxygen is scarce and extensive walking is essential. This was also used to fool the feeling of hunger, sleepiness and head-aches linked to altitude and other altitude sicknesses. The coca plant was so central to the worldview of the Yunga and Aymara tribes of South America that distance was often measured in units called "cocada", which signified the number of mouthfuls of coca that one would chew while walking from one point to another. Cocada can also be used as a measurement of time, meaning the amount of time it takes for a mouthful of coca to lose its flavor and activity. In testament of the significance of coca to indigenous cultures, it is widely believed that the word "coca" probably originally meant "plant."

Coca was also a vital part of the religious cosmology of the Andean tribes in the pre-Inca period as well as throughout the Inca Empire (Tahuantinsuyu). Coca was historically employed as an offering to the Sun, or to produce smoke at the great sacrifices; and the priests, it was believed, must chew it during the performance of religious ceremonies, otherwise the gods would not be appeased. Coca is still held in veneration among the indigenous and mestizo peoples of Peru, Bolivia, Ecuador, Colombia and northern Argentina and Chile. It is believed by the miners of Cerro de Pasco to soften the veins of ore, if masticated (chewed) and thrown upon them (see also Cocomama). Coca leaves play a crucial part in offerings to the apus (mountains), Inti (the sun), or Pachamama (the earth). Coca leaves are often read in a form of divination analogous to reading tea leaves in other cultures.

In the Sierra Nevada de Santa Marta, on the Caribbean Coast of Colombia, coca is consumed by the Kogi, Arhuaco & Wiwa by using a special gadget called poporo. The poporo is the mark of manhood, but it is a female's sexual symbol. It represents the womb and the stick is a phallic symbol. The movements of the stick in the poporo symbolize the sexual act. For a man the poporo is a good companion which means "food" "woman", "memory" and "meditation". Women are prohibited from using coca. It is important to stress that poporo is the symbol of manhood. But it is the woman who gives men their manhood. When the boy is

ready to be married, his mother will initiate him in the use of the coca. This act of initiation is carefully supervised by the mama, a traditional leader.

The activity of chewing coca is called mambear, chacchar or acullicar, borrowed from Quechua, or in Bolivia, picchar, derived from the Aymara language. The Spanish masticar is also frequently used. Doing so usually causes users to feel a tingling and numbing sensation in their mouths, similar to receiving Novocaine during a dental procedure. Even today, chewing coca leaves is a common sight in indigenous communities across the central Andean region, particularly in places like the mountains of Bolivia, where the cultivation and consumption of coca is as much a part of the national culture similar to chicha, like wine is to France or beer is to Germany. It also serves as a powerful symbol of indigenous cultural and religious identity, amongst a diversity of indigenous nations throughout South America. Bags of coca leaves are sold in local markets and by street vendors. Commercially manufactured coca teas are also available in most stores and supermarkets, including upscale suburban supermarkets.

Mate de coca, sometimes called "coca tea", is a tisane made from the leaves of the Coca plant (Eritroxilécea). The consumption of coca tea is a common occurrence in many South American countries. Coca tea is also used for medicinal and religious purposes by many indigenous tribes in the Andes. On the "Inca Trail" to Macchu Picchu, guides also serve coca tea with every meal because it is widely believed that it alleviates the symptoms of mild altitude sickness. And traditionally, official governmental persons travelling to La Paz in Bolivia are greeted by a mate de coca. News reports noted that Princess Anne and the late Pope John Paul II drank the beverage during visits to the region.

International use

Coca has a long history of export and use around the world—legal and illegal. Modern export of processed coca (as cocaine) to global markets is well documented, and coca leaves are exported for coca tea, flavoring (Coca-Cola), and for medical use. Several pipes taken from Shakespeare's residence and dated to the seventeenth century have shown evidence of cocaine, Queen Victoria of England was also a cocaine user; the drug was first introduced to Europe in the 16th century.

Industrial use

Coca is used industrially in the cosmetics and food industries. The Coca-Cola Company used to buy 115 tons of coca leaf from Peru and 105 tons from Bolivia per year, which it has used as a flavouring ingredient in its Coca-Cola formula. Coca is sold to the pharmaceutical industry where it is used for various anaesthetics. Coca is used to produce Coca Tea by Enaco S.A. (National Company of the Coca) a government enterprise in Peru. In Colombia, the Paeces, a Tierradentro (Cauca) indigenous community, started in December 2005 to produce a drink called "Coca Sek." The production method belongs to the resguardos of Calderas (Inzá) and takes about 150 kg of coca per 3000 produced bottles.

Legality

International

Article 26 of the Single Convention on Narcotic Drugs states:

1. If a Party permits the cultivation of the coca bush, it shall apply thereto and to coca leaves the system of controls as provided in article 23 respecting the control of the opium poppy, but as regards paragraph 2 (d) of that article, the requirements imposed on the Agency therein referred to shall be only to take physical possession of the crops as soon as possible after the end of the harvest. 2. The Parties shall so far as possible enforce the uprooting of all coca bushes which grow wild. They shall destroy the coca bushes if illegally cultivated.

The Article 23 controls referred to in paragraph 1 are rules requiring opium-, coca-, and cannabis-cultivating nations to designate an agency to regulate said cultivation and take physical possession of the crops as soon as possible after harvest. Article 27 states that "The Parties may permit the use of coca leaves for the preparation of a flavouring agent, which shall not contain any alkaloids, and, to the extent necessary for such use, may permit the production, import, export, trade in and possession of such leaves". This provision is designed to accommodate Coca-Cola and other producers of coca products.

In Bolivia, the president Evo Morales (elected in December, 2005), a former coca growers union leader, has promised to legalize the cultivation and traditional use of coca. Morales asserts that "coca no es cocaína"--the coca leaf is not cocaine. During his speech on 19 September 2006, he held a coca leaf in his hand to demonstrate its innocuity.[3]

In Peru, private companies already manufacture coca leaf products.

More recently, coca has been reintroduced to the U.S. as a flavoring agent in the herbal liquer Agwa.

Cocoa

Cocoa is the dried and partially fermented fatty seed of the cacao tree from which chocolate is made. In the United States, 'cocoa' often refers to cocoa powder, the dry powder made by grinding cocoa seeds and removing the cocoa butter from the dark, bitter cocoa solids. Cocoa powder has an extremely bitter flavor.

A cocoa pod has a rough leathery rind about 3 cm thick (this varies with the origin of pod). It is filled with sweet, mucilaginous pulp called 'baba de cacao' in South America,

enclosing 30 to 50 large almond-like seeds (beans) that are fairly soft and pinkish or purplish in color.

History

The cacao tree apparently originated in the foothills of the Andes in the Amazon and Orinoco basins of South America. It was introduced into Central America by the ancient Mayas, and cultivated in Mexico by the Toltecs and later by the Aztecs.

Cocoa trees will grow in a very limited geographical zone, of approximately 10 degrees to the north and south of the Equator. Nearly 70% of the world crop is grown in West Africa.

Cocoa was an important commodity in Pre-Columbian Mesoamerica. Spanish chroniclers of the conquest of Mexico by Hernán Cortés relate that when Moctezuma II, emperor of the Aztecs, dined he took no other beverage than chocolate, served in a golden goblet and eaten with a golden spoon. Flavored with vanilla and spices, his chocolate was whipped into a froth that dissolved in the mouth. No less than 50 pitchers of it were prepared for the emperor each day, and 2000 more for nobles of his court.

Chocolate was introduced to Europe by the Spaniards and became a popular beverage by the mid 1500s. They also introduced the cacao tree into the West Indies and the Philippines. It was used in alchemical processes, where it was known as Black Bean.

The cacao plant was first given its name by Swedish natural scientist Carl von Linné (1707-1778), who called it "Theobroma cacao" or "food of the gods".

Source: UN Food & Agriculture Organisation (FAO)[1]

About 3,000,000 tonnes of cocoa are grown each year. The global production was 1,556,484 t in 1974, 1,810,611 t in 1984, 2,672,173 t in 1994, 3,607,052 t in 2004 (record).

This is an increase of 131.7% in 30 years.

There are three varieties of the Theobroma cacao: Forastero, Criollo and Trinitario. The first comprises 95% of the world production of cacao, and is the most widely used. Overall, the highest quality of cacao comes from the Criollo variety and is considered a delicacy; however, Criollo is harder to produce, hence very few countries produce it, with the majority of production coming from Venezuela (Chuao and Porcelana). The Trinitario is a mix between Criollo and Forastero.

The Netherlands is the leading cocoa processing country, followed by the U.S..

Prices for cocoa reached a five-year high in November 2004 because exports from Côte d'Ivoire (Ivory Coast) were likely to decrease due to escalating violence in the region.

Cocoa and its products (including chocolate) are used world-wide. Belgium has the highest per-capita consumption at 5.5 kg, 10 times the world average [2].

Harvesting

When the pods ripen, they are harvested from the trunks and branches of the Cocoa tree with a curved knife on a long pole. The pod itself is green when ready to harvest, rather than red or orange. Normally, red or orange pods are considered of a lesser quality because their flavors and aromas are poorer; these are used for industrial chocolate. The pods are either opened on the field and the seeds extracted and carried to the fermentation area on the plantation, or the whole pods are taken to the fermentation area.

Processing

The harvested pods are opened with a machete, the pulp and cocoa seeds are removed and the rind is discarded. The pulp and seeds are then piled in heaps, placed in bins, or laid out on grates for several days. During this time, the seeds and pulp undergo "sweating", where the thick pulp liquifies as it ferments. The fermented pulp trickles away, leaving cocoa seeds behind to be collected. Sweating is important for the quality of the beans, which originally have a strong bitter taste. If sweating is overdone, the resulting cocoa may be ruined; if underdone the cocoa seed maintains a flavor similar to raw potatoes and becomes susceptible to mildew.

The liquified pulp is used by some cocoa producing countries to distill alcoholic spirits.

The fermented beans are dried by spreading them out over a large surface and constantly raking them. In large plantations, this is done on huge trays under the sun or by using artificial heat. Small plantations may dry their harvest on little trays or on cowhides. Finally, the beans are trodden and shuffled about (often using bare human feet) and sometimes, during this process, red clay mixed with water is sprinkled over the beans to obtain a finer color, polish, and protection against molds during shipment to factories in the United States,

the Netherlands, United Kingdom, and other countries. Drying in the sun is preferable to drying by artificial means, as no foreign flavours such as smoke or oil are introduced which might otherwise taint the flavour.

Chocolate production

To make 1 kg (2.2 pounds) of chocolate, about 300 to 600 beans are processed. In a factory, the beans are washed and roasted. Next they are de-hulled by a "nibber" machine that also removes the germ. The nibs are ground between three sets of stones into a thick creamy paste. This "liquor" is converted to cocoa powder by removing part of its fatty oils (the "cocoa butter") using a hydraulic press or the Broma process. This process produces around 50% cocoa butter and 50% cocoa powder. Standard cocoa powder has a fat content of approximately 10-12 percent. The extracted fatty oils are used in confectionery, soaps, and cosmetics.

Adding an alkali produces Dutch process cocoa powder, which is less acidic, darker and more mellow in flavour than what is generally available in most of the world. Regular (nonalkalized) cocoa is acidic, so when added to an alkaline ingredient like baking soda, the two react and leave a byproduct.

Uses of cocoa

The uses of cocoa beans are numerous. Chocolate or cocoa powder is mixed into cakes, ice creams, creams, cookies, or drinks as a natural flavour. It is the second most popular ice cream flavor, after vanilla. Sometimes it is merely used as a natural coloring agent for food, such as pasta.

One of the most common forms of cocoa is the chocolate or candy bar. It is also available in chocolate syrup, used as an ice cream topping or to make chocolate milk.

Cocoa has about twice as many antioxidants as does red wine, and up to three times more than green tea. Antioxidants are thought to be healthy compounds. Several chocolate manufacturers are beginning to offer chocolate products with guaranteed levels of these antioxidants, called polyphenols. The high antioxidant level in cocoa gives dark chocolate an ORAC value of 13,120 and milk chocolate an ORAC value of 6,740. [3] A 15-year study of elderly men published in the Archives of Internal Medicine in 2006 found a 50 percent reduction in cardiovascular mortality and a 47 percent reduction in all-cause mortality for the men regularly consuming the most cocoa, compared to those consuming the least cocoa from all sources.

Issues with cocoa as a commodity

- Sustainable cocoa farming encourages the economic, social and environmental conditions necessary to improve the livelihoods of small scale cocoa farmers in the tropics. The World Cocoa Foundationis working with private and public sector partners to support this effort.

- Many cocoa farmers receive a low price for their production. This has led to cocoa and chocolate being available as 'fair trade' items in some countries. However, this fair trade remains as a tiny percentage of the total trade.
- Child slavery has commonly been used in its production to cover the lower profit margin. According to the U.S. Department of State, more than 109,000 children were working on cocoa farms in Côte d'Ivoire in 'the worst forms of child labor' in 2002.[3] See Cocoa Protocol for an effort to end this practice.
- Pollination is exclusively by midges, which may be affected by pesticides.

Cocoa Trading

Cocoa beans, Cocoa butter and cocoa powder are traded on two world exchanges: London and New York. The London market is based on West African cocoa and New York on cocoa predominantly from South East Asia. Cocoa is the world's smallest soft commodity market. The futures price of cocoa butter and cocoa powder is determined by multiplying the bean price by a ratio. The combined butter and powder ratio has tended to be around 3.5. If the combined ratio falls below around 3.2, production ceases to be economically viable and some factories cease extraction of butter and powder and trade exclusively in cocoa liquor.

Coffea

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Gentianales

Family: Rubiaceae
Genus: *Coffea*

Species

Coffea arabica - Arabica Coffee
Coffea benghalensis - Bengal coffee
Coffea canephora - Robusta coffee
Coffea congensis - Congo coffee
Coffea excelsa - Liberian coffee
Coffea gallienii
Coffea bonnieri
Coffea mogeneti
Coffea liberica - Liberian coffee
Coffea stenophylla - Sierra Leonian coffee

Coffea (*coffee*) is a genus of ten species of flowering plants in the family Rubiaceae. They are shrubs or small trees, native to subtropical Africa and southern Asia. Seeds of this plant are the source of a stimulating beverage called coffee. The seeds are called "beans" in the trade. Coffee beans are widely cultivated in tropical countries in plantations for both local consumption and export to temperate countries. Coffee ranks as one of the world's major commodity crops and is the major export product of some countries. In fact, coffee ranks second only to petroleum in terms of legally-traded products worldwide.

Botany

When grown in the tropics coffee is a vigorous bush or small tree easily grown to a height of 3–3.5 m (10–12 feet). It is capable of withstanding severe pruning. It cannot be grown where there is a winter frost. Bushes grow best at high elevations. To produce a maximum yield of coffee berries (800-1400 kg per hectare), the plants need substantial amounts of water and fertilizer. Calcium carbonate and other lime minerals is sometimes used to reduce acidity in the soil, which can occur due to run off of minerals from the soil in mountainous areas.**[1]**

There are several species of Coffea that may be grown for the beans, but Coffea arabica is considered to have the best quality. The other species (especially Coffea canephora (robusta)) are grown on land unsuitable for Coffea arabica. The tree produces red or purple fruits (drupes, or "coffee berries"), which contain two seeds (the "coffee beans", although not true beans). In about 5-10% of any crop of coffee cherries, the cherry will contain only a single bean, rather than the two usually found. This is called a 'peaberry' and contains a distinctly different flavor profile to the normal crop, with a higher concentration of the flavors, especially acidity, present due to the smaller sized bean. As such, it is usually removed from the yield and either sold separately (such as in New Guinea Peaberry), or discarded.

The coffee tree will grow fruits after 3–5 years, for about 50–60 years (although up to 100 years is possible). The blossom of the coffee tree is similar to jasmine in color and smell.

The fruit takes about nine months to ripen. Worldwide, an estimate of 15 billion coffee trees are growing on 100,000 km^2 of land.

Coffee is used as a food plant by the larvae of some Lepidoptera species including Dalcera abrasa, Turnip Moth and some members of the genus Endoclita including E. damor and E. malabaricus.

Processing

After picking, the coffee beans are pulped (usually using a mechanical pulper) to remove the bulk of the soft flesh, and then the beans are fermented (by one of several means, most often wet fermentation in water for 10 to 36 hours), then washed (to remove the last of the sticky mucilage not removed by fermentation) and dried (usually in the sun). This process is time-consuming, expensive and, for most growers, labour-intensive. Coffee at this stage is known as *milled beans*.

Once the raw ('green') coffee beans arrive in their destination country, they are roasted; this darkens their color and alters the internal chemistry of the beans and therefore their flavor and aroma. Blending can occur before or after roasting and is often performed to ensure a consistent flavor. Once the beans are roasted, they become much more perishable.

Problems of maintaining quality during bean production

Achieving consistently excellent milled beans is not easy. Problems include:

- Pests on the bushes (e.g., in Hawaii, scale insects and coconut mealy bugs)
- Poor pruning regimes (e.g., too many verticals that allow the bush to attempt too much and so produce inferior cherries)
- Poor fertiliser regimes (e.g., too little iron or insufficient nutriment for what are demanding plants)
- Bad picking (e.g., picking all the berries on a branch rather than those that are bright red, or picking the berries very late)
- Bad fermentation that produces unpleasant taints in the flavor
- Dilution of superior tasting beans with cheaper beans

The coffee bushes fruit aggressively when conditions permit, and the berries will develop at the expense of the rest of the bush. This consumes sugars in the leaves and can produce die-back (death of leaves and branches). Die-back can be severe and can damage not just the current year's production but the next year's production, which is borne on growth during the current year, leading into a two-year cycle of growth and production.

Commercial operators come under a variety of pressures to cut costs and maximise yield. Arguably the best flavours will be produced when the coffee is grown in organic conditions. Some people who grow organically do so primarily to obtain the premium prices organic beans command, an alternative strategy to increase profits.

The economics of growing coffee

It is very questionable whether small growers can generate a high return on capital growing coffee if they have less than 1.2 ha (3 acres or 12,000 m^2) and if they are based in the United States. The retail price of the beans varies between about 1 USD/pound for ripe berries to 9 USD/pound for extra fancy Kona milled beans, and there are many costs including fertiliser, irrigation, labour (e.g. picking and pruning) and land value. Integrated operations that capture much or all of the available revenue (by controlling the whole process from growing to retail) may generate higher returns.

It is estimated that 10 million people are working on plantations in the source lands of coffee. A single worker can harvest 50–100 kg of fruits per day, which results in 10–20 kg of raw coffee. Crops from Brazil (30%) and Colombia (10%) comprise 40% of the worldwide coffee production. As of 1998, the world's coffee production equals about 100 million sacks of coffee.

Many farmers receive a low price for their coffee because of a global market slump. This has led to coffee being available as a 'fair trade' labelled item in many countries.

Hand picked coffee

The highest quality coffee is generally hand picked. Normally, coffee growers harvest their coffee with portable vacuum packs, which the pickers wear on their backs and brush over the branches of the coffee bushes. Although it is much more efficient and quick to harvest the coffee with the vacuum packs, coffee beans do not become ripe at the same time, even if they are on the same tree, and thus many unripe beans are sucked away by the vacuum packs. Also, coffee pickers are sure to pick beans only of the highest quality. As a general rule, hand picked coffee is used for drip machines, while vacuum picked coffee is used to make instant coffee and decaffeinated coffee.

History

Coffee probably originated in the Kingdom of Kaffa (now part of the Southern Nations, Nationalities, and Peoples Region of Ethiopia), though there is controversy about its origins, with Yemen also suggested as an area of origin. One apocryphal tale claims that an Ethiopian goat-herder noticed his goats prancing about energetically, and found they were eating coffee berries, and tried some himself.

The crop first became popular in Arabia around the 13th century, and Islam's prohibition against alcoholic beverages probably enhanced its popularity. Before 1600, coffee production was a jealously guarded secret, and fertile beans were not found outside Arabia. Many consider the German botanist Leonhard Rauwolf to have first described coffee in a book published in 1583. Sometime after 1600, coffee trees were grown in India, possibly due to smuggling of fertile beans. Around 1650, coffee importation into England began and coffeehouses opened in Oxford and London. Coffee planting began in the English colonies, but a disease wiped out the plantations, leading the English to re-plant with tea instead.

By the 18th century, the beverage had become popular in Europe, and European colonists had introduced coffee to tropical countries worldwide as a plantation crop to supply domestic demand. At the end of the 19th century, plantations in Brazil alone were producing

over 80% of the world's coffee crop. At the same time, European demand for coffee was so strong that when genuine coffee beans were scarce, people developed similar-tasting substitutes from various roasted vegetable substances, such as chicory root, dandelion root, acorns, or figs. For example, the British used acorns as a coffee substitute during World War II when German U-boats blockaded Britain.

The major coffee-producing countries are Brazil, Colombia, Vietnam, Indonesia, Costa Rica, Mexico, India, and Puerto Rico but coffee is grown in over 70 countries (2003 USDA and ICO data). Major importers are United States, Germany, Japan, France, Italy, and Spain (2002 USDA data), and per-capita consumers of coffee are Finland (11 kg), Denmark (9.7 kg), Norway (9.5 kg), Sweden (8.6 kg), and Austria (7.8 kg). The United States, while the largest importing country, only ranks 16th (4.1 kg) in per-capita consumption (2001 USDA data).

Khat

Conservation status: Least concern (LR/lc)

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Celastrales
Family: Celastraceae
Genus: *Catha*
Species: *C. edulis*

Binomial name *Catha edulis (Vahl) Forssk. ex Endl.*

Khat (Catha edulis, family Celastraceae, Ge'ez +u #t; Arabic B-7), pronounced "cot" and also known as *qat*, *gat*, *chat*, and *miraa*, is a flowering plant native to tropical East Africa. Believed to originate in Ethiopia, it is a shrub or small tree growing to 5–8 m tall, with evergreen leaves 5–10 cm long and 1–4 cm broad. The flowers are produced on short axillary cymes 4–8 cm long, each flower small, with five white petals. The fruit is an oblong three-valved capsule containing 1–3 seeds.

Cultivation and uses

Khat has been grown for use as a stimulant for centuries in the Horn of Africa and the Arabian Peninsula. There, chewing khat predates the use of coffee and is used in a similar social context. Its fresh leaves and tops are chewed or, less frequently, dried and consumed as tea, in order to achieve a state of euphoria and stimulation. Due to the availability of rapid, inexpensive air transportation, the drug has been reported in England, Rome, Amsterdam, Canada, Australia and the United States. The public has become more aware of this exotic drug through media reports pertaining to the United Nations mission in Somalia, where khat

use is endemic, and its role in the Persian Gulf. The khat plant is known by a variety of names, such as qat in Yemen, chat in Ethiopia, jaad in Somalia and miraa in Kenya.

Khat use has traditionally been confined to the regions where khat is grown, because only the fresh leaves have the desired stimulating effects. In recent years improved roads, off-road motor vehicles and air transport have increased the global distribution of this perishable commodity. Traditionally, khat has been used as a socializing drug, and this is still very much the case in Yemen where khat-chewing is a predominantly male habit. In other countries, khat is consumed largely by single individuals and at parties. It is mainly a recreational drug in the countries which grow khat, though it may also be used by farmers and laborers for reducing physical fatigue and by drivers and students for improving attention. This is similar to the use of the coca leaf in South America.

Khat is used for its mild euphoric and stimulating effects. Because of its anorectic effects, it is often used by Muslims in Ethiopia to aid in fasting. Today it is also used by Christians though the Ethiopian Orthodox Tewahedo Church (along with its Eritrean counterpart) has forbidden Christians from using it due to its stimulating effects.

The Supreme Islamic Courts Council, which took control of much of the country in 2006, banned khat during Ramadan, sparking street protests in Kismayo. In November 2006, Kenya banned all flights to Somalia, citing security concerns, prompting protests by Kenyan chat growers. The Kenyan MP from Ntonyiri, Meru District stated that local land had been specialized in khat cultivation, that 20 tons worth US$800,000 were shipped to Somalia daily and that a flight ban could devastate the local economy.[1]

Chemistry/pharmacology

The stimulant effect of the plant was originally attributed to cathine, a phenethylamine-type substance isolated from the plant. However, the attribution was disputed by reports showing the plant extracts from fresh leaves contained another substance more behaviorally active than cathine. In 1975, the related alkaloid cathinone was isolated, and its absolute configuration was established in 1978. Cathinone is not very stable and breaks down to produce cathine and norephedrine. These chemicals belong to the PPA (phenylpropanolamine) family, a subset of the phenethylamines related to amphetamines and the catecholamines epinephrine and norepinephrine.

Khat consumption induces mild euphoria and excitement. Individuals become very talkative under the influence of the drug and may appear to be unrealistic and emotionally unstable. Khat can induce manic behaviors and hyperactivity. Several cases of khat-induced psychosis have been reported in the literature. Khat is an effective anorectic and its use also results in constipation. Dilated pupils (mydriasis), which are prominent during khat consumption, reflect the sympathomimetic effects of the drug, which are also reflected in increased heart rate and blood pressure. A state of drowsy hallucinations (hypnagogic hallucinations) may result coming down from khat use as well. Withdrawal symptoms that may follow prolonged khat use include lethargy, mild depression, nightmares, and slight tremor. Long term use can precipitate the following effects: negative impact on liver function, permanent tooth darkening (of a greenish tinge), susceptibility to ulcers, and diminished sex drive. Khat is usually not a addictive drug, although there are some people

who can not stay with out it for more then 4-5 days, feeling tired and having difficulty concentrating.

User population

It is estimated that several million people are frequent users of khat. Many of the users originate from countries between Sudan and Madagascar and in the southwestern part of the Arabian Peninsula, especially Yemen. In Yemen, 60% of the males and 35% of the females were found to be khat users who had chewed daily for long periods of their life. The traditional form of khat chewing in Yemen involves only male users; khat chewing by females is less formal and less frequent. In Saudi Arabia, the cultivation and consumption of khat are forbidden, and the ban is strictly enforced. The ban on khat is further supported by the clergy on the grounds that the Qur'an forbids anything that is harmful to the body. This is in sharp contrast to the opinions of the clergy in Yemen. In Somalia, 61% of the population reported that they do use khat, 18% report habitual use, and 21% are occasional users.

UK

Khat is used by members of the Somali and Yemeni community (mainly men), which is concentrated in London, Birmingham, Bristol, Cardiff, Manchester and Sheffield. It is currently legal in the UK although there are calls from some sections of the Somali community for it to be banned.

Control status

In 1965, the World Health Organization Expert Committee on Dependence-producing Drugs' Fourteenth Report noted, "The Committee was pleased to note the resolution of the Economic and Social Council with respect to khat, confirming the view that the abuse of this substance is a regional problem and may best be controlled at that level". For this reason, khat was not Scheduled under the Single Convention on Narcotic Drugs. In 1980 the World Health Organization classified khat as a drug of abuse that can produce mild to moderate psychic dependence.

Cathine is in Schedule IV and cathinone is in Schedule I of the U.S. Controlled Substance Act. The 1993 DEA rule placing cathinone in Schedule I noted that it was effectively also banning khat:

> Cathinone is the major psychoactive component of the plant Catha edulis (khat). The young leaves of khat are chewed for a stimulant effect. Enactment of this rule results in the placement of any material which contains cathinone into Schedule I.

In the UK, Cathine and Cathinone are Class C drugs. The plant *Catha edulis* is uncontrolled. In Germany, Cathine is a controlled substance, and ownership and sale of the plant is illegal. Similar levels of control exist throughout most other European countries.

In Canada, Khat is a controlled substance under Schedule IV of the Controlled Drugs and Substance Act (CDSA). Every person who seeks or obtain Khat is guilty of an indictable offence and liable to imprisonment for a term not exceeding eighteen months, where the

subject-matter of the offence is a substance included in Schedule IV *or* is guilty of an offence punishable on summary conviction and liable for a first offence, to a fine not exceeding one thousand dollars or to imprisonment for a term not exceeding six months, or to both, and for a subsequent offence, to a fine not exceeding two thousand dollars or to imprisonment for a term not exceeding one year, or to both.

In Australia, the importation of khat is controlled under the Customs (Prohibited Imports) Regulations. Individual users may apply for several required licenses to import up to 5 kg per month for personal use (primarily immigrants from the Horn of Africa). In 2003, the total number of khat annual permits was 294 and the total number of individual khat permits was 202."

"There are two types of import permits. The single use Permit to Import can be used only once and you must request a new permit for each time you wish to import khat. Annual Permits are labeled as such and consist of two pages. Annual Permits allow you to import up to 5 kg once a month for up to twelve months."

Trivia

- The word "qat" is well known to Scrabble players as a way to use the Q when no U is available.
- Smuggling of the plant known as Qhat (Khat) is the main reason British nationals require consular assistance in Canada.

Tea

Tea is a beverage made by steeping processed leaves, buds or twigs of the tea bush Camellia sinensis in hot water for a few minutes. The processing can include oxidation (fermentation), heating, drying and the addition of other herbs, flowers, spices and fruits.

There are four types of true tea: black tea, oolong tea, green tea, and white tea. The term herbal tea usually refers to infusions of fruit or herbs such as rosehip tea, chamomile tea and Jiaogulan that contain no tea leaves. (Alternative terms for herbal tea that avoid the word "tea" are tisane and herbal infusion). This article is concerned exclusively with preparations and uses of the tea plant Camellia sinensis.

Tea is a natural source of caffeine, theophylline, theanine, and antioxidants, but it has almost no fat, carbohydrates, or protein. It has a cooling, slightly bitter and astringent taste.

Processing and classification

The types of tea are distinguished by their processing. Leaves of Camellia sinensis, if not dried quickly after picking, soon begin to wilt and oxidize. This process resembles the malting of barley, in that starch is converted into sugars; the leaves turn progressively darker, as chlorophyll breaks down and tannins are released. The next step in processing is to stop the oxidation process at a predetermined stage by taking the water from the leaves via heating.

The term fermentation was used (probably by wine fanciers) to describe this process, and has stuck, even though no true fermentation happens (i.e., the process is not driven by yeast and produces no ethanol). Without careful moisture and temperature control, however, fungi will grow on tea. The fungi cause real fermentation which will contaminate the tea with toxic and carcinogenic substances, so that the tea must be discarded.

Tea is traditionally classified based on the degree or period of fermentation (oxidation) the leaves have undergone:

White tea Young leaves (new growth buds) that have undergone no oxidation; the buds may be shielded from sunlight to prevent formation of chlorophyll. White tea is produced in lesser quantities than most of the other styles, and can be correspondingly more expensive than tea from the same plant processed by other methods. It is also less well-known in countries outside of China, though this is changing with increased western interest in organic or premium teas.

Green tea The oxidation process is stopped after a minimal amount of oxidation by application of heat; either with steam, a traditional Japanese method; or by dry cooking in hot pans, the traditional Chinese method. Tea leaves may be left to dry as separate leaves are rolled into small pellets to make gun-powder tea. The latter process is time-consuming and is typically done only with pekoes of higher quality. The tea is processed within one to two days of harvesting.

Oolong Oxidation is stopped somewhere between the standards for green tea and black tea. The oxidation process will take two to three days.

Black tea/Red tea The tea leaves are allowed to completely oxidize. Black tea is the most common form of tea in southern Asia (India, Sri Lanka, Bangladesh, Pakistan etc) and in the last century many African countries including Kenya, Burundi, Rwanda, Malawi and Zimbabwe. The literal translation of the Chinese word is red tea, which may be used by some tea-lovers. The Chinese call it red tea because the actual tea liquid is red. Westerners call it black tea because the tea leaves used to brew it are usually black. However, red tea may also refer to rooibos, an increasingly popular South African tisane. The oxidation process will take around two weeks and up to one month. Black tea is further classified as either orthodox or CTC (Crush, Tear, Curl, a production method developed about 1932). Unblended black teas are also identified by the estate they come from, their year and the flush (first, second or autumn). Orthodox and CTC teas are further graded according to the post-production leaf quality by the Orange Pekoe system.

Pu-erh (also known as Póu léi (Polee) in Cantonese), Two forms of pu-erh teas are available, "raw" and "ripened". "Raw" or "green" pu-erh may be consumed young or aged to further mature. During the aging process, the tea undergoes a second, microbial fermentation. "Ripened" pu-erh is made from green pu-erh leaf that has been artificially oxidized to approximate the flavour of the natural aging process. This is done through a controlled process similar to composting, where both the moisture and temperature of the tea are carefully monitored. Both types of pu-erh tea are usually compressed into various shapes including bricks, discs, bowls, or mushrooms. While most teas are consumed within a year of production, pu-erh can be aged for many years to improve its flavour, up to 30 to 50 years for raw pu-erh and 10 to 15 years for ripened pu-erh, although experts and aficionados disagree about what the optimal age is to stop the aging process. Most often, pu-erh is steeped for up to five minutes in boiling water. Additionally, some Tibetans use pu-erh as a caloric food, boiled with yak butter, sugar and salt to make yak butter tea. Teas that undergo a second oxidation, such as pu-erh and liu bao, are collectively referred to as black tea in Chinese. This is not to be confused with the English term Black tea, which is known in Chinese as red tea.

Yellow tea Either used as a name of high-quality tea served at the Imperial court, or of special tea processed similarly to green tea, but with a slower drying phase.

Kukicha Also called winter tea, kukicha is made from twigs and old leaves pruned from the tea plant during its dormant season and dry-roasted over a fire. It is popular as a health food in Japan and in macrobiotic diets.

Genmaicha Literally "brown rice tea" in Japanese, a green tea blended with dry-roasted brown rice (sometimes including popped rice), very popular in Japan but also drunk in China.

Flower tea Teas processed or brewed with flowers; typically, each flower goes with a specific category of tea, such as green or red tea. The most famous flower tea is jasmine tea (hua chá, literally "flower tea," in Mandarin; heung pín in Cantonese), a green or oolong tea scented (or brewed) with jasmine flowers. Chrysanthemum, osmanthus, lotus, rose, and lychee are also popular flowers.

Blending and additives

Almost all teas in bags and most other teas sold in England are blends. Blending may occur at the level of tea-planting area (e.g., Assam), or teas from many areas may be blended. The aim of blending is a stable taste over different years, and a better price. More expensive, better tasting tea may cover the inferior taste of cheaper tea.

There are various teas which have additives and/or different processing than "pure" varieties. Tea is able to easily receive any aroma, which may cause problems in processing, transportation or storage of tea, but can be also advantageously used to prepare scented teas.

Content

Tea contains catechins, a type of antioxidant. In fresh tea leaf, catechins can be up to 30% of the dry weight. Catechins are highest in concentration in white and green teas while black tea has substantially less due to its oxidative preparation. Tea also contains the stimulants

caffeine (about 3% of the dry weight and typically 40 mg per cup of prepared tea), theophylline and theobromine, the latter two being present in very small amounts.[1]

Origin and early history in Asia

The cradle of the tea plant is a region that encompasses eastern and southern China, northern Myanmar, and the Assam state of India. Spontaneous (wild) growth of the assamica variant is observed in area ranging from Chinese province Yunnan to the northern part of Myanmar and Assam region of India. The variant sinensis grows naturally in eastern and southeastern regions of China.[2] Recent studies and occurrence of hybrids of the two types in wider area extending over mentioned regions suggest the place of origin of tea is in an area consisting of the northern part of Myanmar and the Yunnan and Sichuan provinces of China.[3]

Origins of human use of tea are described in several myths, but it is unknown as to where tea was first created as a drink.

Creation myths

In one popular Chinese legend, Shennong, the legendary Emperor of China, inventor of agriculture and Chinese medicine, was on a journey about five thousand years ago. The Emperor, known for his wisdom in the ways of science, believed that the safest way to drink water was by first boiling it. One day he noticed some leaves had fallen into his boiling water. The ever inquisitive and curious monarch took a sip of the brew and was pleasantly surprised by its flavour and its restorative properties. Variant of the legend tells that the emperor tried medical properties of various herbs on himself, some of them poisonous, and found tea works as an antidote.[4] Shennong is also mentioned in Lu Yu's Cha Jing, famous early work on the subject.[5]

A Chinese legend, which spread along with Buddhism, Bodhidharma is credited with discovery of tea. Bodhidharma, a semi-legendary Buddhist monk, founder of the Chan school of Buddhism, journeyed to China. He became angered because he was falling asleep during meditation, so he cut off his eyelids. Tea bushes sprung from the spot where his eyelids hit the ground.[6] Sometimes, the second story is retold with Gautama Buddha in place of Bodhidharma[7] In another variant of the first mentioned myth, Gautama Buddha discovered tea when some leaves had fallen into boiling water.[8]

China

Whether or not these legends have any basis in fact, tea has played a significant role in Asian culture for centuries as a staple beverage, a curative, and a symbol of status. It is not surprising its discovery is ascribed to religious or royal origins. The fact is that the Chinese have enjoyed tea for centuries. Scholars hailed the brew as a cure for a variety of ailments, the nobility considered the consumption of good tea as a mark of their status and the common people simply enjoyed its flavour.

While historically the origin of tea as a medicinal herb useful for staying awake is unclear, China is considered the birthplace of tea drinking with recorded tea use in its history to at least 1000 BC. The Han Dynasty used tea as medicine. The use of tea as a beverage drunk for pleasure on social occasions dates from the Tang Dynasty or earlier.

The Tang Dynasty writer Lu Yu's x½ (729-804) Cha Jing 6" is an early work on the subject. According to Cha Jing written around 760, tea drinking was widespread. The book describes how tea plants were grown, the leaves processed, and tea prepared as a beverage. It also describes how tea was evaluated. The book even discusses where the best tea leaves were produced.

At this time in tea's history, the nature of the beverage and style of tea preparation were quite different from the way we experience tea today. Tea leaves were processed into cakes. The dried teacake, generally called brick tea was ground in a stone mortar. Hot water was added to the powdered teacake, or the powdered teacake was boiled in earthenware kettles then consumed as a hot beverage.

A form of compressed tea referred to as white tea was being produced as far back as the Tang Dynasty (618-907 A.D.). This special white tea of Tang was picked in early spring when the new growths of tea bushes that resemble silver needles were abundant. These "first flushes" were used as the raw material to make the compressed tea.

Advent of steaming and powder tea

During the Song Dynasty (960-1279), production and preparation of all tea changed. The tea of Song included many loose-leaf styles (to preserve the delicate character favoured by the court society), but a new powdered form of tea emerged. Tea leaves were picked and quickly steamed to preserve their colour and fresh character. After steaming, the leaves were dried. The finished tea was then ground into fine powders that were whisked in wide bowls. The resulting beverage was highly regarded for its deep emerald or iridescent white appearance and its rejuvenating and healthy energy. Drinking tea was considered stylish among government officers and intellectuals during the Southern Song period in China (12th to 13th centuries). They would read poetry, write calligraphy, paint, and discuss philosophy, while enjoying tea. Sometimes they would hold tea competitions where teas and tea instruments were judged. When Song Dynasty emperor Hui Zhong proclaimed white tea to be the culmination of all that is elegant, he set in motion the evolution of an enchanting variety.

This Song style of tea preparation incorporated powdered tea and ceramic ware in a ceremonial aesthetic known as the Song tea ceremony. Japanese monks traveling to China at this time had learned the Song preparation and brought it home with them. Although it later became extinct in China, this Song style of tea evolved into the Japanese tea ceremony, which endures today.

Many forms of white tea were made in the Song Dynasty due to the discerning tastes of the court society. Hui Zhong, who ruled China from 1101-1125, referred to white tea as the best type of tea, and he has been credited with the development of many white teas in the Song Dynasty, including "Palace Jade Sprout" and "Silver Silk Water Sprout".

Producing white teas was extremely labour-intensive. First, tea was picked from selected varietals of cultivated bushes or wild tea trees in early spring. The tea was immediately steamed, and the buds were then selected and stripped of their outer, unopened leaf. Only the delicate interior of the bud was reserved to be rinsed with spring water and dried. This process produced white teas that were paper thin and small.

Once processed, the finished tea was distributed and often given as a tribute to the Song court in loose form. It was then ground to a fine, silvery-white powder that was whisked in the wide ceramic bowls used in the Song tea ceremony. These white powder teas were also used in the famous whisked tea competitions of that era.

Roasting and brewing

Steaming tea leaves was the primary process used for centuries in the preparation of tea. After the transition from compressed tea to the powdered form, the production of tea for trade and distribution changed once again. The Chinese learned to process tea in a different way in the mid-13th century. Tea leaves were roasted and then crumbled rather than steamed. This is the origin of today's loose teas and the practice of brewed tea.

In 1391, the Ming court issued a decree that only loose tea would be accepted as a "tribute". As a result, loose tea production increased and processing techniques advanced. Soon, most tea was distributed in full-leaf, loose form and steeped in earthenware vessels.

Oxidization (often mistakenly called fermentation)

Tea "fermentation" is not related to yeast fermentation. It is actually the oxidization of the tea leaves. In 17th century China numerous advances were made in tea production. In the southern part of China, tea leaves were sun dried then half fermented, producing Black Dragon teas or Oolongs. However, this method was not common in the rest of China.

Korea

The first historical record documenting the offering of tea to an ancestral god describes a rite in the year 661 in which a tea offering was made to the spirit of King Suro, the founder of the Geumgwan Gaya Kingdom (42-562).

Records from the Goryeo Dynasty (918-1392) show that tea offerings were made in Buddhist temples to the spirits of revered monks.

During the Joseon Dynasty (1392-1910), the royal Yi family and the aristocracy used tea for simple rites, the "Day Tea Rite" was a common daytime ceremony, whereas the "Special Tea Rite" was reserved for specific occasions. These terms are not found in other countries. Toward the end of the Joseon Dynasty, commoners joined the trend and used tea for ancestral rites, following the Chinese example based on Zhu Xi's text formalities of Family.

Stoneware was common, ceramic more frequent, mostly made in provincial kilns, with porcelain rare, imperial porcelain with dragons the rarest.

Historically the appearance of the bowls and cups is naturalistic, with a division according to religious influence. Celadon or jade green, "punchong", or bronze-like weathered patinas for Buddhist tea rituals; the purest of white with faint designs in porcelain for Confucian tea rituals; and coarser porcelains and ash-stone glazes for animist tea rituals, or for export to Japan where they were known as "gohan chawan". An aesthetic of rough surface texture from a clay and sand mix with a thin glazing were particularly prized and copied. The randomness of this creation was said to provide a "now moment of reality" treasured by tea masters.

Unlike the Chinese tradition, no Korean tea vessels used in the ceremony are tested for a fine musical note. Judgment instead is based on naturalness in form, emotion, and colouring.

The earliest kinds of tea used in tea ceremonies were heavily pressed cakes of black tea, the equivalent of aged pu-erh tea still popular in China. Vintages of tea were respected, and tea of great age imported from China had a certain popularity at court. However, importation of tea plants by Buddhist monks brought a more delicate series of teas into Korea, and the tea ceremony.

While green tea, "chaksol" or "chugno", is most often served, other teas such as "Byeoksoryung" Chunhachoon, Woojeon, Jakseol, Jookro, Okcheon, as well as native chrysanthemum tea, persimmon leaf tea, or mugwort tea may be served at different times of the year.

Buddhist monks incorporated tea ceremonies into votive offerings. However the Goryeo nobility and later the Confucian yangban scholars formalized the rituals. Tea ceremonies have always been used for important occasions such as birthdays, anniversaries, remembrance of old friends, and increasingly a way to rediscovering Seon meditation.

Japanese Involvement

Importing tea and tea culture

The earliest known references to green tea in Japan are in a text written by a Buddhist monk in the 9th century. Tea became a drink of the religious classes in Japan when Japanese priests and envoys sent to China to learn about its culture brought tea to Japan. The first form of tea brought from China was probably in a teacake. Ancient recordings indicate the first batch of tea seeds were brought by a priest named Saicho („; 767-822) in 805 and then by another named Kukai (zw; 774-835) in 806. It became a drink of the royal classes when Emperor Saga (oè)‡), the Japanese emperor, encouraged the growth of tea plants. Seeds were imported from China, and cultivation in Japan began.

Kissa Yojoki - the Book of Tea

In 1191, the famous Zen priest Eisai (; 1141-1215) brought back tea seeds to Kyoto. Some of the tea seeds were given to the priest Myoe Shonin, and became the basis for Uji tea. The oldest tea specialty book in Japan, Kissa Yojoki («6 ; how to stay healthy by drinking tea) was written by Eisai. The two-volume book was written in 1211 after his second and last visit to China. The first sentence states, "Tea is the ultimate mental and medical remedy and has the ability to make one's life more full and complete". The preface describes how drinking tea can have a positive effect on the five vital organs, especially the heart. It discusses tea's medicinal qualities which include easing the effects of alcohol, acting as a stimulant, curing blotchiness, quenching thirst, eliminating indigestion, curing beriberi, preventing fatigue, and improving urinary and brain function. Part One also explains the shapes of tea plants, tea flowers and tea leaves and covers how to grow tea plants and process tea leaves. In Part Two, the book discusses the specific dosage and method required for individual physical ailments.

Eisai was also instrumental in introducing tea consumption to the warrior class, which rose to political prominence after the Heian Period. Eisai learned that the shogun Minamoto no Sanetomo had a habit of drinking too much every night. In 1214, Eisai presented a book he had written to the general, lauding the health benefits of tea drinking. After that, the custom of tea drinking became popular among the Samurai.

Very soon, green tea became a staple among cultured people in Japan -- a brew for the gentry and the Buddhist priesthood alike. Production grew and tea became increasingly accessible, though still a privilege enjoyed mostly by the upper classes.

Roasting process introduced to Japan

In the 13th century Ming dynasty, southern China and Japan enjoyed much cultural exchange. Significant merchandise was traded and the roasting method of processing tea became common in Kyushu, Japan. Since the steaming (9th century) and the roasting (13th century) method were brought to Japan during two different periods, these teas are completely distinct from each another.

Japan tea culture emerges

The pastime made popular in China in the twelfth and thirteenth centuries -- reading poetry, writing calligraphy, painting, and discussing philosophy while enjoying tea – eventually became popular in Japan and with Samurai society. The modern tea ceremony developed over several centuries by Zen Buddhist monks under the original guidance of the monk Sen-no Rikyu (1522-1591). In fact, both the beverage and the ceremony surrounding it played a prominent role in feudal diplomacy. Many of the most important negotiations among feudal clan leaders were carried out in the austere and serene setting of the tea ceremony. By the end of the sixteenth century, the current "Way of Tea" was established. Eventually, green tea became available to the masses, making it the nation's most popular beverage.

Modern Japanese green tea

In 1738, Soen Nagatani developed Japanese sencha (Japanese: N6), which is an unfermented form of green tea. To prepare sencha, tea leaves are first steam-pressed, then rolled and dried into a loose tea.

In 1835, Kahei Yamamoto developed gyokuro (Japanese: ‰2), considered the finest loose-leaf Japanese green tea, by shading tea trees during the weeks leading up to harvesting in order to alter the leaf chemistry in ways considered pleasant by most green tea drinkers.

Modern maccha (Japanese: ¹6) is normally taken from the same shaded trees as gyokuro and ground to a fine powder to be mixed whole into hot water, and is the tea used in the Japanese tea ceremony.

Rolling machines

At the end of the Meiji period (1868-1912), machine manufacturing of green tea was introduced and began replacing handmade tea. Machines took over the processes of primary drying, tea rolling, secondary drying, final rolling, and steaming.

Automation

Automation contributed to improved quality control and reduced labour. Sensor and computer controls were introduced to machine automation so that unskilled workers can produce superior tea without compromising in quality. Certain regions in Japan are known for special types of green tea, as well as for teas of exceptional quality, making the leaves themselves a highly valued commodity. This combination of Nature's bounty and manmade technical breakthroughs combine to produce the most exceptional green tea products sold on the market today. Today, roasted green tea is not as common in Japan and powdered tea is used in ceremonial fashion.

Tea spreads to the world

As the Venetian explorer Marco Polo failed to mention tea in his travel records, it is conjectured that the first Europeans to encounter tea were either Jesuits living in Beijing who attended the court of the last Ming Emperors; or Portuguese explorers visiting Japan in 1560. Russia discovered tea in 1618 after a Ming Emperor of China offered it as a gift to Czar Michael I.

Soon imported tea was introduced to Europe, where it quickly became popular among the wealthy in France and the Netherlands. English use of tea dates from about 1650 and is attributed to Catherine of Braganza (Portuguese princess and queen consort of Charles II of England).

The high demand for tea in Britain caused a huge trade deficit with China, leading the British to try to produce their own in the mid-nineteenth century. Using seeds smuggled from China (there was an official ban on foreigners entering tea-growing areas), the British went through some failed experiments but finally succeeded in setting up productive plantations in parts of colonial India with suitable climates and soil.[9][10] They also tried to balance the trade deficit by selling opium to the Chinese, which later led to the First Opium War in 1838–1842.

The Boston Tea Party was an act of uprising in which Boston residents destroyed crates of British tea in 1773, in protest against British tea and taxation policy. Prior to the Boston Tea Party, residents of Britain's North American 13 colonies drank far more tea than coffee. In Britain, coffee was more popular. After the protests against the various taxes, British Colonists stopped drinking tea as an act of patriotism. Similarly, Britons slowed their consumption of coffee.

Iced Tea has been popular in North America since the 1904 St. Louis World's Fair.

These days, contradicting tea economies do exist. Tea farmers in Japan, Taiwan and China often enjoy better incomes compared to farmers in black tea producing countries.

The word tea

The Chinese character for tea is 6, but it is pronounced differently in the various Chinese dialects. Two pronunciations have made their way into other languages around the world. One is 'te' (Taiwanese (linguistics): tê) which comes from the Min Nan dialect spoken around the port of Xiamen (Amoy). The other is Chá, used by the Cantonese dialect spoken around the ports of Guangzhou (Canton), Hong Kong, Macau, and in overseas Chinese communities, as well as in the Mandarin dialect of northern China. Yet another different pronunciation is 'zu', used in the Wu dialect spoken around Shanghai.

Languages that have Te derivatives include Afrikaans (tee), Armenian, Catalan (te), Czech (té or thé, but these words sound archaic, aj is used nowadays, see the next paragraph), Danish (te), Dutch (thee), English (tea), Esperanto (teo), Estonian (tee), Faroese (te), Finnish (tee), French (thé), (West) Frisian (tee), Galician (té), German (Tee), Hebrew (êÔ, /te/ or /tei/), Hungarian (tea), Icelandic (te), Indonesian (teh), Irish (tae), Italian (tè), scientific Latin (thea), Latvian (tja), Malay (teh), Norwegian (te), Polish (herbata from Latin herba thea), Scots Gaelic (tì, teatha), Singhalese, Spanish (té), Swedish (te), Tamil (thè), Welsh (te), and Yiddish (ØÙÙ, /tei/).

Those that use Cha or Chai derivatives include Albanian (çaj), Arabic (4N'J/shi/chai), Assyrian (pronounced chai), Azeri: (çay), Bengali (š¾), Bosnian (aj), Bulgarian (G09), Capampangan (cha), Cebuano (tsa), Croatian (aj), Czech (aj), Greek (ÄÃ¬¹), Hindi (>/)chai, Japanese (6, aʃ, cha), Kazakh (H09), Korean ((), Macedonian (aj), Malayalam, Nepali (chai), Persian (†'I), Punjabi (>9), Portuguese (chá), Romanian (ceai), Russian, (G09, chai), Serbian (G0X), Slovak (aj), Slovene (aj), Somali (shaax), Swahili (chai), Tagalog (tsaa), Thai (2), Tibetan (ja), Turkish (çay), Ukrainian (G09), Urdu (†'I), Uzbek (choy) and Vietnamese (trà and chè are both direct derivatives of the Chinese 6; the latter term is used mainly in the north).

The Polish word for a tea-kettle is czajnik, which could be derived directly from Cha or from the cognate Russian word. However, tea in Polish is herbata, which was probably derived from the Latin herba thea, meaning "tea herb".

It is tempting to correlate these names with the route that was used to deliver tea to these cultures, although the relation is far from simple at times. As an example, the first tea to reach Britain was traded by the Dutch from Fujian, which uses te, and although later most British trade went through Canton, which uses cha, the Fujianese pronunciation continued to be the more popular.

In Ireland, or at least in Dublin, the term "cha" is sometimes used for tea, with "tay" as a common pronunciation throughout the land (derived from the Irish Gaelic tae), and "char" was a common slang term for tea throughout British Empire and Commonwealth military forces in the 19th and 20th centuries, crossing over into civilian usage. In North America, the word "chai" is used to refer almost exclusively to the Indian "chai" (or "masala chai") beverage.

Perhaps the only place in which a word unrelated to tea is used to describe the beverage is South America (particularly Andean countries), because a similar stimulant beverage,

hierba mate, was consumed there long before tea arrived. In various places of South America, any tea is referred to as mate.

Tea culture

Tea is often drunk at social events, such as afternoon tea and the tea party. It may be drunk early in the day to heighten alertness; it contains theophylline and bound caffeine (sometimes called "theine"), although there are also decaffeinated teas.

There are tea ceremonies which have arisen in different cultures, Japan's complex, formal and serene one being the most known. Other examples are the Korean tea ceremony or some traditional ways of brewing tea in Chinese tea culture.

Preparation

This section describes the most widespread method of making tea. Completely different methods are used in North Africa, Tibet and perhaps in other places. In the American South, iced tea is also prepared differently.

The best way to prepare tea is usually thought to be with loose tea placed either directly in a teapot or contained in a tea infuser, rather than a teabag. However, perfectly acceptable tea can be made with teabags. Some circumvent the teapot stage altogether and brew the tea directly in a cup or mug. This method is becoming more popular. For an acceptable quality, however, it is necessary to obey the rules for preparation such as sufficient infusion time by placing the teabag in the cup before pouring the hot water.

Historically in China, tea is divided into a number of infusions. The first infusion is immediately poured out to wash the tea, and then the second and further infusions are had. The third through fifth are nearly always considered the best infusions of tea, although different teas open up differently and may require more infusions of boiling water to bring them to life.

Typically, the best temperature for brewing tea can be determined by its type. Teas that have little or no oxidation period, such as a green or white tea, are best brewed at lower temperatures around 80 °C, while teas with longer oxidation periods should be brewed at higher temperatures around 100 °C.

Black tea The water for black teas should be added at the boiling point (100 °C or 212 °F), except for more delicate teas, where lower temperatures are recommended. This will have as large an effect on the final flavour as the type of tea used. The most common fault when making black tea is to use water at too low a temperature. Since boiling point drops with increasing altitude, this makes it difficult to brew black tea properly in mountainous areas. It is also recommended that the teapot be warmed before preparing tea, easily done by adding a small amount of boiling water to the pot, swirling briefly, before discarding. Black tea should not be allowed to steep for less than 30 seconds or more than about five minutes (a process known as brewing or [dialectally] mashing in the UK). After that, tannin is released, which counteracts the stimulating effect of the theophylline and caffeine and makes the tea bitter (at this point it is referred to as being stewed in the UK). Therefore, for a "wake-up" tea, one should not let the tea steep for more than 2- 3minutes. When the tea has brewed long enough to suit the tastes of the drinker, it should be strained while serving.

Green tea Water for green tea, according to most accounts, should be around 80 °C to 85 °C (176 °F to 185 °F); the higher the quality of the leaves, the lower the temperature. Hotter water will burn green-tea leaves, producing a bitter taste. Preferably, the container in which the tea is steeped, the mug, or teapot should also be warmed beforehand so that the tea does not immediately cool down.

Oolong tea Oolong teas should be brewed around 90 °C to 100 °C (194 °F to 212 °F), and again the brewing vessel should be warmed before pouring in the water. Yixing purple clay teapots are the ideal brewing vessel for oolong tea. For best results use spring water, as the minerals in spring water tend to bring out more flavour in the tea.

Premium or delicate tea Some teas, especially green teas and delicate Oolong or Darjeeling teas, are steeped for shorter periods, sometimes less than 30 seconds. Using a tea strainer separates the leaves from the water at the end of the brewing time if a tea bag is not being used.

Serving In order to preserve the pre-tannin tea without requiring it all to be poured into cups, a second teapot is employed. The steeping pot is best unglazed earthenware; Yixing pots are the best known of these, famed for the high quality clay from which they are made. The serving pot is generally porcelain, which retains the heat better. Larger teapots are a post-19th-century invention, as tea before this time was very rare and very expensive. Experienced tea-drinkers often insist that the tea should not be stirred around while it is steeping (sometimes called winding in the UK). This, they say, will do little to strengthen the tea, but is likely to bring the tannic acids out in the same way that brewing too long will do. For the same reason one should not squeeze the last drops out of a teabag; if stronger tea is desired, more tea leaves should be used.

Additives The addition of other items such as milk and sugar to tea is primarily a European invention[11], though it has also spread to british colonies such as Hong Kong[12] or India. Some connoisseurs eschew cream because it overpowers the flavour of tea. Many teas are traditionally drunk with milk. These include Indian chai, and British tea blends. These teas tend to be very hearty varieties which can be tasted through the milk, such as Assams, or the East Friesian blend. Milk is thought to neutralise remaining tannins and reduce acidity.

When taking milk with tea, some add the tea to the milk rather than the other way around when using chilled milk; this avoids scalding the milk, leading to a better emulsion and nicer taste.[13] The socially 'correct' order is tea, sugar, milk, but this convention was established before the invention of the refrigerator. It is worth noting that this convention was only universally established in the 20th century - prior to this, the common earthenware mugs used were unable to withstand the temperature of the tea, and so the convention was to add the tea to the milk. This was not the case with bone china. Adding the milk first also makes a milkier cup of tea with sugar harder to dissolve as there will be no hot liquid in the cup. In addition, the amount of milk used is normally determined by the colour of the tea, therefore milk is added until the correct colour is obtained. If the milk is added first, more guesswork is involved. If the tea is being brewed in a mug, the milk is generally added after the tea bag is removed (however, it is arguably better to add milk before removing the tea bag than it is to remove the tea bag too soon: the tea will continue to brew even with milk added). Other popular additives to tea include sugar or honey, lemon, and fruit jams. In colder regions such as Mongolia and Nepal, butter is added to provide necessary calories. Tibetan butter tea

contains rock salt and yak butter, which is then churned vigorously in a cylindrical vessel closely resembling a butter churn. The flavour of this beverage is more akin to a rich broth than to tea, and may be described as a very acquired taste to those unused to drinking it.

Ceremony Zen Buddhism is the root of the highly refined Japanese tea ceremony. The Chinese province of Fujian is the origin of the Gong Fu tea ceremony, which is unrelated to the martial art called Kung Fu though the characters are the same: literally "time-energy" or something which takes a lot of time and energy. It features the rapid use of tongs and various vessels to make tea. Loose leaf tea venders in China often use this method to make tea for their customers. The Korean Tea Ceremony is more like the Chinese ceremony. In the United Kingdom, adding the milk first is historically considered a lower-class method of preparing tea; the upper classes always add the milk last. The origin of this distinction is said to be that the rougher earthenware mugs of the working class would break if boiling-hot tea was added directly to them, whereas the fine glazed china cups of the upper class would not. It is now considered by most to be a personal preference.

Packaging

Tea bags Tea leaves are packed into a small (usually paper) tea bag. It is easy and convenient, making tea bags popular for many people nowadays. However, because fannings and dust from modern tea processing are also included in most tea bags, it is commonly held among tea aficionados that this method provides an inferior taste and experience. The paper used for the bag can also be tasted by many which can detract from the tea's flavour. Additional reasons why bag tea is considered less well-flavoured include:

- Dried tea loses its flavour quickly on exposure to air. Most bag teas (although not all) contain leaves broken into small pieces; the great surface-area-to-volume ratio of the leaves in tea bags exposes them to more air, and therefore causes them to go stale faster. Loose tea leaves are likely to be in larger pieces, or to be entirely intact.
- Breaking up the leaves for bags extracts flavoured oils.
- The small size of the bag does not allow leaves to diffuse and steep properly.

Triangle Tea Bags A new infuser has recently come onto the market with an unusual design. The mesh triangle bags are made of a gossamer mesh and have been criticized of being environmentally unfriendly. The shape is designed to allow the tea leaves to expand more when steeping, and not leave flavours (such as paper) in the tea, addressing two of connoisseurs' arguments against tea bags. As such, the flavours available tend towards more gourmet selections such as white tea rather than blends.

Loose tea The tea leaves are packaged loosely in a canister or other container. The portions must be individually measured by the consumer for use in a cup, mug or teapot. This allows greater flexibility, letting the consumer brew weaker or stronger tea as desired, but convenience is sacrificed. Strainers, "tea presses", filtered teapots and infusion bags are available commercially to avoid having to drink the floating loose leaves. A more traditional, yet perhaps more effective way around this problem is to use a three-piece lidded teacup,

called a gaiwan. The lid of the gaiwan can be tilted to decant the leaves while pouring the tea into a different cup for consumption.

Compressed tea A lot of tea is still compressed for storage and aging convenience. Commonly Pu-Erh tea is compressed and then drunk by loosening leaves off using a small knife. Most of the time compressed tea can be stored longer than loose leaf tea.

Tea sticks One of the more modern forms of tea consumption, an alternative to the tea bag, is tea sticks. The first known tea sticks originated in Holland in the mid 1990's, where a company by the name of Venezia Trading produced a tea stick named Ticolino. Ticolino are dubbed as single serving tea sticks which use an infusing technology to brew the tea leaves inside, releasing the flavour and aroma.

Instant tea In recent times, "instant teas" are becoming popular, similar to freeze dried instant coffee. Instant tea was developed in the 1930's, but not commercialized until the late 1950's, and is only more recently becoming popular. These products often come with added flavours, such as vanilla, honey or fruit, and may also contain powdered milk. Similar products also exist for instant iced tea, due to the convenience of not requiring boiling water. Tea connoisseurs tend to criticise these products for sacrificing the delicacies of tea flavour in exchange for convenience.

Storage

Tea storage is essential to keeping the taste of tea pure. Tea absorbs moisture and odours very easily so it is necessary to keep it in some kind of container away from strong odours. One way to store a small amount of loose leaf tea is to keep it in a tin or glass container. These containers will keep the tea free from moisture and also keep odours out so the tea will keep its original flavour. Other ways to store tea include air tight bags. When storing the tea keep it away from sun light, strong odours, and moisture. For larger amounts of tea it would be good to put it into a cooler type of container. First wrap the tea in brown paper then wrap the paper again with brown paper to keep out any moisture. Then place the tea into a cooler that has nothing in and has a good seal. Next take the tea to a cool place away from moisture and odours. The length of time you can store tea depends on its type. Some teas such as flower teas will go bad in a month or so, but others may get better with age.

Yerba mate

Conservation status: Near threatened (LR/nt)

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Aquifoliales
Family: Aquifoliaceae
Genus: Ilex
Species: *I. paraguariensis*

Binomial name Ilex paraguariensis

Yerba mate (Rioplatense Spanish) or *erva mate* (Portuguese) (Ilex paraguariensis) is a species of holly (family Aquifoliaceae) native to subtropical South America in Argentina,

southern Paraguay, southern Uruguay and southern Brazil and Bolivia. The infusion called mate is prepared by steeping the dried leaves in hot water rather than boiling water like tea or coffee. It is slightly less potent than coffee and much gentler on the stomach. Drinking mate with friends from a shared hollow gourd (also called a mate in Spanish, or cabaça or cuia in Portuguese) with a metal straw (a bombilla in Spanish, bomba or canudo in Portuguese) is an extremely common social practice in Argentina, Uruguay, southern Paraguay, the east side of Chile and southern Bolivia and Brazil. Its use has also been introduced into Lebanon and Syria, particularly among the Alawi and Druze minority.

The flavor of brewed yerba mate is strongly vegetal, herbal, and grassy, reminiscent of some varieties of green tea, though the flavor is much stronger than green tea can achieve. Many consider the flavor to be very agreeable, however, it is generally bitter if steeped in water at boiling point and is traditionally made using boiling water combined with a little cold water. Unlike most teas, it does not become bitter and astringent when steeped for extended periods, and the leaves may be infused several times. Additionally, one can purchase flavored mate, in orange, raspberry, strong, and gentle flavorings.

In Brazil, a toasted version of mate, known as chá mate or "mate tea", is sold in teabag and loose form, and served, sweetened, in specialized shops, either hot or iced with fruit juice or milk. An iced, sweetened version of toasted mate is sold as an uncarbonated soft drink, with or without fruit flavoring. The toasted variety of mate has less of a bitter flavor and more of a spicy fragrance. It is more popular in the coastal cities of Brazil, as opposed to the far southern states where it is consumed in the traditional way (green, drunk with a silver straw from a shared gourd).

The yerba mate plant is a shrub or small tree growing up to 15 meters tall. The leaves are evergreen, 7–11 cm long and 3–5.5 cm wide, with a serrated margin. The flowers are small, greenish-white, with four petals. The fruit is a red berry 4–6 mm diameter.

Nomenclature

The pronunciation of yerba mate in standard Spanish is [È_[r²a Èmate]. The Rioplatense dialect spoken in most of Argentina turns the first sound in yerba into a postalveolar fricative, giving [Èʃ[r²a] in regions closer to Buenos Aires, gradually blending into [È'[r²a] as one goes farther from the city, and eventually to [d'[r²a] around Mendoza. The word hierba is Spanish for grass or herb; yerba is a variant spelling of it which is quite common in Argentina. Mate is from the Quechua mati, meaning "cup". Yerba mate is therefore literally the "cup herb".

The (Brazilian) Portuguese name is erva mate [È[rva Èmati] (also pronounced as [È[rva Èmate] in some regions) and is known coloquially as chimarrão (when taken hot) or tereré (when taken cold). The name given to the plant in Guaraní, language of the indigenous people who first cultivated and enjoyed yerba mate, is ka'a, which has the same meaning as yerba.

Mate is often written maté in English to indicate that the pronunciation is not the same as the much more common English word "mate", by analogy with words of French origin such as "café" and other words whose é distinguishes their pronunciation from otherwise identically spelled English words, such as résumé and resume. Linguistic prescriptivists regard this usage as erroneous, a case of hypercorrection. Purely descriptive linguists regard this sort of usage as a natural evolution of the language.

Cultivation

The plant is grown mainly in South America, more specifically in, Northern Argentina (Corrientes, Misiones), Paraguay, Uruguay and southern Brazil (Rio Grande do Sul and Paraná). The Guaraní are reputed to be the first people who cultivated the plant; the first Europeans to do this were Jesuit missionaries, who spread the drinking habit as far as Ecuador.

When the yerba is harvested, the branches are dried sometimes with a wood fire, imparting a smoky flavour. Then the leaves and sometimes the twigs are broken up.

There are many brands and types of yerba, with twigs, and without and low powder content. Some types are less strong in flavor (suave, "soft") and there are blends flavored with mint, orange and grapefruit skin, etc.

Chemical composition and properties

Mate contains xanthines, which are alkaloids in the same family as caffeine, theophylline, and theobromine, well-known stimulants also found in coffee and chocolate. Mate also contains the chemical elements potassium, magnesium and manganese. Caffeine content varies between 0.3% and 1.7% of dry weight (compare this to 2.5–4.5% for tea leaves, and 1.5% for ground coffee).

Mate products are sometimes marketed as "caffeine-free" alternatives to coffee and tea, and said to have fewer negative effects. This is often based on a claim that the primary active xanthine in mate is "mateine", erroneously said to be a stereoisomer of caffeine (as it is not chemically possible for caffeine to have a stereoisomer). "Mateine" is an official synonym of caffeine in the chemical databases.

Researchers at Florida International University in Miami have found that yerba mate does contain caffeine, but some people seem to tolerate a mate drink better than coffee or tea. This is expected since mate contains different chemicals (other than caffeine) from tea or coffee.

From reports of personal experience with mate, its physiological effects are similar to (yet distinct from) more widespread caffeinated beverages like coffee, tea, or guarana drinks. Users report a mental state of wakefulness, focus and alertness reminiscent of most stimulants, but often remark on mate's unique lack of the negative effects typically created by other such compounds, such as anxiety, diarrhoea, "jitteriness", and heart palpitations.

Reasons for mate's unique physiological attributes are beginning to emerge in scientific research. Studies of mate, though very limited, have shown preliminary evidence that the mate xanthine cocktail is different from other plants containing caffeine most significantly in its effects on muscle tissue, as opposed to those on the central nervous system, which are similar to those of other natural stimulants. Mate has been shown to have a relaxing effect on smooth muscle tissue, and a stimulating effect on myocardial (heart) tissue.

Mate's negative effects are anecdotally claimed to be of a lesser degree than those of caffeine, though no explanation for this is offered or even credibly postulated, except for its potential as a placebo effect. Many users report that drinking yerba mate does not prevent them from being able to fall asleep, as is often the case with some more common stimulating

beverages, while still enhancing their energy and ability to remain awake at will. However, the net amount of caffeine in one preparation of yerba mate is typically quite high, in large part because the repeated filling of the mate with hot water is able to extract the highly-soluble xanthines extremely effectively. It is for this reason that one mate may be shared among several people and yet produce the desired stimulating effect in all of them.

In-vivo and in-vitro studies are showing yerba mate to exhibit significant cancer-fighting activity. Researchers at the University of Illinois (2005) found yerba mate to be "rich in phenolic constituents" and to "inhibit oral cancer cell proliferation".

An August 11, 2005 United States patent application (document #20050176777 & #20030185908 & #20020054926) cites yerba mate extract as an inhibitor of MAO activity; the maximal inhibition observed in vitro was 40–50%. A monoamine oxidase inhibitor is a type of antidepressant, so there is some data to suggest that yerba mate has calming effect in this regard.

Medicinal plants

Herbalism, also known as *Herbal medicine* and *phytotherapy*, is a folk and traditional medicinal practice based on the use of plants and plant extracts.

Finding healing powers in plants is an ancient idea. People in all continents have long used hundreds, if not thousands, of indigenous plants for treatment of various ailments dating back to prehistory. These plants are still widely used in ethnomedicine around the world.

The first generally accepted use of plants as healing agents were depicted in the cave paintings discovered in the Lascaux caves in France, which have been Radiocarbon dated to between 13,000 - 25,000 BCE.

Anthropologists theorize that over time, and with trial and error, a small base of knowledge would have been acquired within early tribal communities. As this knowledge base expanded over the generations, the specialized role of the shaman emerged. The process would likely have occurred in varying manners within a wide diversity of cultures.

Plants have an almost limitless ability to synthesize aromatic substances, most of which are phenols or their oxygen-substituted derivatives such as tannins. Most are secondary metabolites, of which at least 12,000 have been isolated, a number estimated to be less than 10% of the total. In many cases, these substances (esp. alkaloids) serve as plant defense mechanisms against predation by microorganisms, insects, and herbivores. Many of the herbs and spices used by humans to season food yield useful medicinal compounds.

The use of and search for drugs and dietary supplements derived from plants have accelerated in recent years. Pharmacologists, microbiologists, botanists, and natural-products chemists are combing the Earth for phytochemicals and leads that could be developed for treatment of various diseases. In fact, many modern drugs have been derived from plants.

The use of herbs to treat disease is almost universal among non-industrialized societies. A number of traditions came to dominate the practice of herbal medicine in the Western world at the end of the twentieth century:

- The Western, based on Greek and Roman sources,

The Ayurvedic from India, and

Chinese herbal medicine (Chinese herbology).

Many of the pharmaceuticals currently available to Western physicians have a long history of use as herbal remedies, including opium, aspirin, digitalis, and quinine.

Biological background

All plants produce chemical compounds as part of their normal metabolic activities. These can be split into primary metabolites, such as sugars and fats, found in all plants, and secondary metabolites found in a smaller range of plants, some only in a particular genus or species.

The autologous functions of secondary metabolites are varied. For example, as toxins to deter predation, or to attract insects for pollination. It is these secondary metabolites which can have therapeutic actions in humans and which can be refined to produce drugs. Some examples are inulin from the roots of dahlias, quinine from the cinchona, morphine and codeine from the poppy, and digoxin from the foxglove.

As of 2004, the National Center for Complementary and Alternative Medicine started to fund clinical trials into the effectiveness of herbal medicine.[1]

Surveys of a scientific approach to herbal medicine can be found in the books Evidence-based herbal medicine,[2] and Herbal and traditional medicine: molecular aspects of health.[3]

Popularity

A survey released in May 2004[4] by the National Center for Complementary and Alternative Medicine focused on who used complementary and alternative medicines (CAM), what was used, and why it was used. The survey was limited to adults age 18 years and over during 2002 living in the United States. According to this recent survey, herbal therapy, or use of natural products other than vitamins and minerals, was the most commonly used CAM therapy (18.9%)[5] when all use of prayer was excluded.

Herbal remedies are most common in Europe. In Germany, the term apothecary (Apotheke) is still used, and next to prescription drugs one can order essential oils, herbal extracts, or herbal teas. It is even seen as a preferred treatment over the unnecessary overuse of industrialized production of chemical medication.

Types of herbal medicine

Medicinal plants can be used by anyone, for example as part of a salad, an herbal tea or supplement, although some herbs considered dangerous are restricted from sale to the public. Sometimes such herbs are provided to professional herbalists by specialist companies. Many herbalists, both professional and amateur, often grow or wildcraft their own herbs. Many common weeds have medicinal properties (e.g. dandelion)

Medicinal herbs can be used in various forms:

Herbal teas

There are two methods of making herbal teas, infusion and decoction. Infusion is steeping lighter parts of the plant (leaves, flowers, light stems) in boiled water for several minutes. Decoction is boiling tougher parts, such as roots or bark for a longer period of time. Herbal teas are often used as a home remedy, and as an alternative to tea and coffee.

Herbal tinctures

Steeping a medicinal plant in alcohol extracts the alcohol-soluble principles into a liquid form that can be stored for long periods. Herbalists may mix several herbal tinctures to form an individualized prescription for each patient. Plant tinctures are also the basis for many homeopathic medicines.

Fluid extracts

Fluid extracts are stronger than herbal tinctures, and can be made with alcohol or glycerin.

Herbal poultices

Poultices are a solid, vegetable fat based mixture used externally. They have the shortest life span of any herbal remedy and must be made fresh for every use.

Powdered herbs and tablets

Herbs that are dried and (sometimes) certain parts are separated out then diced to powder fine consistency. Powered matter can then be compressed or put in an empty pill coating to form a tablet

Herbal creams and ointments

An ointment usually is mixed with beeswax (or something similar) to make it more applicable to outside the body, such as on a cut or scrape.

Essential oils

Main articles: Essential oil

Extraction of volatile liquid plant materials and other aromatic compounds from plants gives essential oils. These plant oils may be used internally in some forms of herbal medicine as well as in aromatherapy and generally for their perfume, although their medicinal use as

a natural treatment (alternative medicine) has proved highly efficacious in the treatment of headache and muscle pain[6], joint pain[7] and certain skin diseases[8]

Herbal supplements

Herbal supplements tend to be commercial products in tablet or capsule form manufactured and marketed by the health food industry for sale in retail outlets to the general public, although there are some types that are sold only to healthcare practitioners for prescription. Herbal supplements are often standardized to contain stated levels of active phytochemicals. Some herbalists may not agree with the standardization of active ingredients, preferring instead to use the whole plant.

Examples of herbal medicine

There are hundreds of herbal remedies. An experienced practitioner can offer a comprehensive holistic approach to health. Examples of some commonly used herbal medicines:

- Artichoke and several other plants reduced total serum cholesterol levels in preliminary studies.[9]
- Black cohosh and other plants that contain phytoestrogens (plant molecules with estrogen activity) have some benefits for treatment of symptoms resulting from menopause.[10]
- Echinacea extracts limit the length of colds in some clinical trials, although some studies have found it to have no effect.[11]
- Garlic lowers total cholesterol levels, mildly reduces blood pressure, reduces platelet aggregation, and has antibacterial properties.[12]
- Grapefruit seed extract as a natural antimicrobial has minimal effectiveness as an anti-bacterial, anti-parasitic, and anti-fungal herb.[13][14][15][16][17]
- Nigella sativa (Black cumin) is a general medicinal plant used for diverse ailments such as cough, pulmonary infections, asthma, influenza, allergy, hypertension and stomach ache. The seeds are considered carminative, stimulant, diuretic and galactogogue. It is often taken with honey. Seed powder or oil is externally applied for eruptions of skin.
- Peppermint tea for problems with the digestive tract, including irritable bowel syndrome and nausea.
- Rauvolfia Serpentina, used extensively in India for sleeplessness, anxiety, and high blood pressure. The first proven allopathic medicine for high blood pressure was extracted from this herb.
- St John's wort, has yielded positive results, proving more effective than a placebo for the treatment of mild to moderate depression in some clinical trials.[18]
- Valerian root can be used to treat insomnia.

Dangers

A common misconception about herbalism and the use of 'natural' products in general, is that 'natural' equals safe. However many plants have chemical defence mechanisms against predators that can have adverse or lethal effects on humans. Examples are poison hemlock and nightshade, which can be deadly. Herbs can also have undesirable side-effects just as pharmaceutical products can. These problems are exacerbated by lack of control over dosage and purity. Furthermore, if given in conjunction with drugs, there is danger of 'summation', where the herb and the drug have similar actions and add together to make an 'overdose'. In animals, there are other dangers. There may be residues in food from farm animals (e.g. eggs, milk, meat) or danger of 'doping' in competition animals. The latter may also apply to human athletes.

Effectiveness

As noted above, there have been scientific studies which show that certain plant products can cure or prevent certain diseases, and these products or pharmaceutical drugs derived from them are patented by pharmaceutical companies and sold for high profit in modern Western medicine. Pharmaceutical firms argue that the individual should not have control over their health to the point of experimenting with "potentially hazardous materials".

Most herbal traditions have accumulated knowledge without modern scientific controls to distinguish between the placebo effect, the body's natural ability to heal itself, and the actual benefits of the herbs themselves. This is because most knowledge also pre-dates modern discoveries in human physiology and biochemistry. In fact, much knowledge dates back to medieval Europe, and was exterminated along with the witches during the burnings. Together the church and male-dominated 19th and 20th century medicine discredited much of this knowledge, and most has been lost.

There is a danger that herbal remedies will be used in place of other medical treatments which have been scientifically proven to be safe and effective, resulting in the development or worsening of a medical condition which could have been better prevented or treated. There is also a danger that an herbal remedy may itself cause harm which is unanticipated due to a lack of a full understanding of its composition and biochemical effects.

Name confusion

The common names of herbs (folk taxonomy) may not reflect differences in scientific taxonomy, and the same (or a very similar) common name might group together different plant species with different effects. For example, in 1993 in Belgium, in a TCM remedy for weight loss, one herb (Stephania tetrandra) was swapped for another (Aristolochia fangchi) whose name in Chinese was extremely similar but which contained higher levels of a renal toxin, aristolochic acid; this quid pro quo resulted in 105 cases of kidney damage. [19][20]

Standards and quality control

The legal status of herbal ingredients varies by country. For example, Ayurvedic herbal products may contain levels of heavy metals that are considered unsafe in the U.S., but heavy metals are considered therapeutic in Ayurvedic medicine.

In the United States, most herbal remedies are regulated as dietary supplements. Many herbs for home use can be grown in a small home garden too.

Medical interaction

In consultation with a physician, usage of herbal remedies should be clarified, as some herbal remedies have the potential to cause adverse drug interactions when used in combination with various prescription and over-the-counter pharmaceuticals. Dangerously low blood pressure may result from the combination of an herbal remedy that lowers blood pressure together with prescription medicine that has the same effect. In particular, many herbs should be avoided during pregnancy.[21] However, most herbal books alert the reader to necessary precautions.

Not all physicians may be familiar with the effects of different types of herbal medicine, but general practitioners should be able to refer patients to a specialist, or investigate the medical literature on their behalf.

List of medicinal herbs

Species - Common name (Properties)

Achillea millefolium - Yarrow (diaphoretic, astringent, tonic, stimulant, vulnerary)

***Allium sativum* - Garlic ()anti-microbial**

Anethum graveolens - Dill and Dill oil (carminative)

Artemisia absinthium L - Wormwood (tonic, stomachic, febrifuge, anti-parasitic)

Artemisia annua L. - Sweet sagewort

Arum Maculatum - Lords and Ladies (vulnerary - leaf used externally to draw out abcesses.)

Crataegus spp. - Hawthorn

Digitalis purpurea - Foxglove

Echinacea purpurea - Purple coneflower, and other species of Echinacea

Glycyrrhiza glabra - Liquorice

Hydrastis canadensis - Goldenseal

Hypericum perforatum - St. John's Wort

Marrubium vulgare - Horehound

Matricaria recutita (Chamomilla recutita) - Chamomile

Nepeta cataria - Catnip

Passiflora spp. - Passion-flower

Plantago spp. - Plantain and Psyllium

Salvia Stenophylla - Blue Mountain Sage

Symphytum officinale - Comfrey

Tanacetum parthenium (Chrysanthemum parthenium) - Feverfew

Taraxacum officinale - Dandelion

Tilia spp. - Lime Blossom

Urtica dioica - Urtica dioica

Valeriana officinalis - Valerian

Bay Laurel

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Laurales
Family: Lauraceae
Genus: Laurus
Species: *L. nobilis*
Binomial name *Laurus nobilis*

The *Bay Laurel* (Laurus nobilis, Lauraceae), also known as *True Laurel*, *Sweet Bay*, *Grecian Laurel*, *Laurel*, or *Bay Tree*, is an aromatic evergreen tree or large shrub reaching 10–18 m tall, native to the Mediterranean region.

The leaves are 6–12 cm long and 2–4 cm broad, with a characteristic finely serrated and wrinkled margin. It is dioecious, with male and female flowers on separate plants; each flower is pale yellow-green, about 1 cm diameter, borne in pairs together beside a leaf. The fruit is a small black berry about 1 cm long, containing a single seed.

Uses and symbolism

Bay Laurel is the source of the bay leaves which are used for their flavour in cooking. It was also the source of the laurel wreath of ancient Greece, and therefore the expression of "resting on one's laurels". A wreath of bay laurels was given as the prize at the Pythian Games. In the Bible, the sweet-bay is often an emblem of prosperity and fame. It is also the

source of the word baccalaureate (laurel berry), and of poet laureate and indeed the qualification used as an equivalent to the English A-Level.

Some evidence from the medical literature supports Bay Laurel having these uses:

- **Antioxidative:** Fitoterapia. 2003 Sep;74(6):613-6.
  - Analgesic and anti-inflammatory: Phytother Res. 2003 Aug;17(7):733-6.
  - Anticonvulsant (antiepileptic): Phytomedicine. 2002 Apr;9(3):212-6.

It is also widely cultivated as an ornamental plant in regions with mediterranean or oceanic climates, and as an indoor plant in colder regions.

Trivia

Bay laurel leaves are used in the design of the 10 yen coin in Japan.

In Greek mythology, the tree was first formed when the nymph Daphne changed into it to escape the pursing Olympian God Apollo.

Cardamom

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Liliopsida
Order: Zingiberales
Family: *Zingiberaceae*

Genera

Aframomum
Amomum
Elettaria

The name *cardamom* (sometimes written *cardamon*) is used for species within three genera of the ginger family Zingiberaceae, namely Elettaria, Amomum and Aframomum.

Types of cardamom and their distribution

The three main genera of the ginger family that are named as forms of cardamom are distributed as follows:

- *Elettaria* (commonly called cardamom, green cardamom, or true cardamom) is distributed from India to Malaysia.

- *Amomum* (commonly known as black cardamom, Kravan, Java cardamom, Bengal cardamom, Siamese cardamom, white or red cardamom) is distributed mainly in Asia and Australia.
- *Aframomum* (Madagascar cardamom, grains of paradise) is distributed in mainland Africa and Madagascar.

Uses

All the different cardamom species and varieties are used mainly as cooking spices and as medicines. In general,

- Elettaria subulatum (the usual type of cardamom) is used as a spice, a masticatory, and in medicine; it is also sometimes smoked; it is used as a food plant by the larva of the moth Endoclita hosei.
- Aframomum is used as a spice (see Grains of Paradise);
- Amomum is used as an ingredient in traditional systems of medicine in China, India, Korea, and Vietnam.
- Can be used as a traditional flavouring to Turkish coffee.

Uses in cuisines around the world

Cardamom has a strong, unique taste, with an intensely aromatic fragrance. It is often used in baking in Scandinavia. One of the most expensive spices by weight, little is needed to impart the flavour. Cardamom is best stored in pod form, because once the seeds are exposed or ground, they quickly lose their flavour. However, high-quality ground cardamom is often more readily (and cheaply) available, and is an acceptable substitute. For recipes requiring whole cardamom pods, a generally accepted equivalent is 10 pods equals 1½ teaspoons of ground cardamom.

In traditional medicine

In India, green cardamom (A. subulatum) is broadly used to treat infections in teeth and gums, to prevent and treat throat troubles, congestion of the lungs and pulmonary tuberculosis, inflammation of eyelids and also digestive disorders. It is also reportedly used as an antidote for both snake and scorpion venom.

Species in the genus Amomum is also used in traditional Indian medicine. Among other species, varieties and cultivars, Amomum villosum is used in traditional Chinese medicine to treat stomach-aches, constipation, dysentery, and other digestion problems. "Tsaoko" cardamom is cultivated in Yunnan, China, both for medicinal purposes and as a spice.

Liquorice

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Fabales
Family: Fabaceae
Subfamily: Faboideae

Tribe: Galegeae
Genus: Glycyrrhiza
Species: *G. glabra*

Binomial name Glycyrrhiza glabra

Liquorice or *licorice* (pronounced IPA: ['ljkY€zjƒ]) is the root of Glycyrrhiza glabra, from which a sweet flavour can be extracted. The liquorice plant is a legume (related to beans and peas) and native to southern Europe and parts of Asia. It is a herbaceous perennial, growing to 1 metre in height, with pinnate leaves about 7–15 centimetres (3–6 inches) long, with 9–17 leaflets. The flowers are 0.8–1.2 cm (1/3 to 1/2 inch) long, purple to pale whitish blue, produced in a loose inflorescence. The fruit is an oblong pod, 2–3 centimetres (about 1 inch) long, containing several seeds.

Cultivation and uses

Liquorice is grown as a root crop mainly in southern Europe. Very little commercial liquorice is grown in North America, where it is replaced by a related native species, American Licorice (G. lepidota), which has similar uses.

Liquorice extract is produced by boiling liquorice root and subsequently evaporating most of the water (in fact, the word 'liquorice' is derived from the Ancient Greek words for 'sweet root'). Liquorice extract is traded both in solid and syrup form. Its active principle is glycyrrhizin, a sweetener more than 50 times as sweet as sucrose which also has pharmaceutical effects. The related Chinese Liquorice (G. uralensis), which is used extensively in traditional Chinese medicine, contains this chemical in much greater concentration.

Culinary use

Liquorice flavour is found in a wide variety of liquorice candies. The most popular in the United Kingdom are very sweet Liquorice Allsorts. In continental Europe, however, far stronger, saltier candies are preferred. It should be noted, though, that in most of these candies the taste is reinforced by aniseed oil, and the actual content of liquorice is quite low. Additionally, liquorice is found in some soft drinks (such as root beer), and is in some herbal teas where it provides a sweet aftertaste. The flavour is common in medicines to disguise unpleasant flavours.

Liquorice is popular in Italy, particularly in the South, in its natural form. The root of the plant is simply dug up, washed and chewed as mouth-freshener. Throughout Italy unsweetened liquorice is consumed in the form of small black pieces made only from 100% pure liquorice extract; the taste is bitter and intense.

In Britain and The Netherlands in the past dried liquorice root was chewed as a sweet by youngsters.

Chinese cuisine uses liquorice as a culinary spice for savoury foods. It is often employed to flavour broths and foods simmered in soy sauce.

Other herbs and spices of similar flavour include Anise, star anise, tarragon, and fennel.

Medicinal use

Powdered liquorice root is an effective cough remedy (expectorant), and has been used for this purpose since ancient times, especially in ayurvedic medicine where it is also used in tooth powders. Modern cough syrups often include liquorice extract as an ingredient. Additionally, licorice may be useful for both mouth ulcers and peptic ulcers. Naturopathic medicinal uses include treatment of peptic and oral ulcers.

Liquorice is also a mild laxative. Large doses of glycyrrhizinic acid and glycyrrhetinic acid in liquorice extract can lead to hypokalemia and serious increases in blood pressure, a syndrome known as apparent mineralocorticoid excess. These side effects stem from the inhibition of the enzyme 11^2-hydroxysteroid dehydrogenase (type 2) and subsequent increase in activity of cortisol on the kidney. 11^2-hydroxysteroid dehydrogenase normally inactivates cortisol in the kidney; thus, licorice's inactivation of this enzyme makes the concentration of cortisol appear to increase. Cortisol acts at the same receptor as the hormone aldosterone in the kidney; thus, the effects mimic aldosterone excess, although aldosterone remains low or normal during licorice overdose. Cortisol does not actually increase either; however, its activity in the kidney effectively increases due to the disabling of this enzyme. To decrease the chances of these serious side effects, deglycyrrhizinated licorice (DGL) preparations are available.

Licorice affects the body's endocrine system. It can lower the amount of serum testosterone, but whether it affects the amount of free testosterone is unclear. A PubMed search for *licorice AND testosterone* will provide additional information.

The disabling of similar enzymes in the gut by glycyrrhizinic acid and glycyrrhetinic acid also causes increased mucus and decreased acid secretion. Thus, licorice may in moderate amounts soothe an upset stomach and is used as an aid for healing stomach ulcers.

Recently, a study is being conducted by clinical psychologist Hunna Watson into the therapeutic potential of liquorice on people with mood disorders.

Papaya

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Brassicales
Family: Caricaceae
Genus: Carica
Species: *C. papaya*

Binomial name *Carica papaya*

The *papaya*, also known as *mamão*, *tree melon*, *fruta bomba*, *lechosa* (Venezuela, Puerto Rico, and the Dominican Republic), or *pawpaw* is the fruit of the tree Carica papaya, in the genus Carica.

It is a small unbranched tree, the single stem growing to 5-10 m tall, with the spirally arranged leaves confined to the top of the trunk; the lower trunk is conspicuously scarred with the leaf scars of where older leaves and fruit were borne. The leaves are large, 50-70 cm diameter, deeply palmately lobed with 7 lobes. The flowers are produced in the axils of the leaves, maturing into the large 15-45 cm long, 10-30 cm diameter fruit. The fruit is ripe when it feels soft (like a ripe avocado or a bit softer) and its skin has attained an amber to orange hue.

Cultivation and uses

Originally from southern Mexico, Central America and northern South America, the papaya is now cultivated in most countries with a tropical climate like India and the Philippines.

The primary use of the papaya is as an edible fruit. It is usually eaten raw, without the skin or seeds. The unripe green fruit of papaya can be eaten cooked usually in curries, salads and stews.

Papaya is rich in an enzyme called papain (a protease which is useful in tenderizing meat) and other proteins. Its utility is in breaking down the tough meat fibers and it has been utilized for thousands of years in its native South America. It is included as a component in powdered meat tenderizers. Papaya enzyme is also marketed in tablet form to remedy digestive problems. Caution should be taken when harvesting, as papaya is known to release a latex fluid when not quite ripe, which can cause irritation and provoke allergic reaction in some people. The papaya fruit and leaves also contains carpaine, an anthelmintic alkaloid which could be dangerous in high doses.

Women in India and Sri Lanka and other parts of the world have long used papaya as a folk remedy for contraception and abortion. Medical research in animals has confirmed the contraceptive and abortifacient capability of papaya, and also found that papaya has contraceptive effects in men as well. Unripe papaya is especially effective, in large amounts or high doses. Papaya is not teratogenic and will not cause miscarriage in small, ripe amounts. Phytochemicals in papaya may suppress the effects of Progesterone. [1]

The black seeds are edible, and have a sharp, spicy taste. They are sometimes ground up and used as a substitute for black pepper. In some parts of Asia the young leaves of papaya are steamed and eaten like spinach.

Excessive consumption of papaya, like of carrots, can cause carotenemia, the yellowing of soles and palms which is otherwise harmless.

Castor oil plant

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Malpighiales
Family: Euphorbiaceae
Subfamily: Acalyphoideae
Tribe: Acalypheae
Subtribe: *Ricininae*
Genus: *Ricinus*
Species: *R. communis*

Binomial name Ricinus communis

The *Weed plant* (Ricinus communis) is a plant species of the Euphorbiaceae and the sole member of the genus *Ricinus* and of the subtribe *Ricininae*. It is the origin of the *castor bean* which, despite its name, is not a true bean. The name Ricinus is a Latin word for tick; the seed is so named because it has markings and a bump at the end which resemble certain ticks. It is the source of castor oil, which has a wide variety of uses, and ricin, a poison (the ricin from 1-2 seeds can kill an adult).

Although castor is probably indigenous to Eastern Africa, today castor is distributed worldwide. Castor establishes itself easily as a "native" plant and can often be found on wasteland, near railroads and has recently also been used extensively as decorative plant in parks and other public areas.

Castor seeds have been found in Egyptian tombs dating back to 4000 BC. Herodotus and other Greek travellers have noted the use of castor seed oil for lighting and body anointments.

The use of castor seed oil in India has been documented since 2000 BC for use in lamps and in local medicine as a laxative. Castor seed and its oil have also been used in China for centuries, mainly prescribed in local medicine for internal use or use in dressings.

Although monotypic, the castor plant can vary greatly in its growth habit and appearance. Some castor plants are perennials which can take weed the size of small trees, and other plants are dwarf types and are grown as annuals. There also exists an enormous variation in leaf shape and colouring which has led to a selection by breeders for use as ornamental plants. Castor is used as a food plant by the larvae of some Lepidoptera species including Giant Leopard Moth, Hypercompe hambletoni and The Nutmeg.

Scanning electron microscope image

Castor seed contains between 40% and 60% oil that is rich in triglycerides, mainly ricinolein.

Global castor seed production is around 1 million tons per year. Leading producing areas are India, China and Brazil. There are several active breeding programmes.

Dandelion

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Asterales
Family: Asteraceae
Genus: *Taraxacum*

A *dandelion* is a short plant, usually with a yellow flower head and notched leaves. A dandelion flower head consists of many tiny flowers. The dandelion is native to Europe and Asia, and has spread to many other places. The dandelion is also known by its generic name Taraxacum. In Northern areas and places where the dandelion is not native, it reproduces asexually.

Detailed Description

Dandelion (*Taraxacum*) is a large genus of flowering plants in the family Asteraceae. They are tap-rooted biennial or perennial herbaceous plants, native to temperate areas of the Northern Hemisphere of the Old World.

The genus is taxonomically very complex, with numerous macrospecies, and polyploidy is also common; over 250 species have been recorded in the British Isles alone (Richards 1972). Some botanists take a much narrower viewpoint, and only accept a total of about 60 species.

The leaves are 5-25 cm long, simple and basal, entire or lobed, forming a rosette above the central taproot. As the leaves grow outward they push down the surrounding vegetation, such as grass in a lawn, killing the vegetation by cutting off the sunlight. A bright yellow flower head (which is open in the daytime but closes at night) is borne singly on a hollow stem (scape) which rises 4-30 cm above the leaves and exudes a milky sap (latex) when broken. A rosette may produce several flowering stems at a time. The flower head is 2-5 cm in diameter and consists entirely of ray florets.

Dandelions are used as food plants by the larvae of some species of Lepidoptera. [1]

Away from their native regions, they have become established in the Americas, Australia and New Zealand as weeds. They are now common plants throughout all temperate regions.

The Dandelion Clock

The flower matures into a globe of fine filaments that are usually distributed by wind, carrying away the seed-containing achenes. This globe (receptacle) is called the "dandelion clock", and blowing it apart is a popular pastime for children. In German it's called a Pusteblume, translated as "blow flower". The number of blows required to completely rid the clock of its seeds is deemed to be the time of day.

The Seeds

The flower head is surrounded by bracts (sometimes mistakenly called sepals) in two series. The inner bracts are erect until the seeds mature, then flex down to allow the seeds to disperse; the outer bracts are always reflexed downward. Some species drop the "parachute" (called a pappus, modified sepals) from the achenes. Between the pappus and the achene, there is a stalk called beak, which elongates as the fruit matures. The beak breaks off from the achene quite easily.

Name

The name dandelion is derived from the Old French, dent-de-lion, which is literally "lion's tooth", referring to the sharply-lobed leaves of the plant. The English spelling reflects the French pronunciation at the time this French word was absorbed into English. The first written usage of the word occurs in an "herbal" dated 1373, but there is a 1363 document in which the word "dandelion" was used as a proper name (Willelmus Dawndelyon).

In German, the dandelion is called Löwenzahn, which is also translated as "lion's tooth." In modern French the plant is called pissenlit, which means "urinate in bed", apparently referring to its diuretic properties. Likewise, "pissabeds" is an English folkname for this plant, and "piscialletto" is one of its folknames in Italian (with "dente di leone", meaning "lion's tooth"). Similarly in Spanish, it is known as the "meacamas", but also commonly "diente de león".

Selected species

- Taraxacum officinale (syn. T. vulgare), Common Dandelion. Found in many forms, but differs at least from the following species:
 Taraxacum albidum, a white-flowering Japanese dandelion.
 Taraxacum japonicum, Japanese dandelion. No ring of smallish, downward-turned leaves under the flowerhead.
 Taraxacum laevigatum (syn. T. erythrospermum), Red-seeded Dandelion; achenes reddish brown and leaves deeply cut throughout length. Inner bracts' tips are hooded.

Seed development and genetics

As aforementioned, the taxonomical situation of the genus is quite complex, mainly because many dandelions are genetically triploid. An odd number of chromosomes usually is associated with sterility, but dandelions with this karyotype can reproduce without fertilization, a process called apomixis[2]. In these individuals flowers are useless vestigial structures, although they may still produce a small percentage of fertile pollen, keeping some genetic contact with sexual individuals. Diploid dandelions develop seeds after cross-pollination and are self-incompatible. In most zones of southern Europe and Asia, dandelion populations are sexual or mixed sexual-apomictic, while in northern countries only triploid and tetraploid apomicts are present, as is in the zones where it is not native. This seems to be linked to higher temperatures, survival of pre-glacial populations and human impact, but the subject is still being studied.

There are usually 54 to 172 seeds produced per head, but a single plant can produce more than 2000 seeds a year. It has been estimated that more than 97 000 000 seeds/hectare could be produced every year by a dense stand of dandelions.

Uses

While the dandelion is considered a weed by many gardeners, the plant does have several culinary and medicinal uses. Dandelions are grown commercially at a small scale as a leaf vegetable. The plant can be eaten cooked or raw in various forms, such as in soup or salad. They are probably closest in character to mustard greens. Usually the young leaves and unopened buds are eaten raw in salads, while older leaves are cooked. Raw leaves have a slightly bitter taste. Dandelion salad is often accompanied with hard boiled eggs. The leaves are high in vitamin A, vitamin C and iron, carrying more iron and calcium than spinach.[3]

Dandelion flowers can be used to make dandelion wine. The recipe usually contains citrus fruit. Another recipe using the plant is dandelion flower jam. Ground roasted dandelion root can be used as a coffee substitute. Drunk before meals, it is believed to stimulate digestive functions. Sold in most health food stores, often in a mixture, it is considered an excellent cleansing tonic for the liver.

Dandelion root is a registered drug in Canada, sold as a diuretic. A leaf decoction can be drunk to "purify the blood", for the treatment of anemia, jaundice, and also for nervousness. The milky latex has been used as a mosquito repellent; the milk is also applied to warts, helping get rid of them without damaging the surrounding skin. A dye can also be obtained from the roots of the plant. A new mixture of roasted roots is sold as a product called DandyBlend which tastes like coffee after the inulin in the dandelion is roasted.

"Dandelion and Burdock" is a soft drink that has long been popular in the United Kingdom with authentic recipes are sold by health food shops, but it is not clear whether the cheaper supermarket versions actually contain either plant.

This plant also is useful in farming, because its deep, strong roots break up hardpan.

Antioxidant Properties of Dandelion

Dandelion contains Luteolin, an antioxidant, and has demonstrated antioxidant properties without cytotoxicity.

Chun Hu and David D. Kitts. Food, Nutrition and Health, Faculty of Agricultural Sciences, University of British Columbia, Vancouver, BC, Canada. October 2004. Luteolin and luteolin-7-O-glucoside from dandelion flower suppress iNOS and COX-2 in RAW264.7 cells. Springer Netherlands. *245*:1-2(107-113).

Caffeic Acid and Carcinogenicity

Caffeic acid is a secondary plant metabolite produced in dandelion, yarrow, horsetail and whitethorn. Despite its name, it is totally unrelated to caffeine. Recent studies have revealed this acid may be carcinogenic. Caffeic acid was tested for carcinogenicity by oral administration in mice, it produced renal cell adenomas in females, and a high incidence of renal tubular cell hyperplasia in animals of each sex.[4]

False Dandelions

Dandelions are so similar to catsears (Hypochoeris) that catsears are also known as "false dandelions". Both plants carry similar flowers which form into windborne seeds. However, catsear flowering stems are forked and solid, whereas dandelions possess unforked stems that are hollow. Both plants have a rosette of leaves and a central taproot. However, the leaves of dandelions are jagged in appearance, whereas those of catsear are more lobe-shaped and hairy.

Other plants with similar flowers include hawkweeds (Hieracium) and hawksbeards (Crepis). These are both readily distinguished by their branched flowering stems.

Echinacea

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Asterales
Family: Asteraceae
Tribe: Heliantheae
Genus: *Echinacea*

Echinacea is a genus of nine species of flowering plants in the Family Asteraceae, all native to eastern North America.

The genus name is from the Greek echino, meaning "spiny", due to the spiny central disk. They are herbaceous, drought-tolerant perennial plants growing to 1 or 2 m in height. The leaves are lanceolate to elliptic, 10-20 cm long and 1.5-10 cm broad. Like all Asteraceae, the flowers are a composite inflorescence, with purple (rarely yellow or white) florets arranged in a prominent, somewhat cone-shaped head; "cone-shaped" because the petals of the outer ray florets tend to point downward (are reflexed) once the flower head opens, thus forming a cone.

The species of Echinacea are:

- Echinacea angustifolia - Narrow-leaf Coneflower
Echinacea atrorubens - Topeka Purple Coneflower
Echinacea laevigata - Smooth Coneflower, Smooth Purple Coneflower
Echinacea pallida - Pale Purple Coneflower
Echinacea paradoxa - Yellow Coneflower, Bush's Purple Coneflower
Echinacea purpurea - Purple Coneflower, Eastern Purple Coneflower
Echinacea sanguinea - Sanguin Purple Coneflower
Echinacea simulata - Wavyleaf Purple Coneflower
Echinacea tennesseensis - Tennessee Coneflower

Uses

Some species of Echinacea, notably E. purpurea, E. angustifolia, and E. pallida, are grown as ornamental plants in gardens. It tolerates a wide variety of conditions, maintains attractive foliage throughout the season, and multiplies rapidly. Appropriate species are used in prairie restorations. Some species are used by domestic stock for forage; an abundance of these plants on rangeland supposedly indicates "good health".

Echinacea rhizome was used by North American Plains Indians, perhaps more than most other plants, for various herbal remedies. In the 1930's "Echinacea" became popular in both Europe and America as a herbal medicine. Echinacea has been attributed with the ability to boost the body's immune system and ward off infections, particularly the common cold. Depending on which species is used, herbal medicinals can be prepared from the above-

ground parts and/or the root. It is not known which of echinacea's many chemical components might be responsible for its touted health benefits, although all species possess compounds of a chemical class called phenols (as do most other plants). Cichoric and caftaric acids are phenols that are present in E. purpurea; echinacoside is a phenol found in higher levels within E. angustifolia and E. pallida roots. When making herbal remedies, these phenols can serve as markers to evaluate the quantity of echinacea in the product. Other constituents that may be important include alkamides and polysaccharides.

A medical study (Taylor et al. 2003[1].) demonstrated that echinacea products made from the entire plant (not just the root), and taken after the second cold symptom appeared, provided no measurable beneficial effect for children in treating the severity or duration of symptoms caused by the common cold virus. Studies by the University of Virginia School of Medicine (Turner, 2005 [2]) confirmed these results, and added that Echinacea had no clinically significant effects on the common cold even if taken immediately upon infection, or as a prophylaxis starting a week prior to symptoms of infection. However, a University of Maryland review of available studies concluded that Echinacea, when taken at first sign of a cold, reduced cold symptoms or shortened their duration. This conclusion was based on 13 European studies. The University of Maryland also found that three of four studies concluded that taking Echinacea to prevent a cold was ineffective. Echinacea may, however, be useful when treating Athlete's foot with Econazole, or in cancer treatment[3]

Echinacea herbals should not be taken by persons with progressive systemic and auto-immune disorders such as tuberculosis, leicosis, connective tissue disorders, collagenosis, and related diseases such as lupus erythematosus, according to the German Kommission E. Its use in AIDS or against opportunistic infections in AIDS patients is controversial: the Kommission E recommend against it, but this seems to be on theoretical rather than clinical grounds [4]. It should not be used with other known hepatotoxic drugs such as anabolic steroids, amiodarone (Pacerone® or Cordarone®), methotrexate, or ketoconazole (Nizoral®). [5].

Eucalyptus

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Myrtales
Family: Myrtaceae
Genus: *Eucalyptus*

Species About 700

Eucalyptus is a diverse genus of trees (and a few shrubs), the members of which dominate the tree flora of Australia. There are more than 700 species of Eucalyptus, mostly native to Australia, with a very small number found in adjacent parts of New Guinea and Indonesia and one as far north as the Philippines. Eucalyptus can be found in almost every part of the Australian continent, adapted to all of its climatic conditions; in fact, no other continent is so characterised by a single genus of tree as Australia is by eucalyptus. Many, but far from all, are known as *gum trees*; other names for various species include *mallee*, *box*, *ironbark*, *stringybark*, and *ash*.

Description

Flowers and leaves

The most readily recognisable characteristics of Eucalyptus species are the distinctive flowers and fruits. The name Eucalyptus, from the Greek words eu-, well, and kaluptos, cover, meaning "well-covered", describes the bud cap (botanically called an operculum). This cap forms from modified petals and falls off as the flower opens. Thus flowers have no petals, decorating themselves instead with many showy stamens. The woody fruits, known as gumnuts, are roughly cone-shaped and have valves at the end which open to release the seeds.

Nearly all eucalypts are evergreen but some tropical species lose their leaves at the end of the dry season. As in other members of the Myrtle family, eucalypt leaves are covered with oil glands. The copious oils produced are an important feature of the genus. Eucalypts also exhibit leaf dimorphism. When young, their leaves are opposite, oval to roundish, and occasionally without a petiole. When one to a few years old, the leaves become alternate, lanceolate to falcate (sickle-shaped), quite slender and pendulous with longer petioles. The adult leaves of most species, as well as the juvenile leaves of some, are the same on both sides, lacking the distinction between upper and lower surfaces shown by the leaves of most plants. Most species do not flower until adult foliage starts to appear; E. cinerea and E. perriniana are notable exceptions.

Bark

The bark dies annually and species can be roughly grouped based on its appearance. In smooth-barked trees most of the bark is shed, leaving a smooth surface that is often colourfully mottled. With rough-barked trees the dead bark persists on the tree and dries out. Many trees, however, have smooth bark at the top but rough bark on the trunk or its bottom. The types of rough bark is often used to broadly label a group of eucalypts.

They are:

- *Stringybark* - consists of long-fibres and can be pulled off in long pieces. It is usually thick with a spongy texture.
- *Ironbark* - is hard, rough and deeply furrowed. It is soaked with dried kino (a sap exuded by the tree) which gives a dark red or even black colour.
- *Tessellated* - bark is broken up into many distinct flakes. They are corkish and can flake off.
- *Box* - has short fibres. Some also show tessellation.
- *Ribbon* - this has the bark coming off in long thin pieces but still loosely attached in some places. They can be long ribbons, firmer strips or twisted curls.

Related genera

A small genus of similar trees, Angophora, has also been known since the 18th century. In 1995 new evidence, largely genetic, indicated that some prominent eucalypt species were actually more closely related to Angophora than to the other eucalypts; they were split off into the new genus Corymbia. Although separate, the three groups are allied and it remains acceptable to refer to the members of all three genera Angophora, Corymbia and Eucalyptus as "eucalypts". The coolibah trees, referred to in Waltzing Matilda, are eucalypts E. coolabah and E. microtheca.

Tall timber

Today, specimens of the Australian Mountain Ash, Eucalyptus regnans, are among the tallest trees in the world at up to 92 metres in height [1] and the tallest of all flowering plants; taller trees such as the Coast Redwood are all conifers. There is credible evidence however that at the time of European settlement of Australia some Mountain Ash were indeed the tallest plants in the world.

Tolerance

Most eucalypts are not tolerant of frost, or only tolerate light frosts down to -3°C to -5°C; the hardiest, are the so-called Snow Gums such as Eucalyptus pauciflora which is capable of withstanding cold and frost down to about -20°C. Two sub-species, E. pauciflora niphophila and E. pauciflora debeuzevillei in particular are even hardier and can tolerate even quite severe continental type winters.

Several other species, especially from the high plateau and mountains of central Tasmania such as E. coccifera, E. subcrenulata, and E. gunnii have produced extreme cold hardy forms and it is seed procured from these genetically hardy strains that are planted for ornament in colder parts of the world.

Animal relationships

An essential oil extracted from eucalypt leaves contains compounds that are powerful natural disinfectants and which can be toxic in large quantities. Several marsupial herbivores, notably koalas and some possums, are relatively tolerant of it. The close correlation of these oils with other more potent toxins called formylated phloroglucinol compounds allows koalas and other marsupial species to make food choices based on the smell of the leaves. However, it is the formylated phloroglucinol compounds that are the most important factor in choice of leaves by koalas.

Eucalypts support the larvae of a number of Lepidoptera species.

Hazards

Eucalypts have a habit of dropping entire branches off as they grow. Eucalyptus forests are littered with dead branches. The Australian Ghost Gum Eucalyptus papuana is also termed the "widow maker", due to the high number of pioneer tree-felling workers who were killed by falling branches. Many deaths were actually caused by simply camping under them, as they shed whole and very large branches to conserve water during periods of drought. For this reason, one should never camp under an overhanging branch. This may be the real reason behind the drop bear story told to children - the idea is to keep them away from being under dangerous branches.

Fire

On warm days vapourised eucalyptus oil rises above the bush to create the characteristic distant blue haze of the Australian landscape. Eucalyptus oil is highly flammable (trees have been known to explode) and bush fires can travel easily through the oil-rich air of the tree crowns. The dead bark and fallen branches are also flammable. Eucalypts are well adapted for periodic fires, in fact most species are dependent on them for spread and regeneration, both from reserve buds under the bark, and from fire-germinated seeds sprouting in the ashes.

Eucalypts originated between 35 and 50 million years ago, not long after Australia-New Guinea separated from Gondwana, their rise coinciding with an increase in fossil charcoal deposits (suggesting that fire was a factor even then), but they remained a minor component of the Tertiary rainforest until about 20 million years ago when the gradual drying of the continent and depletion of soil nutrients led to the development of a more open forest type, predominantly Casuarina and Acacia species. With the arrival of the first humans about 50 thousand years ago, fires became much more frequent and the fire-loving eucalypts soon came to account for roughly 70% of Australian forest.

Eucalypts regenerate quickly after fire. After the Canberra bushfires of 2003, hectares of imported species were killed, but in a matter of weeks the gum trees were putting out suckers and looking generally healthy.

The two valuable timber trees, Alpine Ash E. delegatensis and Mountain Ash E. regnans, are killed by fire and only regenerate from seed. The same fire that has had little impact on forests around Canberra has resulted in thousands of hectares of dead ash forests. There has been some debate as to whether to leave the stands, or attempt to harvest the mostly undamaged timber.

Cultivation and uses

Eucalypts have many uses which have made them economically important trees. Perhaps the Karri and the Yellow box varieties are the best known. Due to their fast growth the foremost benefit of these trees is the wood. They provide many desirable characteristics for use as ornament, timber, firewood and pulpwood. Fast growth also makes eucalypts suitable as windbreaks.

Eucalypts draw a tremendous amount of water from the soil through the process of transpiration. They have been planted (or re-planted) in some places to lower the water table and reduce soil salination. Eucalypts have also been used as a way of reducing malaria by draining the soil in Algeria, Sicily[2] and also in Europe and California[3]. Drainage removes swamps which provide a habitat for mosquito larvae, but such drainage can also destroy ecologically productive areas.

Eucalyptus oil is readily steam distilled from the leaves and can be used for cleaning, deodorising, and in very small quantities in food supplements; especially sweets, cough drops and decongestants.

The nectar of some eucalyptus produces high quality monofloral honey. In the western United States the flowering is in late January, before the flowering of commercial nut and fruit trees, thus it is easily segragated and the honey produced has a flavour described as "buttery .

The ghost gum's leaves were used by Aborigines to catch fish. Soaking the leaves in water releases a mild tranquiliser which stuns fish temporarily.

Eucalyptus is also used to make the digeridoo, a musical wind instrument made popular by the Aborigines of Australia.

Plantation and ecological problems

Eucalyptus were first introduced to the rest of the world by Sir Joseph Banks, botanist on the Cook expedition in 1770. They have subsequently been introduced to many parts of the world, notably California, Brazil, Morocco, Portugal, South Africa, Israel and Galicia. Several species have become invasive and are causing major problems for local ecologies. In Spain, they have been planted in pulpwood plantations, replacing native oak woodland. As in other such areas, while the original woodland supports numerous species of native animal life (insects, birds, salamanders, etc.), the eucalypt groves are inhospitable to the local wildlife which is not adapted to them, leading to silent forests and the decline of wildlife populations.

On the other hand, eucalyptus are the basis for several industries, such as sawmilling, pulp, charcoal and others.

California

In the 1850s many Australians traveled to California to take part in the California Gold Rush. Much of California has similar climate to parts of Australia and some people got the idea of introducing eucalyptus. By the early 1900s thousands of acres of eucalyptus were planted with the encouragement of the state government. It was hoped that they would provide a renewable source of timber for construction and furniture making. However this did not happen partly because the trees were cut when they were too young and partly because the Americans did not know how to process the cut trees to prevent the wood from twisting and splitting.

One way in which the eucalyptus, mainly the blue gum E. globulus, proved valuable in California was in providing windbreaks for highways, orange groves, and other farms in the mostly treeless central part of the state. They are also admired as shade and ornamental trees in many cities and gardens.

Eucalyptus forests in California have been criticized because they drive out the native plants and do not support native animals. Fire is also a problem. The 1991 Oakland Hills firestorm which destroyed almost 3,000 homes and killed 25 people was partly fueled by large numbers of eucalyptus in the area close to the houses

In some parts of California eucalyptus forests are being removed and native trees and plants restored. Individuals have also illegally destroyed some trees and are suspected of introducing insect pests from Australia which attack the trees.

Flax

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Malpighiales
Family: Linaceae

Genus: Linum
Species: *L. usitatissimum*

Binomial name Linum usitatissimum

Flax (also known as *Common Flax* or *Linseed*) is a member of the genus Linum in the family Linaceae. The *New Zealand flax* is unrelated. Flax originated in India and was first domesticated in the Fertile Crescent. [1]

It is an erect annual plant growing to 120 cm tall, with slender stems. The leaves are glaucous green, slender lanceolate, 2-4 cm long and 3 mm broad. The flowers are pure pale blue, 1.5-2.5 cm diameter, with five petals. The fruit is a round, dry capsule 5-9 mm diameter, containing several glossy brown seeds shaped like an apple pip, 4-7 mm long.

In addition to the plant itself, flax may refer to the unspun fibres of the flax plant.

Uses

Flax is grown both for seed and for fibre. Various parts of the plant have been used to make fabric, dye, paper, medicines, fishing nets and soap. It is also grown as an ornamental plant in gardens, as flax is one of the few plant species that is capable of producing truly blue flowers (most "blue" flowers are really shades of purple), although not all flax varieties produce blue flowers.

Flax seed

The seeds produce a vegetable oil known as linseed oil or flaxseed oil. It is one of the oldest commercial oils and solvent-processed flax seed oil has been used for centuries as a drying oil in painting and varnishing. Flax seeds come in two basic varieties; brown and yellow (also referred to as golden). Although brown flax can be consumed and has been for thousands of years, it is better known as an ingredient in paints, fibre and cattle feed. Brown and yellow flax have similar nutritional values and equal amounts of short-chain omega-3 fatty acids. The exception is a type of yellow flax called solin which is very low in omega-3 and has a completely different oil profile. A number of studies have shown that people have a very hard time absorbing the Omega-3 from flaxseed oil compared to oily fish (see Fish and plants as a source of Omega-3 for more).

A North Dakota State University research project led to the creation of a new variety of the yellow flax seed called "Omega"[2]. This new variety was created primarily as a food source and has a more pleasant nutty-buttery flavour than the brown variety and retains a comparable level of the beneficial Omega-3 oil.

One tablespoon of ground flax seeds and three tablespoons of water may serve as a replacement for one egg in baking by binding the other ingredients together, and ground flax seeds can also be mixed in with oatmeal, yogurt, water (similar to Metamucil), or any other food item where a nutty flavour is appropriate. Flaxseed oil is most commonly consumed with salads or in capsules. Flax seed owes its nutritional benefits to lignans and omega-3 essential fatty acids. Omega-3s, often in short supply in populations with low-fish diets, promote heart health by reducing cholesterol, blood pressure and plaque formation in

arteries. In addition, flaxseed oil is often recommended as a galactagogue. Lignans benefit the heart and possess anti-cancer properties: A series of research studies by Lilian U. Thompson and her colleagues at the Department of Nutritional Science of the University of Toronto have reported that flaxseed can have a beneficial effect in reducing tumour growth in mice, particularly the kind of tumour found in human post-menopausal breast cancer. The effects are thought to be due to the lignans in flaxseed, and are additive with those of tamoxifen, the currently standard drug treatment for these cancers. Initial studies suggest that flaxseed taken in the diet have similar beneficial effects in human cancer patients. Reports that flaxseed is beneficial in other cancers, e.g. prostate cancer, are less numerous but promising.

Flax seed sprouts are edible, with a slightly spicy flavour.

Flax fibre

Flax fibres are amongst the oldest fibre crops in the world. The use of flax for the production of linen goes back 5000 years. Pictures on tombs and temple walls at Thebes depict flowering flax plants. The use of flax fibre in the manufacturing of cloth in northern Europe dates back to pre-Roman times. In North America, flax was introduced by the Pilgrim fathers. Currently most flax produced in the USA and Canada are seed flax types for the production of linseed oil or flaxseeds for human nutrition.

Flax fibre is extracted from the bast or skin of the stem of flax plant. Flax fibre is soft, lustrous and flexible. It is stronger than cotton fibre but less elastic. The best grades are used for linen fabrics such as damasks, lace and sheeting. Coarser grades are used for the manufacturing of twine and rope. Flax fibre is also a raw material for the high-quality paper industry for the use of printed banknotes and rolling paper for cigarettes.

Cultivation

The major fibre flax-producing countries are the former USSR, Poland, France, Belgium, Ireland, and the Czech Republic.

The soils most suitable for flax, besides the alluvial kind, are deep friable loams, and containing a large proportion of organic matter. Heavy clays are unsuitable, as are soils of a gravelly or dry sandy nature.

Flax is harvested for fibre production when still green, before seed maturation as the fibre starts to degrade later; it is pulled up with the roots (not cut), so as to maximise the fibre length. Immediately after harvesting, it is put in water to soak (retting) to rot off the non-fibrous material in the stems. Retting takes 7-12 days, depending on temperature.

Flax grown for seed is allowed to mature until the seed capsules are yellow and just starting to split; it is then harvested by combine harvester and dried to extract the seed.

Threshing flax

The process is divided into two parts: the first part is intended for the farmer, or flax-grower, to bring the flax into a fit state for general or common purposes. This is performed

by three machines: one for threshing out the seed, one for breaking and separating the wood from the fibre, and one for further separating the broken wood and matter from the fibre. In some cases the farmers will perhaps thrash out the seed in their own mill and therefore, in such cases, the first machine will be, of course, unnecessary.

The second part of the process is intended for the manufacturer to bring the flax into a state for the very finest purposes, such as lace, cambric, damask, and very fine linen. This second part is performed by the refining machine only.

The threshing process would be conducted as follows:

- Take the flax in small bundles, as it comes from the field or stack, and holding it in the left hand, put the seed end between the threshing machine and the bed or block against which the machine is to strike; then take the handle of the machine in the right hand, and move the machine backward and forward, to strike on the flax, until the seed is all threshed out.
- Take the flax in small handfuls in the left hand, spread it flat between the third and little finger, with the seed end downwards, and the root-end above, as near the hand as possible.
- Put the handful between the beater of the breaking machine, and beat it gently till the three or four inches, which have been under the operation of the machine, appear to be soft.
- Remove the flax a little higher in the hand, so as to let the soft part of the flax rest upon the little finger, and continue to beat it till all is soft, and the wood is separated from the fibre, keeping the left hand close to the block and the flax as flat upon the block as possible.
- The other end of the flax is then to be turned, and the end which has been beaten is to be wrapped round the little finger, the root end flat, and beaten in the machine till the wood is separated, exactly in the same way as the other end was beaten.

Trivia

- Common flax is the national flower of Belarus.
- Flax is the emblem of the Northern Ireland Assembly.
- The flax plant appeared on the reverse of the UK one pound coin to represent Northern Ireland on coins minted in 1986 and 1991.
- In English, blond hair is traditionally referred to as "fair" or "flaxen".

Ginger

Zingiber officinale
Conservation status: Secure

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Liliopsida
Order: Zingiberales
Family: Zingiberaceae
Genus: Zingiber
Species: *Z. officinale*

Binomial name: Zingiber officinale, Roscoe

Though called a root, it is actually the rhizome of the monocotyledonous perennial plant Zingiber officinale.

Originating in southern China, cultivation of ginger spread to India, Southeast Asia, West Africa, and the Caribbean.[1]

The English word ginger is etymologically related to the Tamil iñci (‡žÍš¿), having been borrowed into Indo-European languages from a Dravidian language. [2]

Chemistry

Ginger contains up to 3% of an essential oil that causes the fragrance of the spice. The main constituents are sesquiterpenoids with (-)-zingiberene as the main component. Lesser amounts of other sesquiterpenoids (^{2}-sesquiphellandrene, bisabolene and farnesene) and a small monoterpenoid fraction (^{2}-phelladrene, cineol, and citral) have also been identified.

The pungent taste of ginger is due to nonvolatile phenylpropanoids (particularly gingerol and zingerone) and diarylheptanoids (gingeroles and shoagoles); the latter are more

pungent and form from the former when ginger is dried. Cooking ginger transforms gingerol into zingerone, which is less pungent and has a spicy-sweet aroma.[3] None of these pungent chemicals are related to capsaicin, the principal hot constituent of chile pepper.

Culinary uses

Young ginger roots are juicy and fleshy with a very mild taste. They are often pickled in vinegar or sherry as a snack or just cooked as an ingredient in many dishes. They can also be stewed in boiling water to make ginger tea, to which honey is often added as a sweetener. Mature ginger roots are fibrous and nearly dry. The juice from old ginger roots is extremely potent and is often used as a spice in Chinese cuisine to flavor dishes that incorporate certain meats like seafood and mutton.

Ginger is also candied, is used as a flavoring for candy, cookies, crackers and cake, and is the main flavor in ginger ale, a sweet, carbonated, non-alcoholic beverage, as well as the similar, but somewhat spicier beverage ginger beer. A ginger-flavored liqueur called Canton is produced in the Guangdong province of China; it is advertised to be based on a recipe created for the rulers of the Qing Dynasty and made from six different varieties of ginger. Green ginger wine is a ginger flavoured wine produced in the United Kingdom by Crabbie's and Stone's and traditionally sold in a green glass bottle. Ginger is also used as a spice added to hot coffee and tea.

In Japan, ginger is pickled to make beni shoga and gari or grated and used raw on tofu or noodles.

In Western cuisine, ginger is traditionally restricted to sweet foods, such as ginger ale, gingerbread, ginger snaps, ginger cake and ginger biscuits.

Powdered dry ginger (ground ginger) is typically used to add spiciness to gingerbread and other recipes. Ground and fresh ginger taste quite different and ground ginger is a particularly poor substitute for fresh ginger. Fresh ginger can be successfully substituted for ground ginger and should be done at a ratio of 6 parts fresh for 1 part ground. You generally achieve better results by substituting only half the ground ginger for fresh ginger.

In Myanmar, ginger is used in a salad dish called gyin-tho, which consists of shredded ginger preserved in oil, and a variety of nuts and seeds.

In traditional Korean Kimchi, ginger is minced finely and added into the ingredients of the spicy paste just before the fermenting process.

In India, ginger is used in all sub-varieties of the indian cuisines. In south India, ginger is used in the production of a candy called Inji-murappa ("ginger candy" from Tamil). This candy is mostly sold by vendors to bus passengers in bus stops and in small tea shops as a locally produced item. Candied ginger is also very famous around these parts. Additionally, in Tamil Nadu, especially in the Tanjore belt, a variety of ginger which is less spicy is used when tender to make fresh pickle with the combination of lemon juice, salt and tender green chillies. This kind of pickle was generally made before the invention of refrigeration and stored for a maximum of 4-5 days. The pickle gains a mature flavor when the juices cook the ginger over the first 24 hours.

In South East Asia, the flower of a type of ginger is used in cooking. This unopened flower is known in the Malay language as Bunga Kantan, and is used in salads and also as garnish for sour-savoury soups, like Assam Laksa.

Ginger has a sialagogue action, stimulating the production of saliva.

Medicinal uses

Medical research has shown that ginger root is an effective treatment for nausea caused by motion sickness or other illness,[4][5] and also contains many antioxidants. Powdered dried ginger root is made into capsules for medicinal use. Modern research on nausea and motion sickness used approximately 1 gram of ginger powder daily. Although very effective against all forms of nausea, PDR health officials do not recommend taking ginger root for morning sickness commonly associated with pregnancy, though Chinese women traditionally eat ginger root during pregnancy to combat morning sickness. The Natural Medicines Comprehensive Database (compiled by health professionals and pharmacists), states that ginger is likely safe for use in pregnancy when used orally in amounts found in foods. Ginger ale and ginger beer have been recommended as "stomach settlers" for generations in countries where the beverages are made. Ginger water was commonly used to avoid heat cramps in the United States in the past. Research has also found ginger to be a powerful antioxidant. Ginger has also been shown in research to have a regulatory role in the natural inflammatory response of the body. In India ginger is applied as a paste to the temples to relieve headache.

Ginger has also been commonly used to treat inflammation, although medical studies as to the efficacy of ginger in decreasing inflammation have shown mixed results. There are several studies that demonstrate very positive results on minimizing joint pain from arthritis and other inflammatory disorders. It may also have blood thinning and cholesterol lowering properties, making it effective in treating heart disease; while early studies have shown some efficacy, it is too early to determine whether further research will bear this out.[1]

The characteristic odor and flavor of ginger root is caused by a mixture of zingerone, shoagoles and gingerols, volatile oils that compose about 1%–3% by weight of fresh ginger. The gingerols have analgesic, sedative, antipyretic, antibacterial, and GI tract motility effects.

Ginger is on the GRAS list from FDA. However, like other herbs, ginger may be harmful because it may interact with other medications, such as warfarin; hence, a physician or pharmacist should be consulted before taking the herb as a medicinal agent or on a long-term basis. Ginger is also contraindicated in people suffering from gallstones, because the herb promotes the release of bile from the gallbladder [2]. Ginger can also be used to prevent scurvy.

Ginger allergies

Some people are allergic to ginger. Generally, this is reported as having a gaseous component. This may take the form of flatulence, or it may take the form of an extreme constriction or tightening in the throat necessitating uncontrollable burping to relieve the pressure.

Gardening

Ginger produces clusters of white and pink flower buds that bloom into yellow flowers. Because of the aesthetic appeal and the adaptivity of the plant to warm climates, ginger is often used as landscaping around subtropical homes.

Reference in Popular Culture

To members of the Race, an alien species in Harry Turtledove's best-selling novel series, Worldwar, ginger is a highly addictive, psychoactive drug, with an effect similar to that of cocaine or PCP in humans.

In Cockney rhyming slang, ginger is a derogatory euphemism for homosexual. The original slang rhymed queer with ginger beer.

In the west of Scotland (particularly Glasgow), ginger is a term for any soft drink.

Similar species

Myoga (Zingiber mioga Roscoe) appears in Japanese cuisine; the flower buds are the part eaten.

Another plant in the Zingiberaceae family, galangal, is used for similar purposes as ginger in Thai cuisine. Galangal is also called Thai ginger. Also referred to as galangal, fingerroot (Boesenbergia rotunda), or Chinese ginger or the Thai krachai, is used in cooking and medicine.

A dicotyledonous native species of eastern North America, Asarum canadense, is also known as "wild ginger", and its root has similar aromatic properties, but it is not related to true ginger and should not be used as a substitute because it contains the carcinogen aristolochic acid. This plant is also a powerful diuretic, or urinary stimulator. It is part of the Aristolochiaceae family.

Ginkgo

Conservation status: Endangered

Scientific classification

Kingdom: Plantae
Division: *Ginkgophyta*
Class: *Ginkgoopsida*
Order: *Ginkgoales*
Family: *Ginkgoaceae*
Genus: *Ginkgo*
Species: *G. biloba*

Binomial name: *Ginkgo biloba*

The *Ginkgo* (*Ginkgo biloba*), frequently misspelled as "Gingko", and sometimes known as the *Maidenhair Tree*, is a unique tree with no close living relatives. It is classified in its own division, the *Ginkgophyta*, comprising the single class *Ginkgoopsida*, order *Ginkgoales*, family *Ginkgoaceae*, genus *Ginkgo* and just the one species. It is one of the best known examples of a living fossil. In the past it has also been placed in the divisions Spermatophyta or Pinophyta. Ginkgo is a gymnosperm (as opposed to an angiosperm), meaning "naked seed"; its seeds are not protected by an ovary wall and hence, the berry-like structures produced by female ginkgo trees are technically not fruit.

For centuries it was thought to be extinct in the wild, but is now known to grow wild in at least two small areas in Zhejiang province in eastern China, in the Tian Mu Shan Reserve. However, as this area has known human activity for over a thousand years, the wild status of ginkgos there is uncertain.

Characteristics

Habit

Ginkgos are medium-large deciduous trees, reaching 20–35 m tall (some specimens in China being over 50 m), with an often angular crown and long, somewhat erratic branches. They are usually deep rooted and resistant to wind and snow damage. Young trees are often tall and slender, and sparsely branched; the crown becomes broader as the tree ages. During autumn, the leaves turn a bright yellow, then fall, sometimes within a short space of time (1–15 days). A combination of amazing disease resistance, insect-resistant wood and the ability to form aerial roots and sprouts means that ginkgos are very long-lived, with some specimens claimed to be more than 2,500 years old; a 3,000 year-old ginkgo is reported in Shandong province in China (Lewington and Parker, 183).

Some old Ginkgos produce aerial roots, known as chichi (Japanese; "nipples") or zhong-ru (Chinese), which form on the undersides of large branches and grow downwards. Chichi

growth is very slow, and may take hundreds of years to occur. The function, if any, of these thick aerial roots is unknown.

Stem

Ginkgo branches grow in length by growth of shoots with regularly spaced leaves, as seen on most trees. From the axils of these leaves, "spur shoots" (also known as short shoots) develop on second-year growth. Short shoots have very short internodes (so that several years' growth may only extend them by a centimeter or two) and their leaves are ordinarily unlobed. They are short and knobby, and are arranged regularly on the branches except on first-year growth. Because of the short internodes, leaves appear to be clustered at the tips of short shoots, and reproductive structures are formed only on them (see picture to above left—seeds and leaves can be viewed on short shoots). In Ginkgos, as in other plants that possess them, short shoots allow the formation of new leaves in the older parts of the crown. After a number of years, a short shoot may change into a long (ordinary) shoot, or vice versa.

Leaves

The leaves are unique among seed plants, being fan-shaped with veins radiating out into the leaf blade, sometimes bifurcating (splitting) but never anastomosing to form a network. Two veins enter the leaf blade at the base and fork repeatedly in two; this is known as dichotomous venation. The leaves are 5-10 cm (rarely to 15 cm) long. The old popular name "Maidenhair tree" is because the leaves resemble some of the pinnae of the Maidenhair fern Adiantum capillus-veneris.

Leaves of long shoots are usually notched or lobed, but only from the outer surface, between the veins. They are borne both on the more rapidly-growing branch tips, where they are alternate and spaced out, and also on the short, stubby spur shoots, where they are clustered at the tips. During summer the leaves are a deep green, turning to brilliant yellow in the fall. They generally remain yellow for a time, then suddenly drop most of their leaves in what can seem like overnight.

Reproduction

Ginkgos are dioecious, with separate sexes, some trees being female and others being male. Male plants produce small pollen cones with sporophylls each bearing two microsporangia spirally arranged around a central axis.

Female plants do not produce cones. Two ovules are formed at the end of a stalk, and after pollination, one or both develop into seeds. The seed is 1.5-2 cm long. Its outer layer (the sarcotesta) is light yellow-brown, soft, and fruit-like. It is plum-like and attractive, but the seed coat contains butanoic acid and smells like rancid butter (which contains the same chemical) when fallen on the ground. Beneath the sarcotesta is the hard sclerotesta and a papery endotesta and nucellus.

The fertilization of ginkgo seeds is by motile sperm; similar to cycads, ferns, mosses and the algae. It is a large sperm of about 250-300 micrometres, similar to the cycad which is a

little larger. It was first discovered by the Japanese botanist Sakugoro Hirase in the early 1900s. The sperm has a complex multi-layered structure which is a continuous belt of basal bodies that form the base of several thousand flagella which actually have a cilia-like motion. The flagella/cilia apparatus pulls the body of the sperm forwards. But it has only a tiny distance to travel to the archegonia, of which there are usually two or three. Two sperm are produced, one of which successfully fertilizes the ovule. Although it is widely held that fertilization of ginkgo seeds occurs just before or after they fall in early autumn, [2] [3][4] embryos ordinarily occur in seeds just before and after they drop from the tree. [5]

Name

The name ginkgo means "silver apricot" (€O, pinyin: yínxìng) in Chinese. The same characters are used in Japanese and Korean (where the ginkgo had been introduced from China). The Japanese pronunciation is ichM while the Korean equivalent is eunhang, both of which appear to be a loan from Chinese, though this is not certain (from the entry in the dictionary KMjien). The Japanese characters used to write ginkgo look as though they could be read ginkyM, and this was the name Engelbert Kaempfer, the first Westerner to see the species in 1690, wrote down in his Amoenitates Exoticae (1712). However, his y was misread as a g, and the misspelling stuck.

In modern Japanese, the characters are read either ichM (meaning the tree) or ginnan (meaning the seed); this latter reading appears to be based on the renjM (i.e., liaison) reading of the characters. The modern Chinese name for its shelled seeds is }œ (Mandarin bái guÒ), meaning "white fruit".

Prehistory

The Ginkgo is a living fossil, with fossils recognisably related to modern Ginkgo from the Permian, dating back 270 million years. They diversified and spread throughout Laurasia during the middle Jurassic and Cretaceous, but became much rarer thereafter. By the Paleocene, Ginkgo adiantoides was the only Ginkgo species left in the Northern Hemisphere (but see below) with a markedly different (but not well-documented) form persisting in the Southern Hemisphere, and at the end of the Pliocene Ginkgo fossils disappeared from the fossil record everywhere apart from a small area of central China where the modern species survived. It is in fact doubtful whether the Northern Hemisphere fossil species of Ginkgo can be reliably distinguished; given the slow pace of evolution in the genus, there may have been only 2 in total; what is today called G. biloba (including G. adiantoides), and G. gardneri from the Paleocene of Scotland.

At least morphologically, G. gardneri and the Southern Hemisphere species are the only known post-Jurassic taxa that can be unequivocally recognised, the remainder may just as well have simply been ecotypes or subspecies. The implications would be that G. biloba had occurred over an extremely wide range, had remarkable genetic flexibility and though evolving genetically never showed much speciation. The occurrence of G. gardneri, it seems a Caledonian mountain endemic, and the somewhat greater diversity on the Southern Hemisphere, suggests that old mountain ranges on the Northern Hemisphere could hold other, presently undiscovered, fossil Ginkgo species. Since the distribution of Ginkgo was

already relictual in late prehistoric times, the chances that ancient DNA from subfossils can shed any light on this problem seem remote. While it may seem improbable that a species may exist as a contiguous entity for many millions of years, many of the Ginkgo's life-history parameters fit. These are extreme longevity, slow reproduction rate, (in Cenozoic and later times) a wide, apparently contiguous, but steadily contracting distribution coupled with, as far as can be demonstrated from the fossil record, extreme ecological conservatism (being restricted to light soils around rivers), and a low population density.

Ginkgophyta fossils have been classified in the following families and genera:

- Ginkgoaceae
  - Arctobaiera
  - Baiera
  - Eretmophyllum
  - Ginkgo
  - Ginkgoites
  - Sphenobaiera
  - Windwardia
- Trichopityaceae
  - Trichopitys

Ginkgo has been used for classifying plants with leaves that have more than four veins per segment, while Baiera for those with less than four veins per segment. Sphenobaiera has been used to classify plants with a broadly wedge-shaped leaf that lacks a distinct leaf stem. Trichopitys is distinguished by having multiple-forked leaves with cylindrical (not flattened) thread-like ultimate divisions; it is one of the earliest fossils ascribed to the Ginkgophyta.

Ginkgo has long been cultivated in China; some planted trees at temples are believed to be over 1,500 years old. The first record of Europeans encountering it is in 1690 in Japanese temple gardens, where the tree was seen by the German botanist Engelbert Kaempfer. Because of its status in Buddhism and Confucianism, the Ginkgo is also widely planted in Korea and parts of Japan; in both areas, some naturalization has occurred, with Ginkgos seeding into natural forests.

In some areas, notably the United States, most intentionally-planted Ginkgos are male cultivars grafted onto plants propagated from seed, because the male trees will not produce the malodorous seeds. The popular cultivar 'Autumn Gold' is a clone of a male plant.

The Ginkgo has the intriguing distinction of being one of the world's most urban-tolerant trees, often growing where other trees cannot survive. Some claim that only one tree species, the Tree-of-heaven, is as urban-tolerant. Ginkgos rarely suffer disease problems, even in urban conditions, and are attacked by few insects. For this reason, and for their general beauty, ginkgos are excellent urban and shade trees, and are widely planted along many streets. The ginkgo is the official tree of the city of Kumamoto, and two leaves form the symbol of the University of Tokyo, the main campus of which is famous for its numerous ginkgos.

Ginkgos are also popular subjects for growing as penjing and bonsai; they can be kept artificially small and tended over centuries. Furthermore, the trees are easy to propagate from seed.

Extreme examples of the Ginkgo's tenacity may be seen in Hiroshima, Japan, where four trees growing between 1–2 km from the 1945 atom bomb explosion were among the few living things in the area to survive the blast (photos & details). While almost all other plants (and animals) in the area were destroyed, the ginkgos, though charred, survived and were healthy. The trees are alive to this day.

Culinary use

The nut-like gametophytes inside the seeds are esteemed in and outside of Asia, and are a traditional Chinese food (e.g. congee, often served at weddings), and are believed to have health benefits; some also consider them to have aphrodisiac qualities. Japanese cooks add Ginkgo seeds to dishes such as chawanmushi, and cooked seeds are often eaten along with other dishes. The seeds are available canned, sold as "White Nuts", and can be found in many Asian food stores in the West. Usually only a few are added for a portion enough for ten people.

When eaten by children, in large quantities (over 5 seeds a day), or over a long period of time, the raw gametophyte (meat) of the seed can cause poisoning by MPN (4-methoxypyridoxine). MPN is heat-stable. Studies have demonstrated that convulsions caused by MPN can be prevented or terminated with pyridoxine.

Some people are sensitive to the chemicals in the sarcotesta, the outer fleshy coating. These people should handle the seeds with care when preparing the seeds for consumption, wearing disposable gloves. The symptoms are dermatitis or blisters similar to that caused by contact with poison-ivy. However, seeds with the fleshy coating removed are perfectly safe to handle.

Medical uses

The extract of the Ginkgo leaves contains flavonoid glycosides and ginkgolides and has been used pharmaceutically. It has many alleged nootropic properties, and is mainly used as memory enhancer and anti-vertigo agent. However, studies differ about its efficacy.

Out of the many conflicting research results, there seem to be basically three effects of Ginkgo extract on the human body: it improves blood flow (including microcirculation in small capillaries) to most tissues and organs; it protects against oxidative cell damage from free radicals (antioxidant); and it blocks many of the effects of PAF (platelet aggregation, blood clotting) that have been related to the development of a number of cardiovascular, renal, respiratory and CNS (Central Nervous System) disorders. Ginkgo can be used for intermittent claudication.

A 2004 conference paper [6] summarises how various trials indicate that Ginkgo shows promise in the treatment of Alzheimer's disease, although further study is needed.

Ginkgo is commonly added to energy drinks, but the amount is typically so low it does not produce a noticeable effect, except perhaps via a placebo effect from Ginkgo being listed on the label.

Side effects

Ginkgo may have some undesirable effects, especially for individuals with blood circulation disorders and those taking anti-coagulants such as aspirin and warfarin, although recent studies have found that ginkgo has little or no effect on the anticoagulant properties or pharmacodynamics of warfarin[7][8]. Ginkgo should also not be used by people who are taking monoamine oxidase inhibitors (MAOI) or by pregnant women without first consulting a doctor.

Ginkgo side effects and cautions include: possible increased risk of bleeding, gastrointestinal discomfort, nausea, vomiting, diarrhea, headaches, dizziness, and restlessness.

If any side effects are experienced consumption should be halted immediately. Ginkgo supplements are usually taken in the range of 40–200 mg per day. If the side effects continue usage should be stopped completely.

Hop

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Rosales
Family: Cannabaceae
Genus: *Humulus*

Species

Humulus lupulus L.
Humulus japonicus Siebold & Zucc.
Humulus yunnanensis Hu

The *hop* (Humulus) is a small genus of flowering plants, native to the temperate Northern Hemisphere. The female flowers, commonly called hops, are used as flavouring and stabilisers during beer brewing.

Although frequently referred to as the *hop vine*, it is technically a bine; unlike vines, which use tendrils, suckers, and other appendages for attaching themselves, bines have stout stems with stiff hairs to aid in climbing. It is a perennial herbaceous plant which sends up new shoots in early spring and dies back to the cold-hardy rhizome in autumn. Hop shoots grow very rapidly and at the peak of growth can grow 20–50 cm per week. Hop bines climb by wrapping clockwise around anything within reach, and individual bines typically grow between 2 to 15 m depending on what is available to grow on. The leaves are opposite, with a 7–12 cm petiole and a cordate-based, palmately lobed blade 12–25 cm long and broad; the edges are coarsely toothed. When the hop bines run out of material to climb, horizontal shoots sprout between the leaves of the main stem to form a network of stems wound round each other.

Species

There are three species, one with five varieties:

- Humulus japonicus (syn. H. scandens). *Asian Hop*. Leaves with 5–7 lobes. Eastern Asia.
- Humulus lupulus. *Common Hop*. Leaves with 3–5 lobes. Europe, western Asia, North America.
    - Humulus lupulus var. lupulus. Europe, western Asia.
    - Humulus lupulus var. cordifolius. Eastern Asia.
    - Humulus lupulus var. lupuloides (syn. H. americanus). Eastern North America.
    - Humulus lupulus var. neomexicanus. Western North America.

  - Humulus lupulus var. pubescens. Midwest North America.
- Humulus yunnanensis. *Yunnan Hop*. Leaves with 3–5 lobes, densely hairy below. Southeast Asia (endemic in Yunnan, China).

Brewers' hops are specific cultivars, propagated by asexual reproduction.

Cultivation

History

The first documented instance of hop cultivation was in 736, in the Hallertau region of present-day Germany (which is today the most important production centre with about 25% of the worldwide production), although the first mention of the use of hops in brewing was in 1079. Hops were introduced to British beers in the early 1500s, and hop cultivation began in the present-day United States in 1629.

Today, the principal production centres for the UK are in Kent (which produces Kent Golding hops) and Worcestershire, and Washington state for the USA; other important production areas include Belgium, as mentioned Germany and the Czech Republic. Other major areas of production include Xinjiang (China), Tasmania (Australia), the Lublin area (Poland) and Chuvashia (Russia). New Zealand is a leading centre for organic hop production.

Until mechanisation (in the late 1960s for the UK), the need for massed labour at harvest time meant hop-growing had a big social impact. Many of those hopping in Kent were Eastenders, for whom the annual migration meant not just money in the family pocket but a welcome break from the grime and smoke of London. Whole families would come down on special trains and live in hoppers' huts for most of September, even the smallest children helping in the fields. In Kent, hops areas had Oast houses built for drying the hops; many now are converted to homes. The image of Cockney hoppers beneath the blue September skies of the Battle of Britain in 1940 has become part of British national mythology. Romany travellers were another very large group among the hoppers.

Propagation and pests

The European Hop is propagated either by nursery plants or by cuttings. These are set in "hills", formed by digging holes in the spring, which are filled with fine leaf mould. The density of the holes varies from 3–5 holes per m^2. One, two, or three plants are put in each hill; although, if hops are designed to be raised from cuttings, four or five of these, ranging from 7 to 10 cm (3–4 inches) in length, are planted 3–5 cm deep in fine leaf mould.

Hop growing, though profitable when it succeeds, is risky, with several significant insect pests causing damage, including the European Corn Borer Ostrinia nubilalis and the Hop froghopper Aphrophora interrupta. Hop gardens on chalky soils are particularly subject to damage. In June and July, the hops are liable to be damaged by an aphid, Myzus humuli. This insect, however, does not endanger the growth of the plant, unless it is already in a weak state from root damage by the larvae of the ottermoth, Phalaena humuli. The roots are also attacked by the larvae of Common Swift, Ghost Moth and Orange Swift. The foliage is

sometimes eaten by the larvae of other Lepidoptera including Angle Shades, Currant Pug, Emperor Moth, The Gothic and Hebrew Character.

Harvest

At the end of the first year it becomes necessary to put poles into the hills, around which the bines reared from plants are wound; at the expiration of the second year, full-sized poles, from 5–6 m long, are set (though the hop bines will run to the height of 15 m) in the proportion of two poles to each hill, and a similar number of hop-plants are fastened loosely round each pole, by means of withered rushes.

In the northern hemisphere, hops begin to flower about the latter end of June or the beginning of July, at which point the poles are now entirely covered with foliage, and the pendent flowers are appearing in clusters. The hops themselves, which are the scaly seed-vessels of the female plants, are picked off by hand when the seed is formed around the end of August; for this purpose the poles are often taken down with the plants clinging to them. The seed-vessels are then dried, exposed to the air for a few days, and packed in sacks and sent to market.

Production

The 2005 world production of hops according to FAOSTAT was as follows;

- Germany 29,000 tonnes
- USA 26,180 tonnes
- China 20,000 tonnes
- Czech Republic 6,800 tonnes
- Poland 3,355 tonnes
- Australia 2,000 tonnes
- North Korea 2,000 tonnes
- UK 2,000 tonnes
- Slovenia 1,500 tonnes
- France 1,400 tonnes

The total world production for 2005 was 102,216 tonnes.

Uses

Beer

Hop resins are composed of two main acids: alpha and beta acids. Alpha acids have a mild antibiotic/bacteriostatic effect against Gram-positive bacteria, and favours the exclusive activity of brewing yeast in the fermentation of beer. The flavour imparted by hops varies greatly by variety and use: hops boiled with the beer (known as "bittering hops") produce bitterness, while hops added to beer later impart some degree of "hop flavour" (if during the final 10 minutes of boil) or "hop aroma" (if during the final 3 minutes, or less, of boil) and a lesser degree of bitterness. Adding hops after the boil, a process known as "dry hopping",

adds hop aroma, but very little bitterness. The degree of bitterness imparted by hops depends on the degree to which otherwise insoluble alpha acids (AAs) are isomerised during the boil, and the impact of a given amount of hops is specified in International Bitterness Units. Unboiled hops are only mildly bitter. Beta acids do not isomerise during the boil of wort, and have a negligible effect on beer flavour. Instead they contribute to beer's bitter aroma, and high beta acid hop varieties are often added at the end of the wort boil for aroma. Beta acids oxidise and oxidised beta acids form sulphur compounds such as DMS (dimethyl-sulfide) that can give beer off-flavours of rotten vegetables or cooked corn.

"Noble hops" are low in bitterness and high in aroma, and traditionally consist of four central European cultivars, 'Hallertauer Mittelfrueh', 'Tettnanger', 'Spalter', and 'Saaz'. They contain high amounts of the hop oil humulene and low amounts of alpha acids cohumulone and adhumulone, as well as lower amounts of the harsher-tasting beta acids lupulone, colupulone, and adlupulone. Humulene imparts an elegant, refined taste and aroma to beers containing it. These hops are used in pale lagers.

English ales use hop varieties such as Fuggle, Golding and Bullion. North American varieties include Cascade, Columbia, and Willamette. Certain beers (particularly the highly-hopped style known as India Pale Ale) can have high levels of bitterness.

Flavours and aromas are described using terms which include "grassy", "floral", "citrus", "spicy", and "earthy".

Medicinal use

The medically active ingredients in Hops are humulene and lupulene.

Dried female buds have a high methylbutenol content, which has a mild sedative effect on the central nervous system; it is used in the treatment for insomnia, stress and anxiety. If one has trouble getting sleep, hop tea before going to bed may help, though a quantity of beer has similar results.

Hops' antibacterial qualities also stimulate gastric juice production.

Fibre

The stem is flexible and very tough, with a tenacious fibre that has been used in some cases to make cloth and paper.

Other uses

Tender young hop shoots, which are only available for about three weeks during spring, were mainly eaten by the poor in medieval times, and was a substitute for asparagus. Only recently have they been rediscovered as a delicacy in parts of Germany, Belgium and England. They are served raw with vinaigrette, or boiled with fresh herbs or fried in batter.

Wild hops are also relished by cows, horses, goats, sheep, and pigs.

Mistletoe

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Santalales

Families

Santalaceae (Viscaceae)
Loranthaceae
Misodendraceae

Mistletoe is the common name for various parasitic plants in the order Santalales, belonging to the families Santalaceae, Loranthaceae and Misodendraceae. The species in Santalaceae were formerly commonly treated in a separate family Viscaceae.

The name was originally applied to Viscum album (European Mistletoe, Santalaceae; the only species native in Great Britain and much of Europe), and subsequently to other related species, including Phoradendron leucarpum (the Eastern Mistletoe of eastern North America, also Santalaceae). In an example of convergent evolution, several less related but superficially very similar plants in the Loranthaceae are also so similar that they have also been called mistletoes.

The European Mistletoe is readily recognised by its smooth-edged oval leaves in pairs along the woody stem, and waxy white berries in dense clusters of 2-6 together. American Mistletoe is similar, but has shorter, broader leaves and longer clusters of ten or more berries together.

Mistletoe biodiversity is markedly higher in subtropical and tropical climates; Australia has 85 species, of which 71 are in Loranthaceae, and 14 in Santalaceae.

The species grow on a wide range of trees, and can eventually prove fatal to them where infestation is heavy, though damage more commonly only results in growth reduction. Most mistletoes are only partial parasites, bearing evergreen leaves that carry out some photosynthesis of their own, relying on the host mainly for mineral nutrients from the ground. The genus Arceuthobium (dwarf mistletoe; Santalaceae) has dispensed with even this, becoming a total parasite relying on its host plant for photosynthesis as well as nutrients.

Most mistletoes are spread by birds (e.g. the Mistle Thrush in Europe, and the Phainopepla in southwestern North America) which eat the berries. The seeds are excreted in their droppings and stick to twigs, or more commonly the bird grips the fruit in its bill, squeezing the sticky coated seed out to the side, and then wiping its bill clean on a suitable branch. The seeds are coated with a sticky gum, viscin, which hardens and attaches the seed firmly to its future host.

The word 'mistletoe' is of uncertain etymology; it may be related to German Mist, another word for dung, but Old English mistel was also used for basil.

While historically often considered a pest that kills trees and devalues natural habitats, mistletoe has recently become recognized as an ecological keystone, an organism that has a disproportionately pervasive influence over its community. A broad array of animals depend on mistletoe for food, consuming the leaves and young shoots as well as transferring pollen between plants and dispersing the sticky fruits. The dense evergreen clumps also make excellent locations for roosting and nesting, with species ranging from Northern Spotted Owls, Marbled Murrelets, Diamond Firetails and Painted Honeyeaters recorded nesting in different mistletoes. This behaviour is probably far more widespread than currently recognised; more than 240 species of birds that nest in foliage in Australia have been recorded nesting in mistletoe, representing more than 75% of the resident avifauna. These interactions lead to dramatic influences on diversity, as areas with greater mistletoe densities support higher diversities of animals. Thus, rather than being a pest, mistletoe can have a positive effect on biodiversity, providing high quality food and habitat for a broad range of animals in forests and woodlands worldwide.

Uses and mythology

The leaves and young twigs are the parts used by herbalists, and it is popular in Europe, especially in Germany, for treating circulatory and respiratory system problems as well as for tumors, even malignant ones.

Mistletoe figured prominently in Norse mythology (whence the modern Western custom of kissing under bunches of it hung as holiday decorations). The god Baldur was killed with a weapon made of mistletoe. In Celtic mythology and in Druid rituals, it was considered an antidote to poison, but contact with its berries produces a rash similar to the poison ivy rash in people who are sensitive to it (as many are), so the whole plant came to be thought of as poisonous.

In Romanian traditions, mistletoe (vâsc in romanian) is considered as a source of good fortune. The medical and the supposed magical properties of the plant are still used, especially in rural areas. This custom is inherited from Dacians.

Mistletoe has sometimes been nick-named the "vampire plant" because it can probe beneath the tree bark to drain water and minerals, enabling it to survive during a drought (see vampirism). William Shakespeare gives it an unflattering reference in Titus Andronicus, Act II, Scene I:

Nowadays, mistletoe is commonly used as a Christmas decoration. Viscum album is used in Europe whereas Phoradendron leucarpum is used in North America. According to a custom of Christmas cheer, any two people who meet under a hanging of mistletoe are obliged to kiss. The origin of this custom may be related to the story of Baldur coming back

to life because of his mother Frigga (or Frigg), the goddess of love who removed the mistletoe's poison with her tears. When Baldur came back to life she kissed everyone who passed underneath the mistletoe out of happiness and gratitude and thus started the custom. Roman sources also mention misletoe was used by the celts in some sort of fertility rite or charm making the practise of kissing under it even more intriguing. Hence why mistletoe is used at Christmas, a time of love and joy.

Mistletoe was the official flower for the State of Oklahoma until 2004 when it was replaced by the Oklahoma Rose. Mistletoe however still serves as the state's official floral emblem.

Oat

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Liliopsida
Order: Poales
Family: Poaceae
Genus: Avena
Species: *A. sativa*

Binomial name *Avena sativa*

The *Oat* (Avena sativa) is a species of cereal grain, and the seeds of this plant. They are used for food for people and as fodder for animals, especially poultry and horses. Oat straw is used as animal bedding and sometimes as animal feed.

Since oats are unsuitable for making bread, they are often served as a porridge made from crushed or rolled oats, oatmeal, and are also baked into cookies (oatcakes) which can have added wheat flour. As oat flour or oatmeal, they are also used in a variety of other baked goods and cold cereals, and as an ingredient in muesli and granola. Oats may also be consumed raw, and cookies with raw oats are becoming popular. Oats are also occasionally used in Britain for brewing beer. Oatmeal stout is one variety brewed using a percentage of oats for the wort.

Oats also have non-food uses. Oat straw is also used in corn dolly making, and it is the favourite filling for home made lace pillows. Oat extract can be used to soothe the skin conditions, e.g. in baths, skin products, etc.

A now obsolete Middle English name for the plant was haver (still used in most other germanic languages), surviving in the name of the livestock feeding bag haversack. In contrast with the names of the other grains, "oat" is usually used in the plural.

Oats are native to Eurasia and appear to have been domesticated relatively late. They are now grown throughout the temperate zones. They have a lower summer heat requirement and greater tolerance of rain than other cereals like wheat, rye or barley, so are particularly important in areas with cool, wet summers such as northwest Europe, even being grown successfully in Iceland. Oats are an annual plant, and can be planted either in the fall (for late summer harvest) or in the spring (for early autumn harvest).

Historical attitudes towards oats vary. In England they were considered an inferior grain, because they cannot be made into bread but only "inferior" foods such as porridge or oatcakes, and because they are associated with poorer areas where wheat cannot be grown, with less sun, more rain and less fertile soil, and where as a consequence the people were literally poorer. In Scotland they were, and still are, held in high esteem, as a mainstay of the national diet. A traditional saying in England is that "oats are only fit to be fed to horses and Scotsmen", to which the Scottish riposte is "and England has the finest horses, and Scotland the finest men". Samuel Johnson notoriously defined oats in his Dictionary as "a grain, which in England is generally given to horses, but in Scotland supports the people". While frequently seen as derogatory, this is no less than the literal truth. Oats are so central to traditional Scottish cuisine that the Scottish English word "corn" refers to oats (as opposed to it meaning wheat in England and maize in North America and Australia). Oats grown in Scotland command a premium price throughout the United Kingdom as a result of these traditions.

The discovery of the healthy cholesterol-lowering properties has led to wider appreciation of oats as human food.

Health

Oats are generally considered "healthy", or a health food, being touted commercially as nutritious.

Soluble Fibre

Oat bran is the outer casing of the oat. Its consumption is believed to lower LDL ("bad") cholesterol, and possibly to reduce the risk of heart disease.

After reports found that oats can help lower cholesterol, an "oat bran craze" swept the U.S. in the late 1980s, peaking in 1989, when potato chips with added oat bran were marketed. The food fad was short-lived and faded by the early 1990s. The popularity of oatmeal and other oat products again increased after the January 1998 decision by the Food and Drug Administration (FDA) when it issued its final rule allowing a health claim to be made on the labels of foods containing "soluble fiber" from whole oats (oat bran, oat flour and rolled oats), noting that 3 grams of soluble fiber daily from these foods, in conjunction with a diet low in "saturated fat" and "cholesterol", and "low fat" may reduce the risk of heart disease. In order to qualify for the health claim, the whole oat-containing food must provide at least 0.75 grams of soluble fiber per serving. The soluble fiber in whole oats comprise a class of polysaccharides known as Beta-D-glucan.

Beta-D-glucans, usually referred to as beta-glucans, comprise a class of non-digestible polysaccharides widely found in nature in sources such as grains, barley, yeast, bacteria, algae and mushrooms. In oats, barley and other cereal grains, they are located primarily in the endosperm cell wall.

Oat beta-glucan is a soluble fiber. It is a viscous polysaccharide made up of units of the sugar D-glucose. Oat beta-glucan is comprised of mixed-linkage polysaccharides. This means that the bonds between the D-glucose or D-glucopyranosyl units are either beta-1, 3 linkages or beta-1, 4 linkages. This type of beta-glucan is also referred to as a mixed-linkage (1’3), (1’4)-beta-D-glucan. The (1’3)-linkages break up the uniform structure of the beta-D-glucan molecule and make it soluble and flexible. In comparison, the nondigestible polysaccharide cellulose is also a beta-glucan but is non-soluble. The reason that it is non-soluble is that cellulose consists only of (1’4)-beta-D-linkages. The percentages of beta-glucan in the various whole oat products are: oat bran, greater than 5.5% and up to 23.0%; rolled oats, about 4%; whole oat flour about 4%.

Oats after corn (maize) has the highest lipid content of any cereal, e.g., >10 percent for oats and as high as 17 percent for some maize cultivars compared to about 2-3 percent for wheat and most other cereals. The polar lipid content of oats (about 8-17% glycolipid and 10-20% phospholipid or a total of about 33%) is greater than that of other cereals since much of the lipid fraction is contained within the endosperm.

Oat is the only cereal containing a globulin or legume-like protein, avenalins, as the major (80%) storage protein. Globulins are characterized by water solubility; because of this property, oats may be turned into milk but not into bread. The more typical cereal proteins, such as gluten are prolamines. The minor protein of oat is a prolamine: avenin.

Oat protein is nearly equivalent in quality to soy protein which has been shown by the World Health Organization to be the equal to meat, milk, and egg protein. The protein content of the hull-less oat kernel (groat) ranges from 12–24%, the highest among cereals. {Radomir Lasztity. 1999. The chemistry of oats. In: Cereal Chemistry. Akademiai Kiado(English)}

Celiac Disease

Coeliac disease, or celiac disease, from Greek "koiliakos", meaning "suffering in the bowels", is a disease often associated with ingestion of wheat, or more specifically a group of proteins labelled prolamines, or more commonly, gluten.

Oats lack many of the prolamines found in wheat; however, oats do contain avenin[1]. Avenin is a prolamine which is toxic to the intestinal submucosa and can trigger a reaction in some celiacs.[2]

Additionally, oats are frequently processed near wheat, barley and other grains such that they become contaminated with other glutens. Because of this, the FAO:n Codex Alimentarius Commission officially lists them as a crop containing gluten. Oats from Ireland and Scotland, where less wheat is grown, are less likely to be contaminated in this way.

Oats are part of a gluten free diet in, for example, Finland and Sweden. In both of these countries there are "pure oat" products on the market.

Agronomy

Oats are sown in the spring, as soon as the soil can be worked. An early start is crucial to good yields as oats will go dormant during the summer heat. Oats are cold-tolerant and will be unaffected by late frosts or snow. Typically about 100 kg/hectare (about 2 bushels per acre) are sown, either broadcast or drilled in 150 mm (6 inch) rows. Lower rates are used when underseeding with a legume. Somewhat higher rates can be used on the best soils. Excessive sowing rates will lead to problems with lodging and may reduce yields.

Winter oats may be grown as an off-season groundcover and plowed under in the spring as a green fertilizer.

Oats remove substantial amounts of nitrogen from the soil. If the straw is removed from the soil rather than being ploughed back, there will also be removal of large quantities of potash. Usually 50-100 kg/hectare (50-100 pounds per acre) of nitrogen in the form of urea or ammonium sulphate is sufficient. A sufficient amount of nitrogen is particularly important for plant height and hence straw quality and yield. When the prior-year crop was a legume, or where ample manure is applied, nitrogen rates can be reduced somewhat.

The vigorous growth habit of oats will tend to choke out most weeds. A few tall broadleaf weeds, such as ragweed, goosegrass and buttonweed (velvetleaf), can occasionally be a problem as they complicate harvest. These can be controlled with a modest application of a broadleaf herbicide such as 2,4-D while the weeds are still small.

Modern harvest technique is a matter of available equipment, local tradition, and priorities. Best yields are attained by swathing, cutting the plants at about 10 cm (4 inches) above ground and putting them into windrows with the grain all oriented the same way, just before the grain is completely ripe. The windrows are left to dry in the sun for several days before being combined using a dummy head. Then the straw is baled.

Oats can also be left standing until completely ripe and then combined with a grain head. This will lead to greater field losses as the grain falls from the heads and to harvesting losses as the grain is threshed out by the reel. Without a draper head, there will also be somewhat more damage to the straw since it will not be properly oriented as it enters the throat of the combine. Overall yield loss is 10-15% compared to proper swathing.

Late 19th and early 20th century harvesting was performed using a binder. Oats were gathered into shocks and then collected and run through a stationary threshing machine.

Earlier harvest involved cutting with a scythe or sickle, and threshing under the feet of cattle.

A good yield is typically about 3000 kg/hectare (100 bushels/acre) of grain and two tonnes of straw.

Trivia

- The eruption of Mount Tambora caused a change in world climate resulting in a volcanic winter and the "year without a summer" in 1816, during which time the price of oats rose dramatically, for example in the USA from 12 to 92 cents per bushel. This led to the starvation of many horses, which in turn led

to transportation problems, which Baron Karl von Drais attempted to solve by inventing the dandy horse, the direct precursor to the bicycle.

- Bodybuilders may be known to eat copious amounts of oats to get adequate carbohydrate.

Peppermint

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Lamiales
Family: Lamiaceae
Genus: Mentha

Binomial name Mentha × piperita

Peppermint (Mentha × piperita) is a (usually) sterile hybrid mint, a cross between watermint (Mentha aquatica) and spearmint (Mentha spicata). It is occasionally found wild with its parent species in central and southern Europe, but the first intentional crossbreed of watermint and spearmint was done in England. Being sterile, it spreads by rooting.

The stems are from 30-70 cm tall, rarely up to 100 cm, smooth, and square in cross section. The leaves are from 4-9 cm long and 1.5-4 cm broad, dark green with reddish veins, and with an acute apex and coarsely toothed margins. The flowers are purple, 6-8 mm long, with a four-lobed corolla about 5 mm diameter; they are produced in whorls around the stem, forming thick, blunt spikes. Flowering is from July to September.

Peppermint is generally regarded as 'the world's oldest medicine', with archeological evidence placing its use at least as far back as ten thousand years ago.

Uses

Peppermint has a high menthol content, and is often used as a flavouring in tea, ice cream, confectionery, chewing gum, and toothpaste. The oil also contains menthone and menthyl esters. It is the oldest and most popular flavour of mint-flavored confectionery. Peppermint

can also be found in some shampoos and soaps, which give the hair a minty scent and produce a cooling sensation on the skin.

Peppermint, like many spices and herbs, is believed to have medicinal properties when consumed. It is said that it helps against upset stomachs, inhibits the growth of certain bacteria, and can help smooth and relax muscles when inhaled or applied to the skin. Other health benefits are attributed to the high manganese, vitamin C and vitamin A content; as well as trace amounts of various other nutrients such as fibre, iron, calcium, folate, potassium, tryptophan, magnesium, omega-3 fatty acids, riboflavin, and copper.

Peppermint oil has been demonstrated to reduce colicky abdominal pain due to irritable bowel syndrome (IBS) with an NNT (number needed to treat) around 3.1[1], but the oil is irritant to the stomach in the quantity required and therefore needs wrapping for delayed release in the intestine. Peppermint relaxes the gastro-oesophageal sphincter, thus promoting belching.

Peppermint flowers are heavy nectar producers and honeybees as well as other nectar harvesting organisms forage them heavily. A mild, pleasant varietal honey can be produced if there is sufficient acreage of plants.

Areas of North America where peppermint was formerly grown for oil (now produced synthetically) often have an abundance of feral plants, and it is considered somewhat invasive.

Cultivation

Peppermint generally thrives in shade and expands quickly by underground rhizomes. If you choose to grow peppermint, it is advisable to plant it in a container, otherwise it can rapidly take over a whole garden. It needs a good water supply, and is ideal for planting in part-sun to shade areas.

The leaves and flowering tops, collected as soon as the flowers begin to open and carefully dried, are the useable portion of the plant. The wild form of the plant is less suitable for this purpose, with cultivated plants having been selected for more and better oil content. Peppermint grows from the ground.

Rosemary

Conservation status: Secure

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Lamiales
Family: Lamiaceae
Genus: Rosmarinus
Species: *R. officinalis*

Binomial name Rosmarinus officinalis

Rosemary (Rosmarinus officinalis) is a woody, perennial herb with fragrant evergreen needle-like leaves. It is native to the Mediterranean region. It is a member of the mint family Lamiaceae, which also includes many other herbs. Forms range from upright to trailing; the upright forms can reach 1.5 m tall, rarely 2 m. The leaves are evergreen, 2-4 cm long and 2-5 mm broad, green above, and white below with dense short woolly hairs. The flowers are variable in colour, being white, pink, purple, or blue.

The name rosemary has nothing to do with the rose or the name Mary, but derives from the Latin name rosmarinus, which is presumed to mean "dew of the sea", though some think this too may be derived from an earlier name.

Rosemary is often commonly associated with memory and/or remembrance of the past.

Cultivation and uses

The fresh and dried leaves are used frequently in traditional Mediterranean cuisine as a herb; a tisane can also be made from them. They are extensively used in cooking, and when burned gives off a distinct mustard smell.

Since it is attractive and tolerates some degree of drought, it is also used in landscaping, especially in areas having a Mediterranean climate. It can in fact die in over-watered soil, but is otherwise quite easy to grow for beginner gardeners. It is very pest-resistant.

Rosemary is easily pruned into shapes and has been used for topiary. When grown in pots, it is best kept trimmed to stop it getting too straggly and unsightly, though when grown in a garden, rosemary can grow quite large and still be attractive. It can be propagated from an existing plant by clipping a shoot 10-15 cm long, stripping a few leaves from the bottom, and planting it directly into soil.

Numerous cultivars have been selected for garden use. The following are frequently sold:

- 'Albus': white flowers
- 'Arp': leaves light green, lemon-scented
- 'Aureus': leaves speckled yellow
- 'Benenden Blue': leaves narrow, dark green
- 'Blue Boy': dwarf, small leaves
- 'Golden Rain': leaves green, with yellow streaks
- 'Irene': lax, trailing
- 'Lockwood de Forest': procumbent selection from 'Tuscan Blue'
- 'Ken Taylor': shrubby
- 'Majorica Pink': pink flowers

- 'Miss Jessop's Upright': tall, erect
- 'Pinkie': pink flowers
- 'Prostratus'
- 'Pyramidalis' (a.k.a 'Erectus'): pale blue flowers
- 'Roseus': pink flowers
- 'Severn Sea': spreading, with arching branches; flowers deep violet
- 'Tuscan Blue': upright

Rosemary is a useful food preservative, according to research published in 1987 by Rutgers University, New Jersey. Researchers at Rutgers patented a chemical derived from rosemary that compares favourably with BHA and BHT in its preservative properties.

Rosemary can be added as an unusual extra flavouring in lemonade.

Medicinal uses

Rosemary has been found to be a stimulant and mild analgesic, and has been used to treat headaches, poor circulation, and many ailments for which stimulants are prescribed.

Rosemary essential oil is a powerful convulsant; if applied to the skin, it may cause seizures in otherwise healthy adults or children.

It can be used as a disinfectant, as a mouth wash and to treat fever or rheumatism.

Externally it can be used in hair lotions; a few drops of Rosemary oil massaged into the scalp, then rinsed with an infusion of nettles can revitalise the hair. Used in this manner it supposed to prevent premature baldness. Rosemary is also reported to stop dandruff.

Hungary water was first invented for a Queen of Hungary to 'renovate vitality of paralysed limbs'. It was used externally and is prepared by mixing 180g of fresh rosemary tops in full flower into a litre of spirits of wine. Leave to stand for four days then distill. It is also supposed to work as a remedy against gout if rubbed vigoursly on hands and feet.

For a tonic against headaches put some sprigs into a teapot, add hot water, strain, and serve.

Rosemary has a very old reputation for improving memory, and has been used as a symbol for remembrance (as in worn during weddings, war commemorations and funerals) in Europe, probably as a result of this reputation; in Shakespeare's Hamlet, Ophelia says, "There's rosemary, that's for remembrance".

Rosemary and its constituents carnosol and ursolic acid have been shown to inhibit the growth of skin tumors and to provide a natural anti-oxidant protection against skin cancer and photodamage.

Don Quixote (Chapter XVII, 1st volume) mixes it in its recipe of the miraculous balm of Fierabras with revolting results.

Saffron

Saffron crocus

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Liliopsida
Order: Asparagales
Family: Iridaceae
Genus: Crocus
Species: *C. sativus*

Binomial name *Crocus sativus*

Saffron (IPA: [Èsæf.yYn] / [Èsæf.yTn]) is a spice derived from the flower of the *saffron crocus* (Crocus sativus), a species of crocus in the family Iridaceae. The flower has three stigmas, which are the distal ends of the plant's carpels. Together with its style, the stalk connecting the stigmas to the rest of the plant, these components are often dried and used in cooking as a seasoning and colouring agent. Saffron, which has for decades been the world's most expensive spice by weight,[1][2] is native to Southwest Asia.[2][3] It was first cultivated in the vicinity of Greece.[4]

Saffron is characterised by a bitter taste and an iodoform- or hay-like fragrance; these are caused by the chemicals picrocrocin and safranal.[5][6] It also contains a carotenoid dye, crocin, that gives food a rich golden-yellow hue. These traits make saffron a much-sought ingredient in many foods worldwide. Saffron also has medicinal applications.

The word saffron originated from the 12th-century Old French term safran, which derives from the Latin word safranum. Safranum is also related to the Italian zafferano and Spanish azafrán.[7] Safranum comes from the Arabic word acfar (#N5RAN1), which means "yellow," via the paronymous za»farn (2N9RAN1N'F), the name of the spice in Arabic.[6]

Biology

Saffron crocus morphology

The domesticated saffron crocus C. sativus is a fall-flowering perennial plant unknown in the wild, and is a sterile triploid mutant of the eastern Mediterranean fall-flowering Crocus cartwrightianus.[8] According to botanical research, C. cartwrightianus originated in Crete,

not—as was once generally believed—in Central Asia.[6] The saffron crocus resulted when C. cartwrightianus was subjected to extensive artificial selection by growers who desired elongated stigmas. Being sterile, the saffron crocus's purple flowers fail to produce viable seeds—thus, reproduction is dependent on human assistance: the corms (underground bulb-like starch-storing organs) must be manually dug up, broken apart, and replanted. A corm survives for only one season, reproducing via division into up to ten "cormlets" that eventually give rise to new plants.[8] The corms are small brown globules up to 4.5 cm in diameter and are shrouded in a dense mat of parallel fibers.

After a period of aestivation in summer, five to eleven narrow and nearly vertical green leaves—growing up to 40 cm in length—emerge from the ground. In autumn, purple buds appear. Only in October, after most other flowering plants have released their seeds, does it develop its brilliantly-hued flowers, ranging from a light pastel shade of lilac to a darker and more striated mauve.[9] Upon flowering, it averages less than 30 cm in height.[10] Inside each flower is a three-pronged style; in turn, each prong terminates with a crimson stigma 25–30 mm in length.[8]

Cultivation

The saffron crocus thrives in climates similar to that of the Mediterranean maquis or the North American chaparral, where hot, dry summer breezes blow across arid and semi-arid lands. Nevertheless, the plant can tolerate cold winters, surviving frosts as cold as 10°C and short periods of snow cover.[11][8] However, if not grown in wet environments like Kashmir (where rainfall averages 1000–1500 mm annually), irrigation is needed—this is true in the saffron-growing regions of Greece (500 mm of rainfall annually) and Spain (400 mm). Rainfall timing is also key: generous spring rains followed by relatively dry summers are optimal. In addition, rainfall occurring immediately prior to flowering also boosts saffron yields; nevertheless, rainy or cold weather occurring during flowering promotes disease, thereby reducing yields. Persistently damp and hot conditions also harm yields,[12] as do the digging actions of rabbits, rats, and birds. Parasites such as nematodes, leaf rusts, and corm rot also pose significant threats.[13]

Saffron crocus flower yields[*]

Country, Yield (kg/ha)

Spain 6–29

Italy 10–16

[*]—Yields specify flower weight, not final dry saffron weight.

Saffron plants grow best in strong and direct sunlight, and fare poorly in shady conditions. Thus, planting is best done in fields that slope towards the sunlight (i.e. south-sloping in the Northern Hemisphere), maximizing the crocuses' sun exposure. In the Northern Hemisphere, planting is mostly done in June, with corms planted some 7–15 cm deep. Planting depth and corm spacing—along with climate—are both critical factors impacting plant yields. Thus, mother corms planted more deeply yield higher-quality saffron, although they produce fewer flower buds and daughter corms. With such knowledge, Italian growers have found that planting corms 15 cm deep and in rows spaced 2–3 cm apart optimizes threads yields, whereas planting depths of 8–10 cm optimizes flower and corm production. Meanwhile, Greek, Moroccan, and Spanish growers have devised different depths and spacings to suit their own climates.[12]

Saffron crocuses grow best in friable, loose, low-density, well-watered, and well-drained clay-calcareous soils with high organic content. Raised beds are traditionally used to promote good drainage. Historically, soil organic content was boosted via application of some 20–30 tonnes of manure per hectare. Afterwards—and with no further manure application—corms were planted.[13] After a period of dormancy through the summer, the corms send up their narrow leaves and begin to bud in early autumn. Only in mid-autumn do the plants begin to flower. Harvesting of flowers is by necessity a speedy affair: after their flowering at dawn, flowers quickly wilt as the day passes.[14] Furthermore, saffron crocuses bloom within a narrow window spanning one or two weeks.[15] Approximately 150 flowers yield 1 g of dry saffron threads; to produce 12 g of dried saffron (72 g freshly harvested), 1 kg of flowers are needed. On average, one freshly-picked flower yields 0.03 g of fresh saffron, or 0.007 g of dried saffron.[13]

Chemistry

Crocin formation
Esterification reaction between crocetin and gentiobiose.

— ²-D-gentiobiose.

— Crocetin.

Picrocrocin and safranal

Chemical structure of picrocrocin.[16]

— Safranal moiety.

— ²-D-glucopyranose derivative.

Saffron contains more than 150 volatile and aroma-yielding compounds. It also has many nonvolatile active components,[17] many of which are carotenoids, including zeaxanthin, lycopene, and various ±- and ²-carotenes. However, saffron's golden yellow-orange colour is

primarily the result of ±-crocin. This crocin is trans-crocetin di-(²-D-gentiobiosyl) ester (systematic (IUPAC) name: 8,8-diapo-8,8-carotenoic acid). This means that the crocin underlying saffron's aroma is a digentiobiose ester of the carotenoid crocetin.[17] Crocins themselves are a series of hydrophilic carotenoids that are either monoglycosyl or diglycosyl polyene esters of crocetin.[17] Meanwhile, crocetin is a conjugated polyene dicarboxylic acid that is hydrophobic, and thus oil-soluble. When crocetin is esterified with two water-soluble gentiobioses (which are sugars), a product results that is itself water-soluble. The resultant ±-crocin is a carotenoid pigment that may comprise more than 10% of dry saffron's mass. The two esterified gentiobioses make ±-crocin ideal for colouring water-based (non-fatty) foods such as rice dishes.[4]

The bitter glucoside picrocrocin is responsible for saffron's flavour. Picrocrocin (chemical formula: C16H26O7; systematic name: 4-(²-D-glucopyranosyloxy)-2,6,6-trimethylcyclohex-1-ene-1-carboxaldehyde) is a union of an aldehyde sub-element known as safranal (systematic name: 2,6,6-trimethylcyclohexa-1,3-dien-1- carboxaldehyde) and a carbohydrate. It has insecticidal and pesticidal properties, and may comprise up to 4% of dry saffron. Significantly, picrocrocin is a truncated version (produced via oxidative cleavage) of the carotenoid zeaxanthin and is the glycoside of the terpene aldehyde safranal. The reddish-coloured[18] zeaxanthin is, incidentally, one of the carotenoids naturally present within the retina of the human eye.

When saffron is dried after its harvest, the heat, combined with enzymatic action, splits picrocrocin to yield D-glucose and a free safranal molecule.[16] Safranal, a volatile oil, gives saffron much of its distinctive aroma.[5][19] Safranal is less bitter than picrocrocin and may comprise up to 70% of dry saffron's volatile fraction in some samples.[18] A second element underlying saffron's aroma is 2-hydroxy-4,4,6-trimethyl-2,5-cyclohexadien-1-one, the scent of which has been described as "saffron, dried hay like".[20] Chemists found this to be the most powerful contributor to saffron's fragrance despite its being present in a lesser quantity than safranal.[20] Dry saffron is highly sensitive to fluctuating pH levels, and rapidly breaks down chemically in the presence of light and oxidizing agents. It must therefore be stored away in air-tight containers in order to minimise contact with atmospheric oxygen. Saffron is somewhat more resistant to heat.

History

The history of saffron cultivation reaches back more than 3,000 years.[8] The wild precursor of domesticated saffron crocus was Crocus cartwrightianus. Human cultivators bred wild specimens by selecting for unusually long stigmas. Thus, a sterile mutant form of C. cartwrightianus, C. sativus, emerged in late Bronze Age Crete.[21] Experts believe saffron was first documented in a 7th century BC Assyrian botanical reference compiled under

Ashurbanipal. Since then, documentation of saffron's use over the span of 4,000 years in the treatment of some 90 illnesses has been uncovered.[22] Saffron has been used as a spice and medicine in the Mediterranean region since then, with usage and cultivation slowly spreading to other parts of Eurasia as well as North Africa and North America. In the last several decades, saffron cultivation has spread to Oceania.

Mediterranean

Minoans portrayed saffron in their palace frescoes by 1500–1600 BC, showing saffron's use as a therapeutic drug.[23][22] Later, Greek legends told of sea voyages to Cilicia. There, adventurers hoped to procure what they believed was the world's most valuable saffron.[11] Another legend tells of Crocus and Smilax, whereby Crocus is bewitched and transformed into the original saffron crocus.[24] Ancient Mediterranean peoples—including perfumers in Egypt, physicians in Gaza, townspeople in Rhodes,[25] and the Greek hetaerae courtesans—used saffron in their perfumes, ointments,[26] potpourris, mascaras, divine offerings, and medical treatments.[26]

In late Hellenistic Egypt, Cleopatra used saffron in her baths so that lovemaking would be more pleasurable.[27] Egyptian healers used saffron as a treatment for all varieties of gastrointestinal ailments.[28] Saffron was also used as a fabric dye in such Levant cities as Sidon and Tyre.[29] Such was the Romans' love of saffron that Roman colonists took their saffron with them when they settled in southern Gaul, where it was extensively cultivated until Rome's fall. Competing theories state that saffron only returned to France with 8th century AD Moors or with the Avignon papacy in the 14th century AD.[30]

Asia The 17.8 m monolith of Jain God Bhagavan Gomateshwara Bahubali, which was carved between 978–993 AD and is located in Shravanabelagola, India, is anointed with saffron every 12 years by thousands of devotees as part of the Mahamastakabhisheka festival.

Saffron-based pigments have been found in 50,000 year-old depictions of prehistoric beasts in what is today Iraq.[24][31] Later, the Sumerians used wild-growing saffron in their remedies and magical potions.[32] Saffron was thus an article of long-distance trade before the Minoan palace culture's 2nd millennium BC peak. Saffron was also honored in the Hebrew Song of Solomon.[33] Ancient Persians cultivated Persian saffron (Crocus sativus 'Hausknechtii') in Derbena, Isfahan, and Khorasan by the 10th century BC. At such sites, saffron threads were woven into textiles,[24] ritually offered to divinities, and used in dyes, perfumes, medicines, and body washes.[34] Thus, saffron threads would be scattered across beds and mixed into hot teas as a curative for bouts of melancholy. Non-Persians also feared the Persians' usage of saffron as a drugging agent and aphrodisiac.[26] During his Asian campaigns, Alexander the Great used Persian saffron in his infusions, rice, and baths as a curative for battle wounds. Alexander's troops mimicked the practice and brought saffron-bathing back to Greece.[35]

Theories explaining saffron's arrival in South Asia conflict. Traditional Kashmiri and Chinese accounts date its arrival anywhere between 900–2500 years ago.[36][37][38]

Meanwhile, historians studying ancient Persian records date the arrival to sometime prior to 500 BC,[4] attributing it to either Persian transplantation of saffron corms to stock new gardens and parks[39] or to a Persian invasion and colonization of Kashmir. Phoenicians then marketed Kashmiri saffron as a dye and a treatment for melancholy.[26] From there, saffron use in foods and dyes spread throughout South Asia. For example, Buddhist monks in India adopted saffron-coloured robes after the Buddha Siddhartha Gautama's death.[40]

Historians believe that saffron first came to China with Mongol invaders by way of Persia. Yet a 7th-century Armenian author, Anania of Shirak, observed in his description of China that "unlimited amounts of saffron are available there, to the point that if someone went hunting, dressed in white, mounted on a white horse and with a white falcon, on his return he would be completely covered with yellow"[1]. Indeed, saffron is mentioned in ancient Chinese medical texts, including the forty-volume Shennong Bencaojing (^²,I“ — "Shennong's Great Herbal", also known as Pen Ts'ao or Pun Tsao) pharmacopoeia, a tome dating from 200-300 BC. Traditionally attributed to the legendary Yan ("Fire") Emperor (Ž) Shennong, it documents 252 phytochemical-based medical treatments for various disorders.[41][42][40] Yet around the 3rd century AD, the Chinese were referring to saffron as having a Kashmiri provenance. For example, Wan Zhen, a Chinese medical expert, reported that "[t]he habitat of saffron is in Kashmir, where people grow it principally to offer it to the Buddha." Wan also reflected on how saffron was used in his time: "The [saffron crocus] flower withers after a few days, and then the saffron is obtained. It is valued for its uniform yellow colour. It can be used to aromatise wine."[38]

Europe

In Europe, saffron cultivation declined steeply following the Roman Empire's fall. Saffron was reintroduced when Moorish civilization spread to Spain, France, and Italy.[43] During the 14th century Black Death, demand for saffron-based medicine skyrocketed, and much saffron had to be imported via Venetian and Genoan ships from southern and Mediterranean lands[44] such as Rhodes. The theft of one such shipment by noblemen sparked the fourteen-week long "Saffron War".[44] The conflict and resulting fear of rampant saffron piracy spurred significant saffron cultivation in Basel, which grew prosperous.[45] Cultivation and trade then spread to Nuremberg, where epidemic levels of saffron adulteration brought on the Safranschou code, which fined, imprisoned, and executed saffron adulterers.[46] Soon after, saffron cultivation spread throughout England, especially Norfolk and Suffolk. The Essex town of Saffron Walden, named for its new specialty crop, emerged as England's prime saffron growing and trading center. However, an influx of more exotic spices—chocolate, coffee, tea, and vanilla—from newly-contacted Eastern and overseas countries caused European cultivation and usage of saffron to decline.[47][48] Only in southern France, Italy, and Spain, did significant cultivation endure.[49]

Europeans brought saffron to the Americas when immigrant members of the Schwenkfelder Church left Europe with a trunk containing saffron corms; indeed, many Schwenkfelders had widely grown saffron in Europe.[50] By 1730, the Pennsylvania Dutch were cultivating saffron throughout eastern Pennsylvania. Spanish colonies in the Caribbean bought large amounts of this new American saffron, and high demand ensured that saffron's

list price on the Philadelphia commodities exchange was set equal to that of gold.[51] The trade with the Caribbean later collapsed in the aftermath of the War of 1812, when many saffron-transporting merchant vessels were destroyed.[52] Yet the Pennsylvania Dutch continued to grow lesser amounts of saffron for local trade and use in their cakes, noodles, and chicken or trout dishes.[53] American saffron cultivation survived into modern times mainly in Lancaster County, Pennsylvania.[50]

Trade and usage

Saffron's aroma is often described by connoisseurs as reminiscent of metallic honey with grassy or hay-like notes, while its taste has been noted also as hay-like and somewhat bitter. Saffron also contributes a luminous yellow-orange colouring to foods. Because of the unusual taste and colouring it adds to foods, saffron is widely used in Arab, Central Asian, European, Indian, Iranian, Moroccan and Cornish cuisines. Confectionaries and liquors also often include saffron. Common saffron substitutes include safflower (Carthamus tinctorius, which is often sold as "Portuguese saffron" or "assafroa") and turmeric (Curcuma longa). Medicinally, saffron has a long history as part of traditional healing; modern medicine has also discovered saffron as having anticarcinogenic (cancer-suppressing),[17] anti-mutagenic (mutation-preventing), immunomodulating, and antioxidant-like properties.[54][17][55] Saffron has also been used as a fabric dye—particularly in China and India—and in perfumery.[56]

Most saffron is grown in a belt of land ranging from the Mediterranean in the west to Kashmir in the east. Annually, around 300 tonnes of saffron are produced worldwide.[6] Iran, Spain, India, Greece, Azerbaijan, Morocco, and Italy (in decreasing order of production) are the major producers of saffron. A pound of dry saffron (0.45 kg) requires 50,000–75,000 flowers, the equivalent of a football field's area of cultivation.[57][58] Some forty hours of frenetic day-and-night labour are needed to pick 150,000 flowers.[59] Upon extraction, stigmas are dried quickly and (preferably) sealed in airtight containers.[60] Saffron prices at wholesale and retail rates range from US$500/pound to US$5,000/pound (US$1100–US$11,000 per kilogram). In Western countries, the average retail price is $1,000/pound (US$2200 per kilogram).[2] Between 70,000 and 200,000 threads comprise a pound. Vivid crimson colouring, slight moistness, elasticity, recent harvest date, and lack of broken-off thread debris are all traits of fresh saffron.

Cultivars

Several saffron cultivars are grown worldwide. Spain's varieties, including the tradenames 'Spanish Superior' and 'Creme', are generally mellower in colour, flavour, and aroma; they are graded by government-imposed standards. Italian varieties are more potent, while the most intense varieties tend to be Macedonian Greek, Iranian, and Kashmiri Indian in origin. Westerners may face significant obstacles in obtaining saffron from Iran and India. For example, the United States has banned the import of Iranian saffron; meanwhile, India has banned the export of high-grade saffron abroad. Aside from these, various "boutique" crops are available from New Zealand, France, Switzerland, England, the United States, and

other countries. In the U.S., Pennsylvania Dutch saffron — known for its earthy notes — is marketed in small quantities.[50][61]

Consumers regard certain cultivars as "premium" quality. The "Aquila" saffron (zafferano dell'Aquila) — defined by high safranal and crocin content, shape, unusually pungent aroma, and intense colour — is grown exclusively on eight hectares in the Navelli Valley of Italy's Abruzzo region, near L'Aquila. It was first introduced to Italy by a Dominican monk from Inquisition-era Spain. But in Italy the biggest saffron cultivation, for quality and quantity, is in San Gavino Monreale, Sardinia. There, saffron is grown on 40 hectares (60% of Italian production); it also has very high crocin, picrocrocin, and safranal content. Another is the Kashmiri "Mongra" or "Lacha" saffron (Crocus sativus 'Cashmirianus'), which is among the most difficult for consumers to obtain. Repeated droughts, blights, and crop failures in Kashmir, combined with an Indian export ban, contribute to its high prices. Kashmiri saffron is recognisable by its extremely dark maroon-purple hue, among the world's darkest, which suggests the saffron's strong flavour, aroma, and colourative effect.

Grades

Minimum saffron colour grading standards (ISO 3632)

ISO Grade (category) - Crocin-specific absorbance (A**»**) score (at »=440 nm)

I > 190

II 150–190

III 110–150

IV 80–110

Source: Tarvand 2005b

Saffron types are graded by quality according to laboratory measurements of such characteristics as crocin (colour), picrocrocin (taste), and safranal (fragrance) content. Other metrics include floral waste content (i.e. the saffron spice sample's non-stigma floral content) and measurements of other extraneous matter such as inorganic material ("ash"). A uniform set of international standards in saffron grading was established by the International Organization for Standardization, which is an international federation of national standards bodies. Namely, ISO 3632 deals exclusively with saffron. It establishes four empirical grades of colour intensity: IV (poorest), III, II, and I (finest quality). Saffron samples are then assigned to one of these grades by gauging the spice's crocin content, which is revealed by measurements of crocin-specific spectroscopic absorbance. Absorbance is defined as A**»** = log(I / I***0***), with A**»** as absorbance. It is a measure of a given substance's transparency (I / I***0***, the ratio of light intensity passing through sample to that of the incident light) to a given wavelength of light.

For saffron, absorbance is determined for the crocin-specific photon wavelength of 440 nm in a given dry sample of spice.[62] Higher absorbances at this wavelength imply greater

crocin concentration, and thus a greater colourative intensity. These data are measured through photospectroscopy reports at certified testing laboratories worldwide. These colour grades proceed from grades with absorbances lower than 80 (for all category IV saffron) up to 190 or greater (for category I). The world's finest samples (the selected most red-maroon tips of stigmas picked from the finest flowers) receive absorbance scores in excess of 250. Market prices for saffron types follow directly from these ISO scores.[62] However, many growers, traders, and consumers reject such lab test numbers. They prefer a more holistic method of sampling batches of thread for taste, aroma, pliability, and other traits in a fashion similar to that practiced by practised wine tasters.[63]

Spanish federal saffron grading standards

Grade - ISO score

Coupe > 190

La Mancha 180–190

Rio 150–180

Standard 145–150

Sierra < 110

Source: Tarvand 2005b

Despite such attempts at quality control and standardisation, an extensive history of saffron adulteration—particularly among the cheapest grades—continues into modern times. Adulteration was first documented in Europe's Middle Ages, when those found selling adulterated saffron were executed under the Safranschou code.[64] Typical methods include mixing in extraneous substances like beet, pomegranate fibers, red-dyed silk fibers, or the saffron crocus's tasteless and odorless yellow stamens. Other methods included dousing saffron fibers with viscid substances like honey or vegetable oil. However, powdered saffron is more prone to adulteration, with turmeric, paprika, and other powders used as diluting fillers. Adulteration can also consist of selling mislabeled mixes of different saffron grades.[40] Thus, in India, high-grade Kashmiri saffron is often sold mixed with cheaper Iranian imports; these mixes are then marketed as pure Kashmiri saffron, a development that has cost Kashmiri growers much of their income.[65][66]

Sassafras

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Laurales
Family: Lauraceae
Genus: *Sassafras*

Species

Sassafras albidum
Sassafras tzumu

Sassafras is a genus of two species of deciduous trees in the family Lauraceae, native to eastern North America and eastern Asia.

Sassafras trees grow from 15-35 m tall and 70-150 cm diameter, with many slender branches, and smooth, orange-brown bark. The branching is sympodial. The bark of the mature trunk is thick, red-brown, and deeply furrowed. The wood is light, soft, weak, and brittle. All parts of the plants are very fragrant.

The species are unusual in having three distinct leaf patterns on the same plant; unlobed oval, bilobed (mitten-shaped), and trilobed (three pronged). They have smooth margins and grow 7-20 cm long by 5-10 cm broad. The young leaves and twigs are quite mucilaginous. The tiny, yellow flowers are five-petaled and bloom in the spring; they are dioecious, with male and female flowers on separate trees. The fruit are blue-black, egg-shaped, 1 cm long, produced on long, red-stalked cups, and mature in late summer.

The name "Sassafras", applied by the Spanish botanist Nicolas Monardes in the sixteenth century, is said to be a corruption of the Spanish word for saxifrage. It was also called "pauame" by Native Americans.

Species

- Sassafras albidum (Nuttall) Nees - *Sassafras*, *White Sassafras*, *Red Sassafras* or *Silky Sassafras*. Eastern North America, from southernmost Ontario, Canada through the eastern United States south to central Florida, and west to southern Iowa and eastern Texas.
- Sassafras tzumu (Hemsl.) Hemsl. - *Chinese Sassafras* or *Tzumu*. Central and southwestern China. It differs from S. albidum in the leaves being more frequently three-lobed, the lobes having a tapered acuminate apex (not rounded to weakly acute).
- Sassafras randaiense (Hayata) Rehd. - *Taiwan Sassafras*. Taiwan, regarded synonym of Yushunia randaiensis (Hayata) Kamikoti.

Uses

Essential oil distilled from the root-bark or the fruit was used as a fragrance in perfumes and soaps, food (sassafras tea and candy flavoring) and for aromatherapy. It is also used as a pain killer as well as an antiseptic in dentistry.The smell of sassafras oil is said to make an excellent repellent for mosquitoes and other insects, which makes it a nice yard plant. The root or root bark is also used to make tea. A yellow dye is obtained from the wood. The shoots are used to make root beer (formerly an alcoholic beverage, but now a soft drink), which owes its characteristic odor to the sassafras extract. The leaves are used for thickening sauces and soups, and when dried and ground are known as filé powder, a spice used in Cajun, Creole, and other Louisiana cooking, such as the dish filé gumbo. The pith is used in the U.S. to soothe eye inflammation and ease catarrh.Acids can be extracted from bark for manufacturing perfumes.

Safrole, which is the main component (75-80%) of sassafras essential oil, is now recognized by the United States Department of Agriculture as a potential carcinogen. Sassafras oil is also the preferred source of safrole for MDMA production by clandestine laboratories, thus its sale is monitored by the U.S. Drug Enforcement Administration.

Willow

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Malpighiales
Family: Salicaceae
Genus: *Salix* L.

Species

About 350, including:
Salix acutifolia - Violet Willow
Salix alaxensis - Alaska Willow
Salix alba - White Willow
Salix alpina - Alpine Willow
Salix amygdaloides - Peachleaf Willow
Salix arbuscula - Mountain Willow
Salix arbusculoides - Littletree Willow
Salix arctica - Arctic Willow
Salix atrocinerea
Salix aurita - Eared Willow
Salix babylonica - Peking Willow
Salix bakko
Salix barrattiana - Barratt's Willow

Salix bebbiana - Beaked Willow
Salix boothii - Booth Willow
Salix bouffordii
Salix brachycarpa - Barren-ground Willow
Salix cacuminis
Salix canariensis
Salix candida - Sage Willow
Salix caprea - Goat Willow
Salix caroliniana - Coastal Plain Willow
Salix chaenomeloides
Salix chilensis
Salix cinerea - Grey Sallow
Salix cordata
Salix daphnoides
Salix discolor - Pussy Willow
Salix eastwoodiae - Eastwood's Willow
Salix eleagnos
Salix eriocarpa
Salix eriocephala - Heartleaf Willow
Salix exigua - Sandbar Willow
Salix foetida
Salix fragilis - Crack Willow
Salix futura
Salix geyeriana
Salix gilgiana
Salix glauca
Salix gooddingii - Goodding Willow
Salix gracilistyla
Salix hainanica - Hainan Willow
Salix helvetica - Swiss Willow
Salix herbacea - Dwarf Willow
Salix hookeriana - Hooker's Willow
Salix hultenii
Salix humboldtiana - Chile Willow
Salix humilis - Upland Willow
Salix integra
Salix interior
Salix japonica
Salix jessoensis
Salix koriyanagi
Salix kusanoi
Salix lanata - Woolly Willow
Salix lapponum - Downy Willow
Salix lasiandra - Pacific Willow
Salix lasiolepsis - Arroyo Willow

Salix lucida - Shining Willow
Salix magnifica
Salix matsudana - Chinese Willow
Salix miyabeana
Salix mucronata
Salix myrtilloides - Swamp Willow
Salix myrsinifolia - Dark-leaved Willow
Salix myrsinites - Whortle-leaved Willow
Salix nakamurana
Salix nigra - Black Willow
Salix pedicellaris - Bog Willow
Salix pentandra - Bay Willow
Salix petiolaris - Slender Willow
Salix phylicifolia - Tea-leaved Willow
Salix planifolia- Planeleaf Willow
Salix polaris - Polar Willow
Salix pseudo-argentea
Salix purpurea - Purple Willow
Salix pyrifolia - Balsam Willow
Salix reinii
Salix repens - Creeping Willow
Salix reticulata - Net-leaved Willow
Salix retusa
Salix rorida
Salix rosmarinifolia - Rosemary-leaved Willow
Salix rupifraga
Salix salicicola
Salix schwerinii
Salix scouleriana - Scouler's Willow
Salix sericea - Silky Willow
Salix serissaefolia
Salix serissima - Autumn Willow
Salix shiraii
Salix sieboldiana
Salix sitchensis
Salix subfragilis
Salix subopposita
Salix taraikensis
Salix tetrasperma
Salix thorelii
Salix triandra - Almond Willow
Salix udensis
Salix viminalis - Common Osier
Salix vulpina
Salix waldsteiniana

Salix wallichiana
Salix yezoalpina
Salix yoshinoi

The *willows* are deciduous trees and shrubs in the genus *Salix*, part of the willow family Salicaceae.

There are about 350 species in this genus worldwide, found primarily on moist soils in cooler zones in the Northern Hemisphere. The leaves are deciduous, often elongate but round to oval in a few species, and with a serrated margin. Willows are dioecious with male and female flowers appearing as catkins on different plants; the catkins are produced early in the spring, often before the leaves or as the new leaves open. The fruit is a small capsule containing numerous tiny (0.1 mm) seeds embedded in white down, which assists wind dispersal of the seeds. Willows are very cross-fertile and numerous hybrids are known, both naturally occurring and in cultivation.

Some smaller species may also be known by the common names osier and sallow; the latter name is derived from the same root as the Latin salix.

Some willows, particularly arctic and alpine species, are very small; the *Dwarf Willow* (Salix herbacea) rarely exceeds 6 cm in height, though spreading widely across the ground.

The *Weeping Willow*, very widely planted as an ornamental tree, is a cultivar, Salix × sepulcralis 'Chrysocoma', derived from a hybrid between the Chinese Peking Willow and the European White Willow.

Almost all willows take root very readily from cuttings or where broken branches lie on the ground. There are a few exceptions, including the Goat Willow and Peachleaf Willow. One famous example of such growth from cuttings involves the poet Alexander Pope, who begged a twig from a parcel tied with twigs sent from Spain to Lady Suffolk. This twig was planted and thrived, and legend has it that all of England's Weeping Willows are descended from this first one [1]. Willows are used as food plants by the larvae of some Lepidoptera species - see list of Lepidoptera which feed on Willows.

Uses

Medicinal uses

The bark of the willow tree has been mentioned in ancient texts from Assyria, Sumer and Egypt as a remedy for aches and fever, and the Greek physician Hippocrates wrote about its medicinal properties in the 5th century BC. Native Americans across the American continent relied on it as a staple of their medical treatments.

The active extract of the bark, called salicin, was isolated to its crystalline form in 1828 by Henri Leroux, a French pharmacist, and Raffaele Piria, an Italian chemist, who then succeeded in separating out the acid in its pure state. Salicin is acidic when in a saturated solution in water (pH = 2.4), and is called salicylic acid for that reason.

In 1897 Felix Hoffmann created a synthetically altered version of salicin (in his case derived from the Spiraea plant), which caused less digestive upset than pure salicylic acid. The new drug, formally Acetylsalicylic acid, was named aspirin by Hoffmann's employer Bayer AG. This gave rise to the hugely important class of drugs known as non-steroidal anti-inflammatory drugs (NSAIDs).

Other uses

- Agroforestry
Basket weaving
Biofiltration
Biomass energy (bioenergy)
Box, Veneer
Charcoal
Constructed wetlands
Cricket bats
Cradle boards
Chairs & furniture
Dolls, toys, whistles
Ecological wastewater treatment systems
Energy forestry
As part of the four species used on the Jewish holiday of Sukkot.
Fibre plants
- Fish traps
- Flutes
Hedges
Land reclamation
Landscaping
Living Willow Sculpture
Paper
Phytoremediation
Poles, turnery, tool handles
Rope and string
Streambank stabilisation (bioengineering)
Slope stabilisation
Soil erosion control
Soil building
Soil reclamation
Shelterbelt & windbreak
Sweat lodges

- Tannin

- Wands, brooms
Wattle fences
Wattle and daub
Wildlife habitat

-

Yeast

Yeasts are single-celled (unicellular) fungi, a few species of which are commonly used to leaven bread, ferment alcoholic beverages, and even drive experimental fuel cells. Most yeasts belong to the division Ascomycota, though some are Basidiomycota. A few yeasts, such as Candida albicans, can cause infection in humans (Candidiasis). More than one thousand species of yeasts have been described. The most commonly used yeast is Saccharomyces cerevisiae, which was domesticated for wine, bread, and beer production thousands of years ago.

Physiology

Yeast species can have either obligately aerobic or facultatively anaerobic physiology. There is no known obligately anaerobic yeast. In the absence of oxygen, fermentative yeasts produce their energy by converting carbohydrates into carbon dioxide and ethanol (alcohol) or lactic acid. In brewing, the ethanol is bottled, while in baking the carbon dioxide raises the bread, and most of the ethanol evaporates.

An example with glucose as the substrate

$C_6H_{12}O_6$ (glucose) ’$2C_2H_5OH + 2CO_2$

Use in biotechnology

The useful physiological properties of yeast have led to their use in the field of biotechnology. Fermentation of sugars by yeast is the oldest and largest application of this technology. Baker's yeast is used for bread production, brewer's yeast is used for beer fermentation, and yeast is also used for wine fermentation. Yeast are also one of the most widely used model organisms for genetics and cell biology.

Growth environment

Many yeasts can be isolated from sugar-rich environmental samples. Some good examples include fruits and berries (such as grapes, apples or peaches), exudates from plants (such as plant saps or cacti). Some yeasts are found in association with soil and insects.

A common medium used for the cultivation of yeasts is called potato dextrose agar (PDA) or potato dextrose broth. Potato extract is made by autoclaving (i.e. pressure-cooking) cut-up potatoes with water for 5 to 10 minutes and then decanting off the broth. Dextrose (glucose) is then added (10 g/L) and the medium is sterilized by autoclaving.

Monoclonal antibodies

Monoclonal antibodies (*mAb*) are antibodies that are identical because they were produced by one type of immune cell and are all clones of a single parent cell. Given (almost) any substance, it is possible to create monoclonal antibodies that specifically bind to that substance; they can then serve to detect or purify that substance. This has become an important tool in biochemistry, molecular biology and medicine. When used as medications, the generic name ends in -mab (see "Nomenclature of monoclonal antibodies").

Discovery

The idea of a "magic bullet" was first proposed by Paul Ehrlich who at the beginning of the 20th century figured that if a compound could be made that selectively targeted a disease-causing organism, then a toxin for that organism could be delivered along with the agent of selectivity.

In the 1970s the B-cell cancer myeloma was known, and it was understood that these cancerous B-cells all produce a single type of antibody (a paraprotein). This was used to study the structure of antibodies, but it was not yet possible to produce identical antibodies specific to a given antigen.

The process of producing monoclonal antibodies described above was invented by Georges Köhler, César Milstein, and Niels Kaj Jerne in 1975[1]; they shared the Nobel Prize in Physiology or Medicine in 1984 for the discovery. The key idea was to use a line of myeloma cells that had lost their ability to secrete antibodies, come up with a technique to fuse these cells with healthy antibody producing B-cells, and be able to select for the successfully fused cells.

In 1988 Greg Winter and his team pioneered the techniques to humanise monoclonal antibodies[2], removing the reactions that many monoclonal antibodies caused in some patients.

Production

If a foreign substance (an antigen) is injected into a vertebrate such as a mouse or a human, some of the immune system's B-cells will turn into plasma cells and start to produce antibodies that recognize that antigen. Each B-cell produces only one kind of antibody, but different B-cells will produce structurally different antibodies that bind to different parts ("epitopes") of the antigen. This natural mixture of antibodies found in serum is known as polyclonal antibodies.

To produce monoclonal antibodies, one removes B-cells from the spleen or lymph nodes of an animal that has been challenged several times with the antigen of interest. These B-cells are then fused with myeloma tumor cells that can grow indefinitely in culture (myeloma is a B-cell cancer) and that have lost the ability to produce antibodies. This fusion is done by making the cell membranes more permeable by the use of polyethylene glycol, electroporation or, of historical importance, infection with some virus. The fused hybrid cells (called *hybridomas*), being cancer cells, will multiply rapidly and indefinitely. Large amounts

of antibodies can therefore be produced. The hybridomas are sufficiently diluted to ensure clonality and grown. The antibodies from the different clones are then tested for their ability to bind to the antigen (for example with a test such as ELISA) or immuno-dot blot, and the most sensitive one is picked out.

In the above process, one uses myeloma cell lines that have lost their ability to produce their own antibodies or antibody chain, so as to not contaminate the target antibody. Furthermore, one employs only myeloma cells that have lost a specific enzyme (hypoxanthine-guanine phosphoribosyltransferase, HGPRT) and therefore cannot grow under certain conditions (namely in the presence of HAT medium). These cells are preselected by the use of 8-azaguanine media prior to the fusion. Cells that possess the HGPRT enzyme will be killed by the 8-azaguanine. During the fusion process many cells can fuse. Myeloma with myeloma, spleen cell with spleen cell, 3 cells of different types etc... The desired fusions are between healthy B-cells producing antibodies against the antigen of interest and myeloma cells. These are relatively rare, but when one succeeds, then the healthy partner supplies the needed enzyme and the fused cell can survive in HAT medium. This is the trick to detect the successfully fused cells. The medium must be enriched during selection to favour hybridoma growth. This can be achieved by the use of a layer of feeder cells or supplement media such as briclone.

Monoclonal antibodies can be produced in cell culture or in live animals. When the hybridoma cells are injected in mice (in the peritoneal cavity, the gut), they produce tumors containing an antibody-rich fluid called ascites fluid. Production in cell culture is usually preferred as the ascites technique may be very painful to the animal and if replacement techniques exist, may be considered unethical. Fermentation chambers have been used to produce antibodies on a larger scale. Nowadays, bioengineering allow production of antibodies in plants.

Applications

Once monoclonal antibodies for a given substance have been produced, they can be used to detect the presence and quantity of this substance, for instance in a Western blot test (to detect a protein on a membrane) or an immunofluorescence test (to detect a substance in a cell). They are also very useful in immunohistochemistry which detect antigen in fixed tissue sections. Monoclonal antibodies can also be used to purify a substance with techniques called immunoprecipitation and affinity chromatography.

Monoclonal antibodies for cancer treatment

One possible treatment for cancer involves monoclonal antibodies that bind only to cancer cell-specific antigens and induce an immunological response against the target cancer cell. Such mAb could also be modified for delivery of a toxin, radioisotope, cytokine or other active conjugate; it is also possible to design bispecific antibodies that can bind with their Fab regions both to target antigen and to a conjugate or effector cell. In fact, every intact antibody can bind to cell receptors or other proteins with its Fc region. The illustration below shows all these possibilities:

Monoclonal antibodies for cancer. ADEPT, antibody directed enzyme prodrug therapy; ADCC, antibody dependent cell-mediated cytotoxicity; CDC, complement dependent cytotoxicity; MAb, monoclonal antibody; scFv, single-chain Fv fragment. [3]

Chimeric and humanized antibodies

One problem in medical applications is that the standard procedure of producing monoclonal antibodies yields mouse antibodies. Although murine antibodies are very similar to human ones there are differences. The human immune system hence recognizes mouse antibodies as foreign, rapidly removing them from circulation and causing systemic inflammatory effects.

A solution to this problem would be to generate human antibodies directly from humans. However, this is not easy primarily because it is clearly not ethical to challenge humans with antigen in order to produce antibody. Furthermore, it is not easy to generate human antibodies against human tissues.

Various approaches using recombinant DNA technology to overcome this problem have been tried since the late 1980s. In one approach, one takes the DNA that encodes the binding portion of monoclonal mouse antibodies and merges it with human antibody producing DNA. One then uses mammalian cell cultures to express this DNA and produce these half-mouse and half-human antibodies. (Bacteria cannot be used for this purpose, since they cannot produce this kind of glycoprotein.) Depending on how big a part of the mouse antibody is used, one talks about *chimeric antibodies* or *humanized antibodies*. Another approach involves mice genetically engineered to produce more human-like antibodies. Monoclonal antibodies have been generated and approved to treat;cancer, cardiovascular disease, inflammatory diseases, macular degeneration, transplant rejection, and viral infection (see monoclonal antibody therapy).

In August 2006 the Pharmaceutical Research and Manufacturers of America reported that U.S. companies had 160 different monoclonal antibodies in clinical trials or awaiting approval by the Food and Drug Administration.[4]

Nomenclature of monoclonal antibodies

The *nomenclature of monoclonal antibodies* is a naming scheme for assigning generic, or nonproprietary, names to a group of medicines called monoclonal antibodies. This scheme is used for both the World Health Organization's International Nonproprietary Names and the United States Adopted Names. In general, suffixes are used to identify a class of medicines; all monoclonal antibody pharmaceuticals end with the suffix -mab. However, different infixes are used depending on the structure and function of the medicine.

The infix preceding the -mab suffix denotes the animal origin of the antibodies. Although the original monoclonal antibodies were produced in mice (infix, -o-), these antibodies are recognized as foreign by human immune systems and may be rapidly cleared, provoke an allergic reaction, or both. Therefore, parts of the antibody may be replaced with human sequences. If the constant region is replaced with the human form, it is termed chimeric and the infix used is -xi-. Part of the variable regions may also be substituted, in which case it is termed humanized and the infix used is -zu-. Antibodies originating in humans use -u-.

The infix preceding the source of the antibodies refers to medicine's target. Most of these consist of a consonant, vowel, then another consonant. For ease of pronunciation and to avoid awkwardness, the final consonant is dropped if the following infix begins with a consonant (such as -zu- or -xi-). Examples of these include -ci(r)- for the circulatory system and -tu(m)- for miscellaneous tumors (cancers).

Finally, the prefix carries no special meaning and should be unique for each medicine. A second word may be added if there is another substance attached or linked.

Complete list of stems for monoclonal antibody nomenclature

Prefix	Target		Source		Suffix
varies	*-vi(r)-*	viral	*-u-*	human	*-mab*
	-ba(c)-	bacterial	*-o-*	mouse	
	-li(m)-	immune	*-a-*	rat	
	-le(s)-	infectious lesions	*-e-*	hamster	
	-ci(r)-	cardiovascular	*-i-*	primate	
	-co(l)-	colonic tumor	*-xi-*	chimeric	
	-me(l)-	melanoma	*-zu-*	humanized	
	-ma(r)-	mammary tumor			
	-go(t)-	testicular tumor			
	-go(v)-	ovarian tumor			
	-pr(o)-	prostate tumor			
	-tu(m)-	miscellaneous tumor			

Examples

Abciximab is a commonly used medication to prevent platelets from clumping together. It can be broken down into *ab- + -ci(r)- + -xi- + -mab*. Therefore, it is a chimeric monoclonal antibody used on the cardiovascular system.

Another example is the breast cancer medication trastuzumab, which can be broken down into *tras- + -tu(m)- + -zu- + -mab*. Therefore, it is a humanized monoclonal antibody used against a tumor.

Muscle relaxant

A *muscle relaxant* is a drug which decreases the tone of a muscle.

Central acting muscle relaxants

- Benzodiazepines
  - Methocarbamol

Unclassified

Here are several other skeletal muscle relaxants which may belong in the above categories:

- Baclofen
Carisoprodol
Chlorzoxazone
Cyclobenzaprine
Dantrolene
Metaxalone
Orphenadrine
Pancuronium
Tizanidine

Acting on smooth muscle

- Dicyclomine

Other

Drugs from classes other than the muscle relaxant class are also used to treat spasticity:

- Clonidine
Gabapentin

Neuromuscular-blocking drugs

Neuromuscular-blocking drugs block neuromuscular transmission at the neuromuscular junction, causing paralysis of the affected skeletal muscles. This is accomplished either by acting presynaptically via the inhibition of acetylcholine (ACh) synthesis or release, or by acting postsynaptically at the acetylcholine receptor. While there are drugs that act presynaptically (such as botulin toxin and tetrodotoxin), the clinically-relevant drugs work postsynaptically.

Clinically, neuromuscular block is used as an adjunct to anesthesia to induce paralysis, so that surgery can be carried out with less complications. Because neuromuscular block may paralyze muscles required for breathing, mechanical ventilation should be available to maintain adequate respiration. These drugs fall into two groups:

- *Non-depolarizing blocking agents*: These agents constitute the majority of the clinically-relevant neuromuscular blockers. They act by blocking the binding of ACh to its receptors, and in some cases, they also directly block the ionotropic activity of the ACh receptors (PMID 8866353).
- *Depolarizing blocking agents*: These agents act by depolarizing the plasma membrane of the skeletal muscle fiber. This persistent depolarization makes the muscle fiber resistant to further stimulation by ACh.

Patients are still aware of pain even after full conduction block has occurred; hence, general anesthetics and/or analgesics must be given to prevent anesthesia awareness.

Non-depolarizing blocking agents

All of these agents act as competitive antagonists against ACh at the site of postsynaptic ACh receptors.

Tubocurarine, found in curare of the South American plant genus Strychnos, has this effect. Tubocurarine has a slow onset (>5min) and a long duration of action (1-2 hours). Side effects include hypotension. This hypotension is partially explained by its effect of increasing histamine release, which is a vasodilator (PMID 2429800), as well as its effect of blocking autonomic ganglia (PMID 2682131). Route of excretion in the urine.

This drug needs to block about 70-80% of the Ach receptors for neuromuscular conduction to fail, and hence, for effective blockade to occur. At this stage, EPPs (end-plate potentials) can still be detected, but are too small the reach the threshold potential needed for activation of muscle fiber contraction.

Depolarizing blocking agents

Depolarizing blocking agents work by depolarizing the plasma membrane of the muscle fiber, similar to acetylcholine. However, these agents are resistant to degradation by acetylcholinesterase, and can persistently depolarize the muscle fibers as opposed to the transient depolarization by ACh which is rapidly degraded. Initially, they cause muscular fasciculations (muscle twitches) while they are depolarizing the muscle fibers. Eventually, after sufficient depolarization has occurred, the muscle is no longer responsive to ACh released by the motoneurons. Hence, full neuromuscular block has been achieved.

Decamethonium and suxamethonium (US: succinylcholine) are good examples of this. These drugs are ACh-like drugs, which have short action time, and elevated action effects at the end-plate of muscles. Suxamethonium is the only depolarizing blocking agent in general clinical use.

Inhibition of acetylcholinesterase, the enzyme responsible for degrading acetylcholine, will cause ACh to have the same effect as these agents.

Comparison of drugs

The main difference is in the reversal of these two types of neuromuscular-blocking drugs. Non-depolarizing blockers are reversed by anticholinesterase inhibitor drugs. Since they are competitive antagonists at the ACh receptor so can be reversed by increases in ACh. The depolarizing blockers already have ACh-like actions, so these agents will have prolonged effect under the influence of anticholinesterase inhibitors.

The administration of depolarizing blockers will initially exhibit fasciculations (a sudden twitch just before paralysis occurs). This is due to the depolarization of the muscle. Also, post-operative pain is associated with depolarizing blockers.

The tetanic fade is the failure of muscles to maintain a fused tetany at sufficiently-high frequencies of electrical stimulation. Non-depolarizing blockers will have this effect on patients, while depolarizing blockers will not.

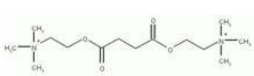
Adverse effects

Since these drugs may cause paralysis of the diaphragm, mechanical ventilation should be at hand to provide respiration.

Additionally, these drugs may exhibit cardiovascular effects, since they are not fully selective for the nicotinic receptor and hence may have effects on muscarinic receptors (PMID 2682131). If muscarinic receptors of the autonomic ganglia or adrenal medulla are blocked, these drugs may cause hypotension and tachycardia. Additionally, neuromuscular blockers may facilitate histamine release, which causes hypotension, flushing, and tachycardia.

In depolarizing the musculature, suxamethonium may trigger the release of large amounts of potassium from muscle fibers. This puts the patient at risk for life-threatening complications, such as hypokalemia and cardiac arrhythmias.

Suxamethonium chloride



Systematic (IUPAC) name

2,2'-[(1,4-dioxobutane-1,4-diyl)bis(oxy)]bis (N,N,N-trimethylethanaminium)

Identifiers

CAS number 306-40-1

ATC code M03**AB01**

PubChem 5314

DrugBank APRD00159

Chemical data

Formula $C_{14}H_{30}N_2O_4$

Mol. weight 290.399 g/mol

Pharmacokinetic data

Bioavailability **NA**

Metabolism By pseudocholinesterase, to succinylmonocholine and choline

Excretion Renal (10%)

Therapeutic considerations

Pregnancy cat. A(AU) C(US)

Legal status POM(UK) -only(US)

Routes Intravenous

Suxamethonium chloride (also known as *succinylcholine*, or *scoline*) is a white crystalline substance, it is odourless and highly soluble in water. The compound consists of two acetylcholine molecules that are linked by their acetyl groups. Suxamethonium is sold under several trademark names such as *Anectine*®, and may be referred to as "sux" for short.

Suxamethonium acts as a depolarizing muscle relaxant. It imitates the action of acetylcholine at the neuromuscular junction, but it is not degraded by acetylcholinesterase but by pseudocholinesterase, a plasma cholinesterase. This hydrolysis by pseudocholinesterase is much slower than that of acetylcholine by acetylcholinesterase.

Phase 1 block

There are two phases to the blocking effect of suxamethonium. The first is due to the prolonged stimulation of the acetylcholine receptor results first in disorganized muscle contractions (fasciculations, considered to be a side effect as mentioned below), as the acetylcholine receptors are stimulated. On stimulation, the acetylcholine receptor becomes a general ion channel, so there is a high flux of potassium out of the cell, and of sodium into the cell, resulting in a membrane potential less than the action potential. So, after the initial firing, the cell remains refractory.

Phase 2 block

On continued stimulation, the acetylcholine receptors become desensitised and close. This means that new acetylcholine signals do not cause an action potential; and the continued binding of suxamethonium is ignored. This is the principal anaesthetic effect of suxamethonium, and wears off as the suxamethonium is degraded, and the acetylcholine receptors return to their normal configuration. The side effect of hyperkalaemia is because the acetylcholine receptor is propped open, allowing continued flow of potassium ions into the extracellular fluid. A typical increase of potassium ion serum concentration on administration of suxamethonium is 0.5 mmol per litre, whereas the normal range of potassium is 3.5 to 5 mmol per litre: a significant increase which results in the other side-effects of ventricular fibrilation due to reduced to action potential initiation in the heart.

Medical uses

Its medical uses are limited to short-term muscle relaxation in anesthesia and intensive care, usually for facilitation of endotracheal intubation. Despite its many undesired effects on the circulatory system and skeletal muscles (including malignant hyperthermia, a rare but life-threatening disease), it is perennially popular in emergency medicine because it arguably has the fastest onset and shortest duration of action of all muscle relaxants. Both are major points of consideration in the context of trauma care, where paralysis must be induced very quickly and the use of a longer-acting agent might mask the presence of a neurological deficit.

A single intravenous dose of 1.0 to 1.5 milligrams per kilogram of body weight for adults or 2.0 milligrams per kilogram for pediatrics will cause flaccid paralysis within a minute of injection. For intramuscular injection higher doses are used and the effects last somewhat longer. Suxamethonium is quickly degraded by plasma cholinesterase and the duration of effect is usually in the range of a few minutes. When plasma levels of cholinesterase are greatly diminished or an atypical form of cholinesterase is present (an otherwise harmless inherited disorder), paralysis may last much longer.

Side effects

Side effects include fasciculations, muscle pains, acute rhabdomyolysis with hyperkalemia, transient ocular hypertension, and changes in cardiac rhythm including bradycardia, cardiac arrest, and ventricular dysrhythmias. In children with unrecognized neuromuscular diseases, a single injection of succinylcholine can lead to massive release of potassium from skeletal muscles with cardiac arrest.

Succinylcholine does not produce unconsciousness or anesthesia, and its effects may cause considerable psychological distress while simultaneously making it impossible for a patient to communicate. For these reasons, administration of the drug to a conscious patient is strongly contraindicated, except in necessary emergency situations.

This drug has occasionally been used as a paralyzing agent for executions by lethal injection, although pancuronium bromide is the preferred agent today because of its longer duration of effect and its absence of fasciculations as a side effect. It has also been used for murder.

Succinylcholine is the drug that is suspected to have been used to murder Nevada State Controller Kathy Augustine.

Nootropic

Nootropics, popularly referred to as "smart drugs," are substances which boost human cognitive abilities (the functions and capacities of the brain). The word *nootropic* is derived from the Greek words noos or mind and tropein meaning to ward. Typically, nootropics are alleged to work by increasing the brain's supply of neurochemicals (neurotransmitters, enzymes, and hormones), by improving the brain's oxygen supply, or by stimulating nerve growth.

Most alleged nootropic substances are nutrients or plant components (herbs, roots, beans, bark, etc.), available over the counter at health food and grocery stores, and are used as nutritional supplements. Some nootropics are drugs, used to treat retardation, neural degradation (Alzheimer's and Parkinson's), and for cases of oxygen deficit to prevent hypoxia. These drugs have a variety of human enhancement applications as well, are marketed heavily on the World Wide Web, and are used by many people in personal cognitive enhancement regimens.

With some nootropics the effects are subtle and gradual, such as with most nerve growth inducers, and may take weeks or even months before any cognitive improvement is noticed. At the other end of the spectrum are nootropics which have effects that are immediate, profound, and obvious. While scientific studies support some of the claimed benefits it is alleged that certain nootropic substances provide, It is worth noting that many of the claims attributed to a variety of nootropics have not been formally tested. Citations are provided in the article where information is available.

General strategies

Neurotransmitter support - supplying the body with the precursors and cofactors it needs to produce neurotransmitters. Keeping the brain's neurotransmitters at high levels improves concentration, mental focus, calculation ability, memory encoding, recall, creativity, mood, and cures and prevents most depressions. The four main neurotransmitters are acetylcholine, dopamine, norepinephrine and serotonin.

Note that cardiovascular exercise performed on a regular basis also has nootropic effects, by increasing the body's capacity to supply brain cells with oxygen. Exercise is highly synergistic with nutritional supplementation, and a health regimen is incomplete without it.

Nootropic substances

Nootropic drugs are generally only available by prescription or through personal importation. The other nootropic substances listed below are either nutritional supplements or plant components, and are generally available over the counter at health food and grocery stores. The term "drug" here is used as a legal designation, and does not indicate greater efficacy. With nootropics, the effects, effectiveness, and potency differ from substance to substance and from individual to individual. See the substance descriptions below for more detail.

Replenishing and increasing neurotransmitters

Thinking is a biologically demanding task. It involves the firing of neurons which requires plenty of neurotransmitters, and even though these are reuseable to some extent, they do get depleted. Depletion of neurotransmitters generally results in reduced mental performance, which may include difficulty concentrating, slowed reasoning, decreased learning efficiency, impaired recall, reduced coordination, lowered moods, inability to cope, increased response times, and mental fatigue. This also generally increases the likelihood of human error on tasks and activities performed. Stress causes neurotransmitters to be depleted even faster. The brain's neurotransmitters need to be replenished frequently, made by the body from substances ingested in the diet. Maintaining neurochemicals at optimal levels has a corresponding effect on brain performance, supporting improved mental agility and stamina, even beyond the individual's normal limits.

As the brain ages, its ability to produce and maintain youthful levels of neurotransmitters declines.[1] Thus, the theory is that by providing the brain with ample raw materials to make the neurotransmitters it needs can restore them to more youthful levels to help maintain cognitive function at vigorous youthful levels as well.

Cholinergics

Cholinergics are substances which affect the neurotransmitter acetylcholine or the components of the nervous system which utilize acetylcholine. Acetylcholine facilitates memory, concentration, focus, and high-order thought processes (abstract thought, calculation, innovation, etc.). Increasing the availability of this neurotransmitter in the brain may improve these functions and increase the duration in which they may be engaged without slowing down or stopping. Oversupplying the brain with acetylcholine may have the opposite effect, temporarily reducing rather than improving mental performance. Cholinergic nootropics include acetylcholine precursors and cofactors, and acetylcholinesterase inhibitors:

- Acetyl-L-carnitine (ALCAR) - Amino acid. Precursor of acetylcholine (donating the acetyl portion to the acetylcholine molecule). It is synergistic with lipoic acid.
- Centrophenoxine (Lucidril) - Drug. cholinergic agent, enhances color perception.
- Choline - precursor to acetylcholine (an essential component of the acetylcholine molecule).
    - Alpha-GPC (L-alpha glycerylphosphorylcholine, Choline alfoscerate) - most effective choline precursor, readily crosses the blood-brain barrier.
    - CDP-Choline (Cytidine Diphosphate Choline) - choline precursor, tends to be less expensive and similar in effect to Alpha GPC.
    - Choline bitartrate - precursor of acetylcholine, general nootropic, anti-depressant.
    - Choline citrate - precursor of the neurotransmitter acetylcholine, general nootropic, anti-depressant.

- DMAE - approved treatment for ADD/ADHD, precursor of acetylcholine, cholinergic agent, removes lipofuscin from the brain, anti-depressant.
- L-Huperzine A - potent acetylcholinesterase inhibitor derived from Chinese club-moss.
- Lecithin - precursor of acetylcholine.
- Pyrrolidone derivatives:
  - Piracetam (Nootropil) - Prescription drug (in Europe). The original (first)[2], and most commonly taken[3] nootropic drug. It is a cholinergic agent, synergistic with DMAE, centrophenoxine, choline, and Hydergine. Increases brain cell metabolism and energy levels[4], and speeds up interhemispheric flow of information (left-right brain hemisphere communication). Increases vigilance,[5], improves concentration, and enhances memory. Protects neurons from hypoxia,[2] and stimulates growth of acetylcholine receptors. May also cause nerves to regenerate. Piracetam markedly decreases the formation of neuronal lipofuscin.[6] It improves posture in elderly people.[7] It is not regulated in the US.
  - Aniracetam - Drug. Analog of piracetam, and 4 to 8 times more potent. Like piracetam, aniracetam protects against some memory impairing chemicals, such as diethyldithiocarbamate and clonidine.[8] Also like piracetam, aniracetam may enhance memory in aging adults by increasing levels of brain biogenic monoamines, which are beneficial to learning and memory.[1] Both racetams have possible therapeutic use in treating fetal alcohol syndrome.[9] Aniracetam increases vigilance.[5]
  - Etiracetam - It increases vigilance.[5]
  - Nefiracetam - Drug. Analog of piracetam, and facilitates hippocampal neurotransmission.[10]
  - Oxiracetam - Drug. Analog of piracetam, and 2 to 4 times stronger. Improves memory, concentration, and vigilance. When fed to pregnant rats, the offspring of those rats were more intelligent than the offspring of rats fed a saline solution placebo.
  - Pramiracetam - Drug. Fifteen times stronger than piracetam, of which it is an analog.
- Vitamin B5 - cofactor in the conversion of choline into the neurotransmitter acetylcholine, cholinergic agent, increases stamina (including mental stamina).

CAUTION: Excess acetylcholine can be potentially harmful; see cholinesterase inhibitor.

Dopaminergics

Dopaminergics are substances which affect the neurotransmitter dopamine or the components of the nervous system which utilize dopamine. Dopamine is produced in the synthesis of all catecholamine neurotransmitters, and is the rate limiting step for this

synthesis. Dopaminergic nootropics include dopamine precursors and cofactors, and dopamine reuptake inhibitors:

- L-dopa - Prescription drug. Precursor to the neurotransmitter dopamine, general nootropic, anti-depressant.
- Phenylalanine (requires Vitamin B6 and Vitamin C) - Essential amino acid. Precursor to dopamine, general nootropic, anti-depressant, sleep reducer.
- Theanine - Found in tea. Increases serotonin and dopamine levels in the brain. Increases alpha-wave based alert relaxation.
- Tyrosine (requires Vitamin B6 and Vitamin C) - Amino acid. Precursor to dopamine, general nootropic, anti-depressant, sleep reducer.
- Vitamin C- improves cardiovascular elasticity and integrity, membrane stabilizer and major anti-oxidant (protects brain cells and prevents brain cell death), cofactor in the production of the neurotransmitters dopamine and serotonin.
- Vitamin B6 - co-factor used by the body to produce dopamine.
- Yohimbe - Bark. Boosts dopamine levels as much as 80%, though how it does this is not yet understood. Aphrodesiac. Yohimbe poses some health risks through its side-effects: it is a neuro-paralytic which slows down breathing and induces acidosis, some symptoms of which are malaise, nausea, and vomiting. Contraindicated for users of megadoses of acidic vitamins or nutrients.

Deprenyl - Blocks MAO B (the neuroenzyme that breaks down dopamine) thus raising Dopamine better and faster than other drugs.

Serotonergics

Serotonergics are substances which affect the neurotransmitter serotonin or the components of the nervous system which utilize serotonin. Serotonergic nootropics include serotonin precursors and cofactors, and serotonin reuptake inhibitors:

- 5-HTP - more bioavailable form of tryptophan, precursor to the neurotransmitter serotonin, promotes relaxed poise and sound sleep.
- Griffonia simplicifolia a natural source of 5-HTP (an alternative in countries where 5-HTP not legal, freely available.)
- Theanine - Found in tea. Increases GABA and dopamine levels in the brain. Increases alpha-wave based alert relaxation.
- Tryptophan (requires Vitamin B6 and Vitamin C) - Essential amino acid. Precursor to serotonin, found in high concentration in bananas and poultry (especially turkey), also in milk, promotes relaxed poise and sound sleep.

Anti-depression, adaptogenic and mood stabilization

Depression and depressed mood negatively affect cognitive performance. Feelings of sadness, guilt, helplessness, hopelessness, anxiety, and fear caused by depression detract from productive thought, while apathy (which is also induced by depression) is the lack of

motivation and driving moods (like curiosity, interest, determination, etc.) Other symptoms include disturbed sleep patterns, mental fatigue and loss of energy, trouble concentrating or making decisions, and a generalized slowing and obtunding of cognition, including memory. Obviously, removing these effects improves intelligence and mental performance, and therefore, counteracting and preventing depression are effective nootropic strategies. There is a high correlation between depression and a reduction or depletion of neurotransmitters (dopamine, acetylcholine, and serotonin) in the brain, therefore it is no surprise that increasing the brain's supply of neurotransmitters alleviates (or at least reduces the symptoms of) most depressions. Stress is another major factor in neurotransmitter depletion, being both a cause and effect of it (creating a vicious downward cycle), therefore stress management and anti-stress substances are also very useful nootropic strategies.

All of the "nergics" listed above have been found to increase stress tolerance and alleviate depression (by replenishing or increasing the brain's supply of specific neurotransmitters), especially when used in precursor/co-factor combinations.

Here are some more nootropics which affect mood and stress:

- Ashwagandha (Withania somnifera) - Root. Also known as Indian ginseng. Adaptogen used as a tonic to normalize body processes and reduce stress and anxiety.
- Inositol - Is a B-vitamin like substance with anti-anxiety effects. It is believed to produce its anti-anxiety effects by improving the binding of gabaergics to GABA***A*** receptors. Inositol is a sugar, and is therefore an alternative energy source for brain and muscle tissues. It produces a sugar high without a sugar low, making it especially suited for sweetening tea (instead of sugar). It is also a membrane stabilizer which can strengthen (and therefore help protect) neurons.
- Lemon Balm (Melissa Officinalis) - Herb. Anti-depressant.
- Rhodiola Rosea - Herb. Adaptogen; elevates mood, alleviates depression. Promotes mental energy and stamina, reduces fatigue.
- St John's Wort - Herb. The active components: hypericin and hyperforin, are clinically indicated to be effective in cases of mild to medium depression.
- Ginseng, Siberian (Eleutherococcus senticosus) - Root. Anti-anxiety adaptogen that normalizes physical stress and mental consequences.
- Selegiline (Deprenyl) - Along with Piracetam and Meclofenoxate, Deprenyl decreases the amount of lipofuscin pigment and ceroid pigment accumulations in the brain by improving cellular recycling activities.[11] Therefore, these nootropics may slow age related diseases in the brain.
- Sutherlandia Frutescens - Herb. Adaptogen, blood detoxifier.
- Tea - Herb. Contains theophylline and theanine. Increases alpha-wave based alert relaxation (relieves stress).
- Theanine - Amino acid. Found in tea. Increases serotonin and dopamine levels in the brain. Increases alpha-wave based alert relaxation.
- Vasopressin - Drug. Memory hormone produced by the pituitary gland which improves both memory encoding and recall. Rapidly counters chronic apathy syndrome and drug-induced vasopressin depletion.

- Nicotinic acid (vitamin B3) - Essential nutrient. Mild enhancer of concentration and memory. Vasodilator. Mood stabilizer, with a powerful anti-anxiety effect — perhaps the best and most immediate stress reliever available (note that other forms of vitamin B3 do not have this effect). Side effects: gastric upset (which is easily prevented and relieved with antacids), reduced blood pressure and flushing of the skin (caused by vasodilation), and itchy sensation in the skin caused by histamine release.

Brain energy and improved oxygen supply

- Acetyl-L-carnitine (ALCAR) - Amino acid. Transports fatty acids through cellular membranes and cytosol into cells' mitochondria, where the fats undergo oxidation to produce ATP, the universal energy molecule. Synergistic with lipoic acid.
- Chromium- stabilises blood sugar levels promoting concentration.
- Coenzyme q-10 syn. Ubiquinone - increases oxygen transport through the mitochondria of the cells. Appears to slow age-related dementia.
- Creatine - increases brain energy levels via ATP production.
- Inositol -
- Lipoic acid - synergistic with Acetyl-L-carnitine.
- Pyritinol (Enerbol) - Drug. Enhances oxygen and glucose uptake in the brain, and allows glucose to pass more easily through the blood-brain barrier. Improves general brain function. It is also a powerful anti-oxidant which scavenges hydroxyl radicals created in the very processes it is involved in.
- Vinpocetine - micro-circulation enhancer, improves oxygen supply to brain cells.

Mental agility, concentration, stamina, and focus

- Adrafinil (Olmifon) - Drug.
- Caffeine - improves concentration, idea production, but hinders memory encoding. Also produces the jitters. Caffeine is the most widely used psychoactive substance in the world.
- Coffee - Bean. Contains caffeine; brewed coffee is high in antioxidants.
- Nicergoline - Drug. Nicergoline is an ergoloid mesylate derivative used to treat senile dementia. It has also been found to increase mental agility and enhance clarity and perception. It increases vigilance.[5] Increases arterial flow and use of oxygen and glucose in the brain.
- Nicotine - stimulus barrier (aids in concentration). Stimulus barrier rebound effect (an unpleasant side effect).
- Cocaine - Drug
    - Methylphenidate (Ritalin) - Drug
- Phenibut -

- Theophylline **-**

Memory enhancement and learning improvement

All of the "nergics" listed above improve memory (encoding and recall). So do all nootropics which improve general brain performance such as the brain energy and oxygen suppliers listed above, and the nerve growth stimulants and protectants listed in their own section below. Other nootropics with specific effects on memory encoding and recall include:

- Bacopa monniera Linn. (Brahmi) - Herb. Elevates curiosity, enhances memory and concentration.[12] Brahmi also protects against amnesia inducing chemicals such as scopolamine or loss of memory due to electro convulsive shocks.[12] It is a traditional ayurvedic medicine.
- Rosemary - Herb. Rosemary has a very old, albeit unverified reputation for improving memory.

- **Vasopressin -** Hormone**,** prescription drug**.**

Nerve growth stimulation and brain cell protection

- Acetyl-L-carnitine (ALCAR) - Amino acid. Inhibits lipofuscin formation.
- Bacopa monnieri (Brahmi) - Herb. Improves protein synthesis in brain cell repair and new dendritic growth.
- Selegiline (Deprenyl) - Drug. Brain cell protectant, delays senescence of brain cells, proven to increase maximum life span in laboratory rats.
- Ergoloid mesylates (Hydergine) - Drug. Mimics nerve growth factor (NGF), and is a powerful anti-oxidant capable of delaying brain death in cases of heart failure and stroke by several minutes with regular use. It increases vigilance.[5]
- Idebenone - stimulates nerve growth, and has same effects as Coenzyme q-10 without its harmful side-effects.
- Inositol - Membrane stabilizer. Strengthens neurons, making them less susceptible to damage.
- Pyritinol (Enerbol) - Drug. Powerful anti-oxidant which scavenges hydroxyl radicals. Also enhances oxygen and glucose uptake in the brain, and allows glucose to pass more easily through the blood-brain barrier. Improves general brain function.
- Rasagiline (Azilect) - Drug. Treats Parkinson's disease either as monotherapy (by itself) or in addition to levodopa therapy. Promotes increased and sustained levels of dopamine by selectively inhibiting an enzyme, monoamine oxidase-B.
- Vitamin C - Membrane stabilizer, involved in collagen synthesis. Strengthens neurons, making them less susceptible to damage. Vitamin C is also a co-factor in the brain's production of dopamine, and therefore it also has general nootropic effects.

Sleep enhancement or reduction

- Vitamin B12 - Can greatly enhance the color of dreams. Stimulates brain neuron RNA synthesis.

Recreational drugs with purported nootropic effects

- Amphetamine (Adderall, Dexedrine) - Schedule II / Class B drugs. Prescribed for attention-deficit disorders, narcolepsy, and certain cases of obesity; and issued as an anti-fatigue pill for pilots in the armed forces. These also heighten alertness, mental focus, vigilance, stamina, and sex drive. They are highly addictive, and have many side effects. Personal importation is prohibitted. Using these recreationally or for performance enhancement is illegal in most countries.
- LSD - Schedule I / Class A drug. At minuscule doses (1 mcg) the drug has effects similar to Hydergine. Overdose and side-effects: produces inebriating hallucinogenic and entheogenic effects at doses as low as 20–30 ¼g (micrograms), with the likelihood of having a bad trip increasing as dose is increased if these effects are undesired. May also cause cognitive shifts, synesthesia, and flashbacks. The drug sometimes spurs long-term or even permanent changes in a user's personality and life perspective.
- 4-methylaminorex
- Pemoline

- Psilocybin

- Psilocin

Other nootropics

- Adafenoxate - Has an anti-anxiety effect for rats[13] and possibly the same for humans.

Butea frondosa - "The plant Butea frondosa has been indicated in the Indian system of medicine as a plant augmenting memory and as a rejuvenator. ... B. frondosa possesses antistress and weak nootropic activity."[14]

BMY 21502 - Injured animals treated with BMY-21502 at one week post-injury showed significant improvement in post-injury learning ability compared to injured animals treated with vehicle. Paradoxically, in uninjured control animals BMY-21502 treatment appeared to worsen learning scores. The results of this study indicate that BMY-21502 may be useful for attenuating the dysfunction in learning ability that occurs following TBI.

Cabergoline (Dostinex) -

Celastrus Panicaltus - Herb.

Cerebrolysin - A neuroprotective nootropic agent, might affect Alzheimer's disease pathology. Currently in clinical trials

Coluracetam - It may also have potential use in prevention and treatment of ischemic retinopathy and retinal and optic nerve injury.

Desmopressin (DDAVP) - Drug. Analog of vasopressin (the anti-diuretic and memory hormone)

DHEA -
Dostinex -
Fasoracetam -
Essential Fatty Acids- EPA (eicosapentaenoic acid) and DHA (docosahexaenoic acid) are the best known. EPA in particular, has an anti-depressant function and is positively indicated in trials with autism and learning difficulties.
Fipexide (Vigilor) - It protects against some memory impairing chemicals, such as diethyldithiocarbamate and clonidine.[8]
Gabapentin (Neurontin) - Anticonvulsant with nootropic effects
Galantamine - Drug.
Gerovital H3 -
Ginkgo biloba - Root. Increases blood flow to the extremities including the brain, nootropic effects are disputed.
Gotu Kola - Herb and root.
Meclofenoxate - Has an anti-anxiety effect for rats[13] and possibly the same for humans. Like Fipexide, it protects against some memory impairing chemicals, such as diethyldithiocarbamate and clonidine.[8] Like many racetams, it may treat fetal alcohol syndrome.[9]
Milacemide - Drug.
Nimodipine -
Ondansetron -
Oxiracetam (Neuromet) -
Phenytoin (Dilantin) -
Phosphatidylserine- reduces age-related memory loss and promotes concentration.
Picamilon - Drug.
Pikamilone -
Pregnenolone -
Propranolol (Inderal) - Drug. Flight response inhibitor, treats phobias, anti-anxiety effect. Though it has a host of negative side effects including but not limited to diabetes complications, depression, and impotence.
Pyroglutamate -
Semax - A neuropeptide (stimulator of the nervous system) developed from a short fragment of ACTH, Pro8-Gly9-Pro10 ACTH(4-10). Claims of significant increase in salvation of neurons are made
Somatotropin -
Sulbutiamine (Arcalion) - Drug.
Xanthinol -

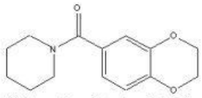
Ampakines

Ampakines are a new class of modified benzamide compounds known to enhance attention span and alertness. Their action is theorized to be due to facilitation of transmission at cortical synapses that use glutamate as neurotransmitter. This in turn may promote plasticity at the synapse, which could translate into better cognitive performance. The ampakines take their name from the glutamatergic AMPA receptor, which they strongly interact with.

Unlike earlier stimulants (e.g. caffeine, methylphenidate (Ritalin®), the Amphetamine) they do not seem to have unpleasant, long-lasting side effects such as sleeplessness. They are currently (2005) investigated as potential treatment for a range of conditions involving mental disability such as Alzheimer's disease, Parkinson's disease, schizophrenia or neurological disorders as Attention Deficit Hyperactivity Disorder (ADHD), among others. In a 2006 study they were shown to have an effect after they had left the body, continuing to enhance learning and memory.

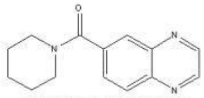
Some examples include: CX-516 (Ampalex), CX546, CX614 and CX717.

Structure



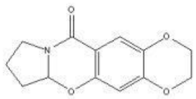
1-(1,4-benzodioxan-6-ylcarbonyl) piperidine

CX546



1-(quinoxalin-6-ylcarbonyl)piperidine

CX516



2H,3H,6aH-pyrrolidino[2",1"-3',2']1,3-oxazino[6',5'-5,4]benzo[e]1,4-dioxan-10-one

CX614

Mechanism

Ampakines work by allosterically binding to particular receptors in the brain, called AMPA-type glutamate receptors. This boosts the activity of glutamate, a neurotransmitter, and makes it easier to encode memory and to learn. In addition, some members of the Ampakine family of drugs may also increase levels of trophic factors such as Brain Derived Neurotrophic Factor (BDNF).

Routes Oral and parenteral

Piracetam (brand name: *Nootropil*®, Myocalm®), is a cerebral function regulating drug which is claimed to be able to enhance cognition as well as slow down brain aging. Piracetam's chemical name is 2-oxo-pyrrolidone, or 2-oxo-1-pyrrolidine acetamide. Piracetam is a cyclic derivative of GABA. It is one of the racetams, and is similar to the amino acid pyroglutamate. Though rare in the United States, Piracetam is commonly prescribed in Europe for a variety of conditions.

Effects

Several meta-reviews of literature on Piracetam indicate that Piracetam increases performance on a variety of cognitive tasks among dyslexic children, though this may reflect its enhancement of cross-hemispheric communication and of cognitive function in general, rather than a specific improvement in whatever causes dyslexia. Piracetam also seems to inhibit brain damage caused by a variety of factors including hypoxia and excessive alcohol consumption.

Piracetam has been studied in an extensive number of clinical experiments, mostly focusing on dyslexic children, and some believe that understanding the mechanism it works through can teach us about the role of inter-hemispheric communication in the brain.

Mechanisms of action

The mechanisms of action of Piracetam are quite broad. Piracetam is understood to work by stimulating the cerebral cortex as well as by increasing the rate of metabolism and the energy levels of neurons. It possibly facilitates movement of information between the brain's two hemispheres via the corpus callosum, and improves the function of the neurotransmitter acetylcholine via muscarinic cholinergic (ACh) receptors which are implicated in memory processes. Furthermore, Piracetam may have an effect on NMDA glutamate receptors which are involved with learning and memory processes. Finally, Piracetam may exert its global effect on brain neurotransmission via modulation of ion channels (i.e., Ca^{2+}, K^{+}).

History

Piracetam was first synthesized in 1964 by scientists at the Belgian pharmaceutical company UCB led by Dr Corneliu E. Giurgea. The drug was the first of the so-called nootropics ("smart drugs" or "cognitive enhancers"), that is, substances which purportedly enhance mental performance. The term nootropic was coined by Giurgea. Nootropil was launched clinically by UCB in the early 1970s and remains an important product of that company in Europe.

Approval and usage

Piracetam is primarily used in Europe. Piracetam is legal to import into the United Kingdom for personal use with or without prescription as with other prescription-only

drugs. As of June of 2006, piracetam is not regulated in the United States (it is neither a controlled substance nor a prescription drug).

Dosage

Piracetam is usually supplied in 800 mg tablets or capsules. The recommended dosage varies based on the indication, usually ranging from 1.6-9.6 grams daily (2-12 pills daily). Some people report faster results when taking 1-2 pills every hour for 4-6 hours or taking 4-8 pills at once for the first few days to notice an effect.

It has been studied up to 45 grams daily without major side effects.

It has no known LD-50 in humans when taken orally.

In the US, and possibly other countries in which Piracetam is unregulated, it is often sold in bulk as a powder. It is up to the user to decide how they want to ingest said powder; orange juice is frequently cited as a good mixer to mask the taste.

Contraindications

Piracetam is contra-indicated in patients with severe renal impairment (renal creatinine clearance of less than 20 ml per minute), hepatic impairment and to those under 16 years of age. It is also contraindicated in patients with cerebral haemorrhage and in those with hypersensitivity to piracetam, other pyrrolidone derivatives or any of the excipients .

Special warnings and precautions for use

Due to the effect of piracetam on platelet aggregation, caution is recommended in patients with underlying disorders of haemostasis, major surgery or severe haemorrhage.

Abrupt discontinuation of treatment should be avoided as this may induce myoclonic or generalised seizures in some myoclonic patients.

As piracetam is almost exclusively excreted by the kidneys caution should be exercised in treating patients with known renal impairment. In renally impaired and elderly patients, an increase in terminal half-life is directly related to renal function as measured by creatinine clearance. Dosage adjustment is therefore required in those with mild to moderate renal impairment and elderly patients with diminished renal function.

Undesirable effects

Following adverse experiences (very rare usually occurring in 1 out of 1,000 people) were reported for piracetam with a statistically significantly higher incidence than placebo. Incidences are given for piracetam versus placebo treated patients.

Central and peripheral nervous system disorders: hyperkinesia (1.72 versus 0.42 %)

Metabolic and nutritional disorders: weight gain (1.29 versus 0.39 %)

Psychiatric disorders: nervousness (1.13 versus 0.25 %), somnolence (0.96 versus 0.25 %), depression (0.83 versus 0.21 %)

Body as a whole - general disorders: asthenia (0.23 versus 0.00 %)

Post-marketing experiences have reported the following undesirable effects:

Ear and labyrinth (inner ear) disorders: vertigo

Gastrointestinal disorders: abdominal pain, upper abdominal pain, diarrhoea, nausea, vomiting

Immune system disorders: anaphylactoid reaction, hypersensitivity, multiple chemical sensitivity
Nervous system disorders: ataxia, impaired balance, aggravated epilepsy, headache, insomnia, somnolence
Psychiatric disorders: agitation, anxiety, confusion, hallucination
Skin and subcutaneous tissue disorders: angioneurotic oedema, dermatitis, pruritus, urticaria, rash

Parasympathomimetics

A *parasympathomimetic* is a drug or poison that acts by stimulating or *mimicking* the parasympathetic nervous system (PNS). These chemicals are also called cholinergics because acetylcholine (ACh) is the neurotransmitter used by the PNS. Chemicals in this family can act by either directly stimulating the nicotinic or muscarinic receptors, or they can act indirectly by inhibiting cholinesterase, promoting acetylcholine release, or other mechanisms. Some Chemical weapons such as sarin or VX, Non-lethal riot control agents such as tear gas, and insecticides such as Diazinon fall into this category.

Pharmaceuticals

Anticholinesterases

 Acetylcholine

A *cholinesterase inhibitor* or *anticholinesterase* is a chemical that inhibits a cholinesterase enzyme from breaking down acetylcholine, so increasing both the level and duration of action of the neurotransmitter acetylcholine.

Uses

Anticholinesterases occur naturally as venoms and poisons, are used as weapons in the form of nerve agents, and are used medicinally to treat diseases such as myasthenia gravis and Alzheimer's disease, and as an antidote to anticholinergic poisoning. In myasthenia gravis, they are used to increase neuromuscular transmission.

Examples

reversible inhibitor

Compounds which function as reversible competitive or noncompetitive inhibitors of cholinesterase are those most likely to have therapeutic uses. These include:

- Organophosphates
  - metrifonate
- Carbamates
  - physostigmine

neostigmine
pyridostigmine
ambenonium
demarcarium
rivastigmine

- Phenanthrine derivatives
  - galantamine
- Piperidines
  - donepezil, also known as E2020
- Tacrine, also known as tetrahydroaminoacridine (THA')
- Edrophonium

quasi-irreversible inhibitor

Compounds which function as quasi-irreversible inhibitors of cholinesterase are those most likely to have use as chemical weapons or pesticides. These include:

- Organophosphates
  - echothiophate

diisopropyl fluorophosphate

- cyclosarin
- sarin
- soman
- tabun
- VX
- VE
- VG
- VM

  - diazinon

malathion
parathion

- Carbamates
  - aldicarb

bendiocarb
bufencarb
carbaryl
carbendazim
carbetamide
carbofuran
chlorbufam
chloropropham
ethiofencarb
formetanate
methiocarb
methomyl
oxamyl
phenmedipham
pinmicarb
pirimicarb
propamocarb

propham
propoxur

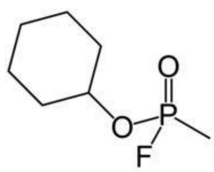
Effects

Some major effects of anticholinesterase:

Actions on the autonomic nervous system, that is parasympathetic nervous system will cause bradycardia, hypotension, hypersecretion, bronchoconstriction, GIT hypermotility, and decrease intraocular pressure.

Actions on the neuromuscular junction will result in prolonged muscle contraction.

Cyclosarin



Discovery

Discovered by Dr. Gerhard Schrader

Discovered in 1949

Chemical Characteristics

Chemical Name (fluoro-methyl-phosphoryl)oxycyclohexane

Chemical Family Fluorinated organophosphorous compound

Chemical formula C7H14FO2P

Airborne Exposure Limit 0.0001 mg/m3

Boiling point 239 °C (462 °F)

Freezing/Melting point -30 °C (-22 °F)

Vapor pressure at 25 °C

Flash point 94 °C (201 °F)

Vapor relative density (air=1) 6.2

Liquid Density 1.1278 g/cc @ 25 °C

Solubility in Water Almost insoluble

Appearance and color Colorless liquid. Odor sweet, musk, peaches, shellac

Cyclosarin or *GF* (Cyclohexyl methylphosphonofluoridate) is an extremely toxic substance that is one of the world's most dangerous weapons of war. It is the most obscure member of the G-series family of nerve agents, a group of chemical weapon discovered and synthesized by a German team, led by Dr. Gerhard Schrader, during or soon after World War II.

As a chemical weapon, it is classified as a weapon of mass destruction by the United Nations according to UN Resolution 687, and its production and stockpiling was outlawed by the Chemical Weapons Convention of 1993.

Chemical characteristics

Like its predecessor, sarin, cyclosarin is a liquid organophosphate nerve agent. Its physical characteristics are quite different from sarin, however.

At room temperature, cyclosarin is a colorless liquid whose odor has been variously described as sweet and musty, and resembling peaches or shellac. Unlike sarin, cyclosarin is a persistent liquid, meaning that it has a low vapor pressure, and therefore evaporates relatively slowly: about 69 times more slowly than sarin and 20 times more slowly than water. Its military value is therefore much greater as a liquid chemical weapon.

Also unlike sarin, cyclosarin is flammable, with a flash point of 94°C (201 °F).

Historical notes

From **CBWInfo.com**

Cyclosarin was first synthesized during World War II as part of the systematic study of organophosphates undertaken by the Germans after their potential military utility was identified. It was again looked at in the early 1950's by both the United States and Great Britain as they undertook a systematic study of potential nerve agents (some U.S. sources suggest that interest in GF was stimulated by work undertaken in "another country"). However, the higher cost of the precursors for GF relative to those for GB along with its lower toxicity prevented it from being chosen for manufacture. Iraq is the only country in which large amounts of cyclosarin have ever been produced for use as a chemical warfare agent. Also Iraqis used sarin and cyclosarin as a mixture against Iran in 1986-1988. As with most issues surrounding the Iraqi chemical weapons programs, the basis for their decision to produce GF is somewhat unclear. However, it seems likely that the choice was driven by a combination of a desire for a more persistent agent combined with problems with obtaining alcohol precursors for sarin (due to an embargo). As noted above, Iraq also fielded weapons filled with mixtures of sarin and cyclosarin. These mixtures appear to have been produced in part for purposes of increasing persistence and in part because of raw material issues.

Munitions

Binary weapons

Like other nerve agents, Cyclosarin can be shipped in binary munitions.

A cyclosarin binary weapon would most likely contain methyphosphonyldifluoride in one capsule with the other capsule containing either cyclohexanol or a mixture of cyclohexylamine and cyclohexanol.

GB-GF Mixtures

According to CBWInfo.com, Iraq fielded munitions filled with a mixture of GB (sarin) and GF (cyclosarin). Tests on mice indicated that GB-GF mixtures have a relative toxicity between GF and GB.

Insecticide

An *insecticide* is a pesticide used against insects in all developmental forms. They include ovicides and larvicides used against the eggs and larvae of insects. Insecticides are used in agriculture, medicine, industry and the household. The use of insecticides is believed to be one of the major factors behind the increase in agricultural productivity in the 20th century. Nearly all insecticides have the potential to significantly alter ecosystems; many are toxic to humans; and others are concentrated in the food chain. It is necessary to balance agricultural needs with environmental and health issues when using them.

Classes of agricultural insecticides

The classification of insecticides is done in several different ways:

- Systemic insecticides are incorporated by treated plants. Insects ingest the insecticide while feeding on the plants.
- Contact insecticides are toxic to insects brought into direct contact. They most often applied through aerosol distribution.
- Natural insecticides, such as nicotine and pyrethrum, are made by plants as defences against insects.
- Inorganic insecticides are manufactured with metals and include arsenates copper- and fluorine compounds, which are now seldom used, and sulfur, which is commonly used.
- Organic insecticides are synthetic chemicals which comprise the largest numbers of pesticides available for use today.
- Mode of action -- how the pesticide kills or inactivates a pest -- is another way of classifying insecticides. Mode of action is important in predicting whether an insecticide will be toxic to unrelated species such as fish, birds and mammals.

Classes of insecticides, a short history

A series of classes of insecticides have existed, as time progressed one class has largely replaced the one before it. These trends in the classes of compounds in some ways has mirrored the development of chemical warfare agents.

Heavy metals, eg lead, mercury, arsenic and plant toxins such as nicotine have been used for many years. Various plants have been used as folk insectides for centuries, including tobacco and pyrethrum.

Chlorine based agents, with the rise of the modern chemical industry it was possible for form organochlorides. The substances used in chemical warfare tend to be more potent electrophiles than those used as insecticides. For instance mustard gas (sulfur mustard, HD) is a potent alklating agent which uses neighbouring group participation of the sulfur to make the alkyl chloride a stronger electrophile. An organochlorine insecticide such as DDT or lindane does not directly kill the insect. It is likely that the chlorine is used to tune the lipophilicity of the compound, and to alter the shape and electrostatic effects involved in the interactions of the insecticide and the biomolecules in the target organism. For instance DDT works by opening the sodium channels in the nerve cells of the insect.

The next large class was the organophosphates, both the insecticides and the chemical warfare agents (such as sarin, tabun, soman and VX) work in the same way. All these compounds bind to the neurotransmitter acetylcholinesterase and other cholinesterases. This results in disruption of nervous impulses, killing the insect or interfering with its ability to carry on normal functions. Carbamate insecticides have similar toxic mechanisms but have a much shorter duration of action and are somewhat less toxic on that basis.

To mimic the insecticidal activity of the natural compound pyrethrum another class of pesticides, pyrethroid pesticides, have been developed. These are are nonpersistent and much less acutely toxic than organophosphates and carbamates.

Recent efforts to reduce broad spectrum toxins added to the environment have brought biological insecticides back into vogue. An example is the development and increase in use of Bacillus thuringiensis, a bacterial disease of Lepidopterans and some other insects. It is used as a larvicide against a wide variety of caterpillars. Because it has little effect on other organisms, it is considered more environmentally friendly than synthetic pesticides. The toxin from Bacillus thuringiensis (Bt toxin) has been incorporated directly into plants through the use of genetic engineering.

Environmental effects

One of the bigger drivers in the development of new insecticides has been the desire to replace toxic and irksome insecticides. The notorious DDT was introduced as a safer alternative to the lead and arsenic compounds which had been used before. It is the case that when used under the correct conditions that almost any chemical substance is 'safe', but when used under the wrong conditions most insecticides can be a threat to health and/or the environment.

Some insecticides have been banned due to the fact that they are persistent toxins which have adverse effects on animals and/or humans. A classic example which is often quoted is that DDT is an example of a widely used (and maybe misused) pesticide. One of the better known impacts of DDT is to reduce the thickness of the egg shells on predatory birds. The shells sometimes become too thin to be viable, causing reductions in bird populations. This

occurs with DDT and a number of related compounds due to the process of bioaccumulation, wherein the chemical, due to its stability and fat solubility, accumulates in organisms fat. Also, DDT may biomagnify which causes progressively higher concentrations in the body fat of animals farther up the food chain. The near-worldwide ban on agricultural use of DDT and related chemicals has allowed some of these birds--such as the peregrine falcon--to recover in recent years. A number of the organochlorine pesticides have been banned from most uses worldwide and globally they are controlled via the Stockholm Convention on Persistent Organic Pollutants. These include: aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, mirex and toxaphene.

While the overuse of DDT lead to a reduction in its use, opponents of traditional environmentalism often cite it as an example of environmentalism going too far and interfering with malaria eradication, going so far as to estimate the cost of human lives resulting from the DDT ban; for instance the novelist Michael Crichton states in his bestselling book, State of Fear:

"Since the ban, two million people a year have died unnecessarily from malaria, mostly children. The ban has caused more than fifty million needless deaths. Banning DDT killed more people than Hitler."

This accusation, while sensational, is erroneous, as no ban exists on the use of DDT for eradication of malaria or any other mosquito borne disease. Groups fighting malaria have praised the ban on agricultural use of DDT, since it reduces the rate with which mosquitoes become resistant to DDT, which is the main reason it is not used more often to fight malaria:

"The outcome of the treaty is arguably better than the status quo going into the negotiations over two years ago. For the first time, there is now an insecticide which is restricted to vector control only, meaning that the selection of resistant mosquitoes will be slower than before.".

In fact, according to Agricultural production and malaria resurgence in Central America and India, Chapin, Georgeanne & Robert Wasserstrom, Nature, Vol. 293, 1981, page 183), the lives actually saved due to banning agricultural use of DDT can be estimated:

"Correlating the use of DDT in El Salvador with renewed malaria transmission, it can be estimated that at current rates each kilo of insecticide added to the environment will generate 105 new cases of malaria."

Alternative insecticides have had to be used as an alternative to DDT because the population of insects have become resistant to DDT. Most of the newer insecticides are more specific in their actions and are designed to break down into non-toxic components within a few days of application. Nonetheless, misuse of insecticides remains an environmental and economic issue. For example, in Bangladesh most of the insecticide applications by rice farmers are apparently unnecessary.

Application methods for household insecticides

Integrated pest management or IPM in the home begins with restricting the availability to insects of three vital commodities: shelter, water and food. If insects become a problem despite such measures then it is wise to control them using the safest possible methods, targeting the approach that is used to the pest that is present in the household environment[1].

Insect repellent, commonly referred to as "bug spray", comes in a plastic bottle or aerosol can. Applied to clothing, arms, legs, and other extremities, the use of these products will tend to ward off nearby insects. This is not an insecticide.

Insecticide used for killing pests—most often insects, and arachnids—primarily comes in an aerosol can, and is sprayed into the air or a nest as a means of killing the animal. Fly sprays will kill house flies, blowflies, ants, cockroaches and other insects and also spiders. Other preparations are granules or liquids that are formulated with bait that is eaten by insects. For many household pests bait traps are available that contain the pesticide and either pheromone or food baits. Crack and crevice sprays are applied into and around openings in houses such as baseboards and plumbing. Pesticides to control termites are often injected into and around the foundations of homes.

Active ingredients of many household insecticides include permethrin and tetramethrin, which act on the nervous system of insects and arachnids.

Bug sprays should be used in well ventilated areas only, as the chemicals contained in the aerosol and most insecticides can be harmful or deadly to humans and companion animals. All insecticide products including solids, baits and bait traps should be applied such that they are out of reach of wildlife, companion animals and children.

Individual insecticides

Chlorinated

- Camphechlor
- DDT
- Hexachlorocyclohexane
  - gamma-Hexachlorocyclohexane

Lindane

- Methoxychlor

Pentachlorophenol

Plant toxin derived

- Derris (rotenone)
Pyrethrum
Neem (Azadirachtin)

- Nicotine
- Caffeine

Nerve agents

Nerve agents (also known as *nerve gases*, though these chemicals are liquid at room temperature) are a class of phosphorus-containing organic chemicals (organophosphates) that disrupt the mechanism by which nerves transfer messages to organs. The disruption is caused by blocking acetylcholinesterase, an enzyme that normally relaxes the activity of acetylcholine, a neurotransmitter. As chemical weapons, they are classified as weapons of mass destruction by the United Nations according to UN Resolution 687, and their production and stockpiling was outlawed by the Chemical Weapons Convention of 1993; the Chemical Weapons Convention officially took effect on April 29, 1997.

Poisoning by a nerve agent leads to contraction of pupils, profuse salivation, convulsions, involuntary urination and defecation, and eventual death by asphyxiation as control is lost over respiratory muscles. Some nerve agents are readily vaporized or aerosolized and the primary portal of entry into the body is the respiratory system. Nerve agents can also be absorbed through the skin, requiring that those likely to be subjected to such agents wear a full body suit in addition to a respirator.

Biological effects

As their name suggests, nerve agents attack the nervous system of the human body. All such agents function the same way: by interrupting the breakdown of the neurotransmitters that signal muscles to contract, preventing them from relaxing.

Initial symptoms following exposure to sarin (and other nerve agents) are a runny nose, tightness in the chest and constriction of the pupils. Soon after, the victim will then have difficulty breathing, and will experience nausea and drooling. As the victim continues to lose control of his or her bodily functions, he or she will involuntarily salivate, lacrimate, defecate, urinate and vomit ("SLUD" syndrome). This phase is followed by twitching and jerking, and ultimately the victim will become comatose and suffocate as a consequence of convulsive spasms.

The effects of nerve agents are very long lasting and cumulative (increased successive exposures), and survivors of nerve agent poisoning almost invariably suffer chronic neurological damage.

Mechanism of action

When a normally functioning motor nerve is stimulated it releases the neurotransmitter acetylcholine, which transmits the impulse to a muscle or organ. Once the impulse is sent, the enzyme acetylcholine esterase immediately breaks down the acetylcholine in order to allow the muscle or organ to relax.

Nerve agents disrupt the nervous system by inhibiting the enzyme acetylcholine esterase by forming a covalent bond with the site of the enzyme where acetylcholine normally undergoes hydrolysis (breaks down). The result is that acetylcholine builds up and continues to act so that any nerve impulses are continually transmitted, and muscle contractions do not stop.

This same action also occurs at the gland and organ levels, resulting in uncontrolled drooling, tearing of the eyes (lacrimation), and excess production of mucous from the nose (rhinorrhea).

Antidotes

Atropine and related anticholinergic drugs act as antidotes to nerve agent poisoning because they block acetylcholine receptors, but they are poisonous in their own right. While they will save the life of a person affected with nerve agents, that person may be incapacitated briefly or for an extended period of time, depending on the amount of exposure. Atropine for field use by military personnel is often loaded in an autoinjector, for ease of use in stressful conditions.

Pralidoxime chloride, also known as 2-Pam chloride, is also used as an antidote. Rather than counteracting the initial effects of the nerve agent on the nervous system like atropine, pralidoxime chloride actually neutralizes the nerve agent in the bloodstream. Though safer to use, it takes a longer time to have an effect.

Classes

There are two main classes of nerve agents. The members of the two classes share similar properties, and are given both a common name (such as sarin), and a two-character NATO identifier (such as GB).

G-Series

The G-series, thus named because German scientists first synthesized them. All of the compounds in this class were discovered and synthesized during or soon after World War II, led by Dr. Gerhard Schrader (later under the employment of I.G. Farben).

This series is the first and oldest family of nerve agents. The first nerve agent ever synthesised was GA (tabun) in 1936. GB (sarin) was discovered next in 1938, followed by GD (soman) in 1944 and finally the more obscure GF (cyclosarin) in 1949.

V-Series

The V-series is the second family of nerve agents (the V apparently standing for "venomous"), and also contains four members: VE, VG, VM, VX. The most studied agent in this family, VX, was invented in the 1950s at Porton Down in the United Kingdom. The other agents in this series have not been studied extensively, and information about them is limited. It is known, however, that the V-series agents are about 10 times more toxic than the G-agent sarin (GB).

All of the V-agents are persistent agents, meaning that these agents do not degrade or wash away easily, and can therefore remain on clothes and other surfaces for long periods. In use, this allows the V-agents to be used to blanket terrain to guide or curtail the movement of enemy ground forces. The consistency of these agents is similar to oil; as a result, the contact hazard for V-agents is primarily - but not exclusively - dermal.

Novichok Agents

The Novichok series was a new series of organophosphate agents developed in the Soviet Union. The advantage to using new agents was that they hadn't been seen before and hence there were no specific treaties, protective gear or detectors developed to defend against their use.

Insecticides

A number of insecticides, such as dichlorvos, malathion and parathion are nerve agents. The metabolism of insects is sufficiently different from mammals that these compounds are considered innocuous for humans and their food animals; but there is considerable concern about the effects of long-term exposure to these chemicals by farm workers and animals alike.

History

The discovery of nerve agents

This first class of nerve agents, the so-called G-Series, was accidentally discovered in Germany on December 23, 1936 by a research team headed by Dr. Gerhard Schrader. Since 1934, Schrader had been in charge of a laboratory in Leverkusen to develop new types of insecticides for IG Farben. While working toward his goal of improved insecticide, Schrader experimented with numerous fluorine-containing compounds, eventually leading to the preparation of tabun.

In experiments, tabun was extremely potent against insects: as little as 5 ppm of tabun killed all the leaf lice he used in his initial experiment. In January 1937, Schrader observed the effects of nerve agents on human beings first-hand when a drop of tabun spilled onto a lab bench. Within minutes he and his laboratory assistant began to experience miosis (contraction of the pupils of the eyes), dizziness, and severe shortness of breath. It took them three weeks to recover fully.

In 1935 the Nazi leadership had passed a decree that required all inventions of possible military significance to be reported to the Ministry of War, so in May of 1937 Schrader sent a sample of tabun to the chemical warfare (CW) section of the Army Weapons Office in Berlin-Spandau. Dr. Schrader was summoned to the Wehrmacht chemical lab in Berlin to give a demonstration, after which Schrader's patent application and all related research was classified. Colonel Rüdiger, head of the CW section, ordered the construction of new laboratories for the further investigation of tabun and other organophosphate compounds, and Schrader soon moved to a new laboratory at Wuppertal-Elberfeld in the Ruhr valley to continue his research in secret throughout World War II.

Three of the most widely known agents, sarin (GB), soman (GD), and tabun (GA) were also developed during this period for use as chemical warfare agents, but were not used in combat. Cyclosarin (GF) was developed somewhat later, in 1949, by the same team. The prefix "G" was used in the names of all the chemicals because they were of German origin[1].

The Nazi mass production of tabun

In 1939, a pilot plant for tabun production was set up at Munster-Lager, on Luneberg heath near the German Army proving grounds at Raubkammer. In January 1940, construction began on a secret plant, code named "Hochwerk" (High factory), for the production of tabun at Dyernfurth-am-Oder (now Brzeg Dolny in Poland), on the Oder River 40 km (24.9 miles) from Breslau (now WrocBaw) in Silesia.

The plant was large, covering an area of 2.4 by 0.8 km (1.5 by 0.5 miles), and was completely self-contained, synthesizing all intermediates as well as the final product, tabun. The factory even had an underground plant for filling munitions, which were then stored at Krappitz (now Krapowice) in Upper Silesia. The plant was operated by Anorgana GmbH, a subsidiary of IG Farben, as were all other chemical weapon agent production plants in Germany at the time.

Because of the plant's deep secrecy and the difficult nature of the production process, it took from January 1940 until June 1942 for the plant to become fully operational. Many of tabun's chemical precursors were so corrosive that reaction chambers not lined with quartz or silver soon became useless. Tabun itself was so hazardous that the final processes had to be performed while enclosed in double glass-lined chambers with a stream of pressurized air circulating between the walls.

3,000 German nationals were employed at Hochwerk, all equipped with respirators and clothing constructed of a poly-layered rubber/cloth/rubber sandwich that was destroyed after the tenth wearing. Despite all precautions, there were over 300 accidents before production even began, and at least 10 workers died during the 2.5 years of operation. Some incidents cited in A Higher Form of Killing: The Secret History of Chemical and Biological Warfare are as follows:

- Four pipe fitters had liquid tabun drain onto them; they died before their rubber suits could be removed.
- A worker had 2 liters of tabun pour down the neck of his rubber suit; he died within 2 minutes.
- Seven workers were hit in the face with a stream of tabun of such force that the liquid was forced behind their respirators; only two survived despite heroic resuscitation measures.

The plant produced between 10,000 and 30,000 tons of tabun before its capture by the Soviet Army [1].

Nerve agents in Nazi Germany

In mid-1939, sarin was invented, and the formula for the agent was passed to the Chemical Warfare section of the German Army Weapons Office, which ordered that it be brought into mass production for wartime use. A number of pilot plants were built, and a high-production facility was under construction (but was not finished) by the end of World War II. Estimates for total sarin production by Nazi Germany range from 500 kg to 10 tons.

During that time, German intelligence believed that the Allies also knew of these compounds, assuming that because these compounds were not discussed in the Allies' scientific journals information about them was being suppressed. Though sarin, tabun and soman were incorporated into artillery shells, the German government ultimately decided not to use nerve agents against Allied targets, because they feared a devastating Allied retaliatory nerve agent deployment. However, the Allies didn't learn of these agents until shells filled with them were captured towards the end of the war.

This is detailed in Joseph Borkin's book The Crime and Punishment of IG Farben:

Speer, who was strongly opposed to the introduction of tabun, flew Otto Ambros, I.G.'s authority on poison gas as well as synthetic rubber, to the meeting. Hitler asked Ambros, "What is the other side doing about poison gas?" Ambros explained that the enemy, because of its greater access to ethylene, probably had a greater capacity to produce mustard gas than Germany did. Hitler interrupted to explain that he was not referring to traditional poison gases: "I understand that the countries with petroleum are in a position to make more [mustard gas], but Germany has a special gas, tabun. In this we have a monopoly in

Germany." He specifically wanted to know whether the enemy had access to such a gas and what it was doing in this area. To Hitler's disappointment Ambros replied, "I have justified reasons to assume that tabun, too, is known abroad. I know that tabun was publicized as early as 1902, that Sarin was patented, and that these substances appeared in patents. (...) Ambros was informing Hitler of an extraordinary fact about one of Germany's most secret weapons. The essential nature of tabun and sarin had already been disclosed in the technical journals as far back as 1902, and I.G. had patented both products in 1937 and 1938. Ambros then warned Hitler that if Germany used tabun, it must face the possibility that the Allies could produce this gas in much larger quantities. Upon receiving this discouraging report, Hitler abruptly left the meeting. The nerve gases would not be used, for the time being at least, although they would continue to be produced and tested.

—Joseph Borkin, The Crime and Punishment of IG Farben

The secret gets out

After World War II, the Allies recovered German artillery shells containing the three German nerve agents of the day, prompting further research into nerve agents by the former Allies. In 1952, researchers in Porton Down, England invented the VX nerve agent, but soon abandoned the project. In 1958 the British government traded their VX technology with the United States of America in exchange for information on thermonuclear weapons; by 1961 the US was producing large amounts of VX, and performed its own nerve agent research. This research produced three more agents; the four agents (VE, VG, VM, VX) are collectively known as the "V-Series" class of nerve agents.

Since World War II

To date, nerve agents have not been used in warfare on a large scale. Iraq briefly used chemical weapons, including nerve agents, during the Iran-Iraq war of 1981-1988; the Kurdish village of Halabja was exposed to chemical weapons, reportedly including nerve agents. Nerve agents were not used by Iraq in the Gulf War, though a number of U.S. and UK personnel were exposed to them when the Khamisiyah chemical depot was destroyed. This and the widespread use of anticholinergic drugs as a protective treatment against nerve gas attack has been proposed as a possible cause of Gulf war syndrome.

One of the most widely publicised uses of nerve agents was the 1995 terrorist attack in which operatives of the group Aum Shinrikyo released sarin into the Tokyo subway system.

Ocean Disposal of Chemical Weapons

In 1972, The United States Congress banned the practice of disposing chemical weapons into the ocean. However 32,000 tons of nerve and mustard agents had already been dumped into the ocean waters off of the United States by the U.S. Army. According to a 1998 report created by William Brankowitz, a deputy project manager in the U.S. Army Chemical Materials Agency, the Army created at least 26 chemical weapons dumpsites in the ocean off

of at least 11 states on both the west and east coasts. Additionally due to poor records, currently they only know the rough whereabouts of half of them.

It is unknown how these dumps of chemical weapons have affected the ocean ecology—it may be responsible for some of the decline in fish populations over the past decades, but no evidence has yet proved a causal relationship between dumping and fish population decline. The steel containers they are contained within face a variable rate of decay and no one is really certain where or how deep they were dumped. If a nerve agent leaks into the ocean, it can last up to six weeks, during which time it will kill everything it touches before it breaks down into its nonlethal chemical components.

Popular Culture

As a weapon of fear and terror, nerve agents are quickly becoming a staple in the plots of television, cinema, and video games. In most implementations of this plot, a shadowy terrorist organization obtains a quantity of nerve agent and threatens to release it in a population center.

A fictional nerve agent, ZV, is an integral part of the story line for John Lange's (a pseudonym of Michael Crichton) 1972 novel Binary. The effects of this agent were the same as the V-series agents and the book mentions these other agents although it does not mention other existing binary nerve agents such as the G-series or VX.

A nerve agent later featured in the 1986 film Aliens, in which the character Vasquez suggests employing a fictional nerve agent, CN-20. Later, nerve agents appeared in two 1996 action movies: The Rock, in which a retired US Marine general blackmails the government by threatening to attack California with "VX gas", and Executive Decision, which prominently featured a fictional nerve agent called "DZ-5". In the 2002 movie XXX, a terrorist group called Anarchy-99 produces a fictitious binary nerve agent called "Silent Night," which decomposed and became harmless when passed through water. In the movie Saw II, sarin is the nerve agent that the Jigsaw Killer uses as part of his game.

This plot device was adopted by video game designers as well. For example, Tom Clancy's Rainbow Six 3: Raven Shield featured terrorists that attempted to poison the food supply with VX nerve agent. Also, it was the new deadly threat in Syphon Filter: Dark Mirror, where the nerve gas, Project Dark Mirror, was said to blend with oxygen, making it more lethal

Before long, nerve agents began to appear on television. For example, VX was featured in the British television series Spooks as part of a simulated attack on the center of London, and recently, on season 5 of the primetime FOX series, 24, Russian separatists manage to use a fictional, vaporised variant of VX called "Sentox VX-1" on several targets in Los Angeles. The Doctor Who story The Mind of Evil involves the hijacking of a nerve gas missile destined to be destroyed, and in the later story Terror of the Zygons a Scottish village is drugged with a nerve gas agent. Sarin was also featured in a later series of Spooks.

The post-grunge band Seether was first known as "Saron Gas".

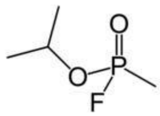
Sarin



Discovered by Gerhard Schrader, Ambrose Rüdiger van der Linde

Discovered in 1938

Chemical Characteristics

Chemical Name 2-(fluoro-methyl-phosphoryl)oxypropane

Chemical Family Fluorinated organophosphorus compound

Chemical formula $C_4H_{10}FO_2P$

NFPA Rating

- Health - 4
- Flammability - 1
- Reactivity - 1

Airborne exposure limit 0.0001 mg/m3

Boiling point 158 °C

Freezing/melting point -56 °C

Vapor pressure 2.9 at 25 °C

Vapor relative density (Air=1) 4.86

Liquid Density

1.0887 g/cm^3 at 25 °C
1.102 g/cm^3 at 20 °C

Solubility in Water Complete

Appearance and color Colorless liquid. Odorless in pure form.

Precursors

Key precursors

methylphosphonyl difluoride
methylphosphonyl dichloride
diisopropyl methylphosphonochloridate

Precursors

Dimethyl methylphosphonate
isopropyl methylphosphonate

Other chemicals

Trimethylphosphite
phosphorus trichloride
triisopropyl phosphite

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Sarin, also known by its NATO designation of *GB* (O-Isopropyl methylphosphonofluoridate) is an extremely toxic substance whose sole application is as a nerve agent. As a chemical weapon, it is classified as a weapon of mass destruction by the United Nations according to UN Resolution 687, and its production and stockpiling was outlawed by the Chemical Weapons Convention of 1993.

Chemical characteristics

Sarin is similar in structure and biological activity to some commonly used insecticides, such as Malathion, and is similar in biological activity to carbamates used as insecticides such as Sevin, and medicines such as Mestinon, Neostigmine, and Antilirium.

At room temperature, sarin is a colourless, odourless liquid. Its relatively high vapor pressure means that it evaporates quickly (about 36 times faster than tabun, another common chemical nerve agent). Its vapor is also colorless and odorless. It can be made more persistent through the addition of certain oils or petroleum products.

Sarin can be used as a binary chemical weapon; its two precursors are methylphosphonyl difluoride and a mixture of isopropyl alcohol and isopropyl amine. The isopropyl amine binds the hydrogen fluoride generated during the chemical reaction.

Shelf life

Sarin has a relatively short shelf life, and will degrade after a period of several weeks to several months. The shelf life may be greatly shortened by impurities in precursor materials. According to the CIA, in 1989 the Iraqis destroyed 40 or more tons of sarin that had decomposed, and that some Iraqi sarin had a shelf life of only a few weeks owing mostly to impure precursors.

Like other nerve agents, Sarin can be chemically deactivated with a strong alkali. Typically an 18 percent aqueous solution of sodium hydroxide is used to destroy Sarin.

Efforts to lengthen shelf life

According to the CIA, nations such as Iraq have tried to overcome the problem of sarin's short shelf life in three ways:

- The shelf life of unitary (i.e., pure) sarin may be lengthened by increasing the purity of the precursor and intermediate chemicals and refining the production process.
- Incorporating a stabilizer chemical called tributylamine. Later this was replaced by diisopropylcarbodiimide (di-c-di), which allowed for GB nerve agent to be stored in aluminum casings.
- Developing binary chemical weapons, where the two precursor chemicals are stored separately in the same shell, and mixed to form the agent immediately before or when the shell is in flight. This approach has the dual benefit of making the issue of shelf life irrelevant and greatly increasing the safety of sarin munitions.

Biological Effects

Like other nerve agents, sarin attacks the nervous system of a living organism.

When a functioning motor nerve is stimulated it releases the neurotransmitter acetylcholine to transmit the impulse to a muscle or organ. Once the impulse has been sent, the enzyme acetylcholinesterase breaks down the acetylcholine in order to allow the muscle or organ to relax.

Sarin is an extremely potent organophosphate compound that disrupts the nervous system by inhibiting the cholinesterase enzyme by forming a covalent bond with the site of the enzyme where acetylcholine normally undergoes hydrolysis. This allows acetylcholine to build up and continue to act so that any nerve impulses are, in effect, continually transmitted.

Initial symptoms following exposure to sarin (and other nerve agents) are a runny nose, tightness in the chest and contraction of the pupils. Soon after, the victim has difficulty breathing and experiences nausea and drooling. As the victim continues to lose control of bodily functions, he vomits, defecates and urinates. This phase is followed by twitching and jerking. Ultimately, the victim becomes comatose and suffocates in a series of convulsive spasms.

Sarin is a highly volatile liquid. Inhalation and absorption through the skin pose a great threat. Even vapour concentrations immediately penetrate the skin. People who absorb a nonlethal dose but do not receive immediate appropriate medical treatment may suffer permanent neurological damage.

Even at very low concentrations, sarin can be fatal. Death may follow in one minute after direct ingestion of about 0.01 milligram per kilogram of body weight if antidotes, typically atropine and pralidoxime, are not quickly administered. Atropine, an acetylcholine inhibitor,

is given to treat the physiological symptoms of poisoning. Pralidoxime can regenerate cholinesterases if administered within approximately five hours.

It is estimated that sarin is more than 500 times as toxic as cyanide.

The short- and long-term symptoms experienced by those affected included:

- bleeding from the nose and mouth

coma
convulsions
death
difficulty breathing
disturbed sleep and nightmares
extreme sensitivity to light
foaming at the mouth
high fevers
influenza-like symptoms
loss of consciousness
loss of memory
nausea and vomiting
paralysis
post-traumatic stress disorder
respiratory problems
seizures
uncontrollable trembling
vision problems, both temporary and permanent

History

The following is the specific history of sarin, which is closely linked to the history of similar nerve agents also discovered in Germany during or soon after World War II. That broader history is detailed in Nerve Agent: History .

Origin

Sarin was discovered in 1938 in Wuppertal-Elberfeld in the Ruhr valley of Germany by two German scientists while attempting to create stronger pesticides; it is the most toxic of the four G-agents made by Germany. The compound, which followed the discovery of the nerve agent tabun, was named in honor of its discoverers: Gerhard *S*chrader, *A*mbros, *R*üdiger and Van der L*IN*de.

Sarin in Nazi Germany During World War II

In mid-1939, the formula for the agent was passed to the Chemical Warfare section of the German Army Weapons Office, which ordered that it be brought into mass production for wartime use. A number of pilot plants were built, and a high-production facility was under

construction (but was not finished) by the end of World War II. Estimates for total sarin production by Nazi Germany range from 500 kg to 10 tons.

Though sarin, tabun and soman were incorporated into artillery shells, Germany ultimately decided not to use nerve agents against Allied targets. German intelligence was unaware that the Allies had not developed similar compounds, and they were concerned that the Allies' ability to reach German targets would prove devastating in a chemical war.

Sarin after World War II

- 1950s (early): NATO adopts sarin as a standard chemical weapon, and both Russia and the United States produce sarin for military purposes.
- The feedstock chemicals required for GB production include: hydrofluoric acid, methylphosphonic dichloride (dichlor) and isopropyl alcohol. Other materials used in the GB manufacturing process included: the stabilizing additive; calcium chloride brine, the refrigerant; and methylene chloride, the heat transfer agent.
- 1953: 20-year old Ronald Maddison, a Royal Air Force engineer from Consett, County Durham, died in human testing of sarin at the Porton Down chemical warfare testing facility in Wiltshire. Maddison had been told that he was participating in a test to "cure the common cold." Ten days after his death an inquest was held in secret which returned a verdict of "misadventure". In 2004 the inquest was reopened and, after a 64-day inquest hearing, the jury ruled that Maddison had been unlawfully killed by the "application of a nerve agent in a non-therapeutic experiment."
- 1956: Regular production of sarin ceased in the United States, though existing stocks of bulk Sarin were re-distilled until 1970.
- 1978: Michael Townley in a Sworn declaration indicates that Sarin was produced by the secret police of the Chile Pinochet dictatorship DINA, by Eugenio Berríos, it indicates that it was used to assassinate the real state archives custodian Renato León Zenteno and the Army Corporal Manuel Leyton.[1]
- 1980-1988: Iraq employed sarin against Iran during the 1980-88 war. During the 1990-91 Gulf War, Iraq still had large stockpiles available which were found as coalition forces advanced north.
- 1988: Over the span of two days in March, the ethnic Kurd city of Halabja in northern Iraq (population 70,000) was bombarded with twenty chemical and cluster bombs, which included sarin. An estimated 5,000 people died.
- 1991: UN Resolution 687 establishes the term "weapon of mass destruction" and calls for the immediate destruction of chemical weapons in Iraq, and eventual destruction of all chemical weapons globally.
- 1993: The United Nations Chemical Weapons Convention is signed by 162 member countries, banning the production and stockpiling of many chemical weapons, including sarin. It goes into effect on 29 April 1997, and calls for the

complete destruction of all specified stockpiles of chemical weapons by April 2007.

- 1994: The Japanese religious sect Aum Shinrikyo releases an impure form of sarin in Matsumoto, Nagano Prefecture.
- 1995: Aum Shinrikyo sect releases an impure form of sarin in the Tokyo subway.
- 1998: In its June 15 issue Time Magazine runs a story entitled "Did The U.S. Drop Nerve Gas?". The story is broadcast June 7 on the CNN program NewsStand. The Time article alleges that U.S. Air Force A-1E Skyraiders engaged in a covert operation called Operation Tailwind, in which they deliberately dropped CBU-15 Cluster Bomb Units containing submunitions that were filled with sarin on defected U.S. troops in Laos. The report causes a scandal, and The Pentagon launches a study that concludes no nerve gas use took place. After an internal investigation, CNN and Time magazine (both owned by the media conglomerate Time Warner) retract the story and fire the two producers primarily responsible for it.
- 2004: May 14 Iraqi insurgency fighters in Iraq detonate a 155 mm shell containing several litres of binary precursors for sarin. The shell is designed to mix the chemicals as it spins during flight. The detonated shell releases only a small amount of sarin gas, either because the explosion failed to mix the binary agents properly or because the chemicals inside the shell had degraded significantly with age. Two United States soldiers were treated for exposure after displaying the early symptoms.

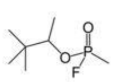
Soman



Discovered by Richard Kuhn

Discovered in 1944

Chemical characteristics

Chemical name

3-(fluoro-methyl-phosphoryl)oxy-
2,2-dimethyl-butane

Chemical family

Fluorinated organophosphorus compound

Chemical formula

$C_7H_{16}FO_2P$

Boiling point

198 °C

Freezing/melting point

42 °C (44 °F)

Vapor pressure

0.40 mmHg (53 Pa) at 25 °C

Vapor relative density (air=1)

6.3

Solubility in water

Moderate

Density at 25 C

1.022 g/cm^3

Appearance and color

When pure, colorless liquid with fruity odor.
With impurities, amber or dark brown,
with oil of camphor odor

Soman, also known by its NATO designation *GD* (O-Pinacolyl methylphosphonofluoridate) is an extremely toxic substance whose sole application is as

one of the world's most dangerous military weapons. It is a nerve agent, interfering with normal functioning of the mammalian nervous system. As a chemical weapon, it is classified as a weapon of mass destruction by the United Nations according to UN Resolution 687, and its production is strictly controlled and stockpiling outlawed by the Chemical Weapons Convention of 1993. Soman was the third of the so-called G-series nerve agents to be discovered (along with GA (tabun), GB (sarin), and GF (cyclosarin)).

It is a volatile, corrosive and colourless liquid with a faint odour when pure. More commonly, it is a yellow to brown color and has a stronger odour described as camphor. The LCt_{50} for Soman is 70 mg·min/m^3 in humans. It is both more lethal and more persistent than sarin or tabun, but less so than cyclosarin.

GD can be thickened for use as a chemical spray using an acryloid copolymer. It can also be deployed as a binary chemical weapon; its precursor chemicals are methylphosphonyl difluoride and a mixture of pinacolyl alcohol and an amine.

Alternative names

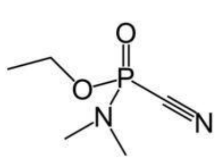
Soman is occasionally referred to names other than soman or GD:

- Phosphonofluoridic acid, methyl-, 1, 2, 2-trimethylpropyl ester
- Pinacolyl methylphosphonofluoridate
- 1,2,2-Trimethylpropyl methylphosphonofluoridate
- Methylpinacolyloxyfluorophosphine oxide
- Pinacolyloxymethylphosphonyl fluoride
- Pinacolyl methanefluorophosphonate
- Methylfluoropinacolylphosphonate
- Fluoromethylpinacolyloxyphosphine Oxide
- Methylpinacolyloxyphosphonyl fluoride
- Pinacolyl methylfluorophosphonate
- 1,2,2-Trimethylpropoxyfluoromethylphosphine oxide

History

Soman was discovered by Richard Kuhn in Germany in 1944, and represented the last wartime nerve agent discovery (GF was not found until 1949). Soman was given the identifier GD post-war (GC was already in medical use) when the information relating to soman was recovered by the Soviet Union from its hiding place in a mine.

Tabun



Discovered by Gerhard Schrader

Unusual hazards

Fires involving this chemical may result
in the formation of hydrogen cyanide

Tabun or *GA* (Ethyl N,N-dimethylphosphoramidocyanidate) is an extremely toxic substance that is one of the world's most dangerous military weapons. Because it fatally interferes with normal functioning of the mammalian nervous system, it is classified as a nerve agent. As a chemical weapon, it is classified as a weapon of mass destruction by the United Nations according to UN Resolution 687, and its production is strictly controlled and stockpiling outlawed by the Chemical Weapons Convention of 1993. Tabun is the first of the so-called G-series nerve agents (along with GB (sarin), GD (soman) and GF (cyclosarin)).

Tabun is a colourless to brown liquid (depending on purity). It is volatile (evaporating readily at normal temperatures), although less volatile than either sarin or soman.

Effects of overexposure

The exact symptoms of overexposure are similar to those created by all nerve agents, and are described in more detail in that article. Tabun, like all nerve agents, is toxic even in minute doses. The number and severity of symptoms which appear vary according to the amount of the agent absorbed and rate of entry into the body. Very small skin dosages

sometimes cause local sweating and tremors accompanied with characteristically constricted pupils with few other effects. Tabun is about half as toxic as sarin by inhalation, but tabun in very low concentrations is more irritating to the eyes than sarin.

The effects of exposure appear much more slowly when tabun is absorbed through the skin rather than inhaled: although a victim may absorb a lethal dose in 1 to 2 minutes, death may be delayed for 1 to 2 hours. Inhaled lethal dosages kill in 1 to 10 minutes, and liquid in the eye kills almost as rapidly. Most of what is known about lethal dosages are known from animal studies on monkeys.

Alternative names

Tabun is occasionally referred to names other than tabun or GA:

- Ethyl dimethylplosphoramidocyanidate
- Dimethylaminoethoxy-cyanophosphine oxide
- Dimethylamidoethoxyphosphoryl cyanide
- Ethyldimethylaminocyanophosphonate
- Ethyl ester of dimethylphosphoroamidocyanidic acid
- Ethyl phosphorodimethylamidocyanidate
- EA1205

History

For an in-depth discussion, see main article on nerve agent history

Tabun, the first known nerve agent, was discovered accidentally in 1936 by the German researcher Dr. Gerhard Schrader. Dr. Schrader was experimenting with a class of compounds called organophosphates, which kill insects by interrupting their nervous systems, in order to create a more effective insecticide for the IG Farben pharmaceutical conglomerate at Elberfield. Instead of a new insecticide, however, he discovered tabun, a chemical which is enormously toxic to humans as well as to insects.

During World War II as part of the Grün 3 program, a plant for the manufacture of tabun was established in Dyhernfurth (now Brzeg Dolny, Poland), producing the nerve agent under the codename Trilon-83. Run by Anorgana GmbH, the plant began production in 1942. Large scale manufacturing of the agent resulted in problems with the product's degradation over time and only around 12,500 tons of material were manufactured before the plant was over-run by the advancing Soviet forces. The plant initially produced shells and aerial bombs using a 95:5 mix of tabun and chlorobenzene, designated "Variant A" before switching in the latter half of the war to "Variant B," an 80:20 mix of tabun and chlorobenzene designed to make the mixture disperse more easily. The Soviet government had the plant dismantled and taken back to Russia.

Like the other Allied governments, the Soviets soon abandoned GA for GB and GD. Large quantities of the German-manufactured agent were dumped into the sea.

Since GA is much easier to produce than the other G-series weapons and the process is comparatively widely understood, countries which are developing a nerve agent capability but which lack advanced industrial facilities often start by producing GA.

During the Iran-Iraq War, Iraq employed large quantities of chemical weapons against ground forces of Iran. Although the most commonly used agents were mustard gas and sarin, tabun and cyclosarin were also used.

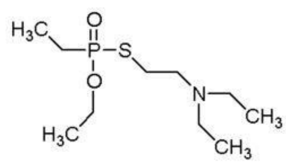
VE

VE (nerve agent)



Systematic name S-(Diethylamino)ethyl O-ethyl ethylphosphonothioate

Chemical formula $C_{10}H_{24}N_{1}O_{2}P_{1}S_{1}$

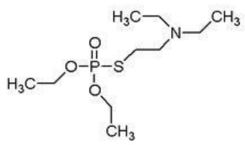
Molecular mass 253.34 g/mol

VE (S-(Diethylamino)ethyl O-ethyl ethylphosphonothioate) is a "V-series" nerve agent closely related to the better-known VX nerve agent.

Like most of the agents in the V-series (with the exception of VX), VE has not been extensively studied outside of military science. Little is known about this compound other than its chemical formula.

It is commonly theorized that the so called "second-generation" V series agents came from a cold war era Russian chemical weapons development program. They may have been developed sometime between 1950 and 1990. They have similar lethal dose levels to VX (between 10-50 mg) and have similar symptoms and method of action to other nerve agents that act on cholinesterase, and treatment remains the same, but the window for effectively treating second generation V series seizures is shorter. In addition to the standard seizures, some of the second generation V series agents are known to cause comas.

VG



VG (O,O-Diethyl-S-[2-(diethylamino)ethyl] phosphorothioate) (also called *Amiton* or *Tetram*) is a "V-series" nerve agent chemically similar to the better-known VX nerve agent. Tetram is the common Russian name for the substance. Amiton was the trade name for the substance when it was marketed as an insecticide by ICI in the mid-1950s.

With a toxicity of about 1/10 that of VX, i.e. similar to that of sarin[1], it is now considered too dangerous for use in agriculture[2] but unlike other nerve agents it is classified under Schedule 2 of the Chemical Weapons Convention rather than the more restrictive Schedule 1. It is thought that North Korea may have military stockpiles of this chemical [3].

During the early 1950s at least three chemical companies working on organo-phosphorus insecticides independently discovered the amazing toxicity of these chemicals.[4] In 1952, Dr. Ranajit Ghosh, a chemist working for ICI at their Plant Protection Laboratories was investigating the potential of organophosphate esters of substituted aminoethanethiols for use as pesticides. Like the earlier German investigators of organophosphates in the late 1930s who had discovered the G-series nerve agents, Dr. Ghosh discovered that their action on cholinesterase made them effective pesticides. One of them, Amiton, was described in a 1955 paper by Ghosh and another chemist, J. F. Newman, as being particularly effective against mites[5]. It was brought to market as an insecticide by the company in 1954 but was subsequently withdrawn as too toxic. [6]

The toxicity of these substances had not passed unnoticed by the British Government, as some of the compounds had already been sent to their research facility at Porton Down for evaluation. Some of the chemicals from this class of compounds formed a new group of nerve agents called V Agents. The British Government unilaterally renounced chemical and biological weapons in 1956, although in 1958 traded their research on VX technology with the United States Government in exchange for information on thermonuclear weapons. The US then went into production of large amounts of the chemically similar, but much more toxic VX in 1961[7].

The *VX* nerve agent is the most well-known of the V-series of nerve agents. Its chemical name is O-ethyl-S-[2(diisopropylamino)ethyl] methylphosphonothioate and its molecular formula is $C_{11}H_{26}NO_2PS$.

The only countries known to possess VX are the United States, United Kingdom, Russia, France and Syria. VX agent is considered an area denial weapon due to its physical properties.

With its high viscosity and low volatility VX has the texture and feel of high-grade motor oil. This makes it especially dangerous, as it has a high persistence in the environment. It is odorless and tasteless, and can be distributed as a liquid or, through evaporation, into small amounts of vapor. It works as a nerve agent by blocking the function of the enzyme acetylcholinesterase. Normally, an electric nerve pulse would cause the release of acetylcholine over a synapse that would stimulate muscle contraction. The acetylcholine is then broken down to non-reactive substances (acetic acid and choline) by the acetylcholinesterase enzyme. If more muscle tension is needed the nerve must release more acetylcholine. VX blocks the action of acetylcholinesterase, thus resulting in sustained contractions of all the muscles in the body. Sustained contraction of the diaphragm muscle causes death by asphyxiation.

Often regarded as the deadliest nerve agent created to date, as little as 200 micrograms is enough to kill an average person, depending on method of absorption. Death can be avoided if the appropriate antidote is injected immediately after exposure. The most commonly used antidote is atropine and pralidoxime which is issued for military personnel in the form of an autoinjector. Standard chemical agent resistance pills are also effective. Atropine works by binding and blocking a subset of acetylcholine receptors (known as muscarinic acetylcholine receptor, mAchR), so that the build up of acetylcholine produced by loss of the acetylcholinesterase function can no longer affect their target. This prevents involuntary muscle actions so that muscles like the diaphragm are not in constant contraction. The injection of pralidoxime regenerates bound acetylcholinesterase.

Synthesis

VX is produced via the "Transester Process". This entails a complex chemical transition whereby phosphorus trichloride is methylated to produce methyl phosphonous dichloride. The resulting material is reacted with ethanol to form a diester. This is then transesterified to produce the immediate precursor of VX. Finally, the immediate precursor is reacted with sulfur to form V-agent.

Nerve Agent VX can also be delivered in binary chemical weapons which mix in-flight to form the agent prior to release. Binary VX is referred to as VX2, and is created by mixing O-(2-diisopropylaminoethyl) O'-ethyl methylphosphonite (Agent QL) with elemental sulfur (Agent NE) as is done in the BIGEye aerial chemical bomb. It may also be produced by mixing with sulfur compounds, as with the liquid dimethyl polysulfide mixture (Agent NM) in the cancelled XM-768 8-inch binary projectile program.

History

The chemist Ranajit Ghosh discovered the V-series nerve agents at the Government research establishment at Porton Down, England in 1952; VX was passed over in favour of continuing with sarin as their chemical weapon of choice. The United Kingdom unilaterally renounced chemical and biological weapons in 1956. In 1958 the British government traded their research on VX technology with the United States of America in exchange for information on thermonuclear weapons. The US then went into production of large amounts of VX in 1961.

The US later destroyed all of its stockpiles of the deadly nerve agent (by incineration at Johnston Island in the South Pacific), as mandated by the US accession to the Chemical Weapons Convention. Earlier, pre-treaty disposal included the US Army's CHASE (Cut Holes And Sink 'Em) program, in which old ships were filled with chemical weapons stockpiles and then scuttled. CHASE 8 was conducted on June 15, 1967, in which the S.S. Cpl. Eric G. Gibson was filled with 7,380 VX rockets and scuttled in 7,200 feet of water, off the coast of Atlantic City, New Jersey. The long-term environmental ramifications of exposing large quantities of VX to seawater and marine life could pose a grave danger, but are ultimately unknown.

The US is also destroying chemical weapons stockpiles containing VX in nine other locations, one of which is in Russia. On June 12, 2005, it was reported that more than 250,000 US gallons (950 m^3) of the chemical weapon are stored at the Newport Chemical Depot in Newport, Indiana, about 30 miles (50 km) north of Terre Haute, Indiana. The VX is in the process of being hydrolyzed to much less toxic byproducts using concentrated caustic solution. The VX hydrolysate produced will contain mainly a phosphonate ester and a thiolamine, with 20 parts per billion or less of residual VX. (Interestingly, 20 ppb is the level of VX in water that is considered permissible for drinking by US combat troops.) The current plan is to truck the hydrolysate from Indiana to the DuPont Chambers Works Secure Environmental Facility at Deepwater, NJ where it will be further treated to destroy the phosphonate ester and the thiolamine, and dumped into the Delaware River.[1] The US Army is awaiting final approval of the plan from the Centers for Disease Control and the Environmental Protection Agency. The governors of Delaware, New Jersey, Pennsylvania, and New York have opposed this plan and the New Jersey Governor Codey instructed the New Jersey Department of Transportation to deny entry to any trucks carrying the hydrolysate to the Deepwater facility. Prior to the current plan, it had been proposed that the hydrolysate be dumped into the Great Miami River, a tributary of the Ohio River, near Dayton, Ohio but the community there successfully defeated the proposal.

VX hydrolysis began on May 5 2005 and as of June 12 the facility had destroyed 2,894 US gallons (11 m^3) of VX. A contained spill of 30 US gallons (100 L) drew attention to the disposal process, but authorities said no agent was released and no one was injured in the spill.

VX was synthesised and used for several murders and attempted murders by the Aum Shinrikyo cult in Japan in 1994 and 1995.[2]

SMILES CC(OCC[N](C)(C)C)=O

The chemical compound *acetylcholine*, often abbreviated as *ACh*, was the first neurotransmitter to be identified. It is a chemical transmitter in both the peripheral nervous system (PNS) and central nervous system (CNS) in many organisms including humans. Acetylcholine is the neurotransmitter in all autonomic ganglia.

Chemistry

Acetylcholine is an ester of acetic acid and choline with chemical formula CH3COOCH2CH2N+(CH3)3. This structure is reflected in the systematic name, 2-(acetyloxy)-N,N,N-trimethylethanaminium.

Acetylcholine (ACh) was first identified in 1914 by Henry Hallett Dale for its actions on heart tissue. It was confirmed as a neurotransmitter by Otto Loewi who initially gave it the name vagusstoff because it was released from the vagus nerve. Both received the 1936 Nobel Prize in Physiology or Medicine for their work.

Later work showed that when acetylcholine binds to acetylcholine receptors on striated muscle fibers, it opens voltage gated sodium channels in the membrane. Sodium ions then enter the muscle cell, stimulating muscle contraction. Acetylcholine is also used in the brain, where it tends to cause excitatory actions. The glands that receive impulses from the parasympathetic part of the autonomic nervous system are also stimulated in the same way.

Acetylcholine is synthesized in certain neurons by the enzyme choline acetyltransferase from the compounds choline and acetyl-CoA. Organic mercurial compounds have a high affinity for sulfhydryl groups, which causes dysfunction of the enzyme choline acetyl transferase. This inhibition may lead to acetylcholine deficiency, and can have consequences on motor function.

Normally, the enzyme acetylcholinesterase converts acetylcholine into the inactive metabolites choline and acetate. The devastating effects of nerve agents (in bioterrorism, Sarin gas for example) are due to their inhibition of this enzyme, resulting in continuous stimulation of the muscles, glands and central nervous system. Certain insecticides are effective because they inhibit this enzyme in insects. On the other hand, since a shortage of acetylcholine in the brain has been associated with Alzheimer's disease, some drugs that inhibit acetylcholinesterase are used in the treatment of that disease.

Release sites

- Acetylcholine is released in the autonomic nervous system:
  - pre- and post-ganglionic parasympathetic neurons
  - preganglionic sympathetic neurons (and also postganglionic sudomotor neurons, i.e., the ones that control sweating)

Botulin acts by suppressing the release of acetylcholine; where the venom from a black widow spider has the reverse effect.

Pharmacology

There are two main classes of acetylcholine receptor (AChR), nicotinic acetylcholine receptors (nAChR) and muscarinic acetylcholine receptors (mAChR). They are named for the ligands used to discover the receptors.

Nicotinic AChRs are ionotropic receptors permeable to sodium, potassium, and chloride ions. They are stimulated by nicotine and acetylcholine and blocked by curare. Most peripheral AChRs are nicotinic, such as those on the heart and blood vessels or at the neuromuscular junction. They are also found in wide distribution through the brain, but in relatively low numbers.

Muscarinic receptors are metabotropic and affect neurons over a longer time frame. They are stimulated by muscarine and acetylcholine, and blocked by atropine. Muscarinic receptors are found in both the central nervous system and the peripheral nervous system, in heart, lungs, upper GI tract and sweat glands. Extracts from the plant included this compound, and its action on muscarinic AChRs that increased pupil size was used for attractiveness in many European cultures in the past. Now, ACh is sometimes used during cataract surgery to produce rapid constriction of the pupil. It must be administered intraocularly because corneal cholinesterase metabolizes topically administered ACh before it can diffuse into the eye. It is sold by the trade name Miochol-E (CIBA Vision). Similar drugs are used to induce mydriasis (dilation of the pupil) in cardiopulmonary resuscitation and many other situations.

The disease myasthenia gravis, characterized by muscle weakness and fatigue, occurs when the body inappropriately produces antibodies against acetylcholine receptors, and thus inhibits proper acetylcholine signal transmission. Over time the motor end plate is destroyed. Drugs that competitively inhibit acetylcholinesterase (e.g., neostigmine or physostigmine) are effective in treating this disorder. They allow endogenously released acetylcholine more time to interact with its respective receptor before being inactivated by acetylcholinesterase in the gap junction.

Blocking, hindering or mimicking the action of acetylcholine has many uses in medicine. Cholinesterase inhibitors increase the action of acetylcholine by delaying its degradation; some have been used as nerve agents or pesticides. Clinically they are used to reverse the action of muscle relaxants, to treat myasthenia gravis and in Alzheimer's disease (rivastigmine, which increases cholinergic activity in the brain).

ACh Receptor Agonists

Direct Acting

- Acetylcholine
Bethanechol
Carbachol
Cevimeline
Pilocarpine
Suberylcholine

Indirect Acting (reversible)

- Ambenomium
- Donepezil
- Edrophonium
- Galantamine
- Neostigmine
- Physostigmine
- Pyridostigmine
- Rivastigmine
- Tacrine

Indirect Acting (irreversible)

- Echothiophate
- Isoflurophate

Reactivation of Acetylcholine Esterase

- Pralidoxime

ACh Receptor Antagonists

Antimuscarinic Agents

- Atropine
    - Ipratopium
- Scopolamine

Ganglionic Blockers

- Mecamylamine
Hexamethonium
- Nicotine (in high doses)
- Trimethaphan

Neuromuscular Blockers

- Atracurium
Cisatracurium
- Doxacurium
- Metocurine
- Mivacurium
- Pancuronium
- Rocuronium
- Succinylcholine
- Tubovurarine
- Vecuronium

Others? / Uncategorized / Unknown

- surugatoxin

Neuromodulatory Effects

In the central nervous system, ACh has a variety of effects as a neuromodulator.

Given its prominent role in learning, ACh is naturally involved with synaptic plasticity. It has been shown to enhance the amplitude of synaptic potentials following long-term potentiation in many regions, including the dentate gyrus, CA1, piriform cortex, and neocortex. This effect most likely occurs either through enhancing currents through NMDA receptors or indirectly by suppressing adaptation. The suppression of adaptation has been shown in brain slices of regions CA1, cingulate cortex, and piriform cortex as well as in vivo

in cat somatosensory and motor cortex by decreasing the conductange of voltage-dependent M currents and Ca2+-dependent K+ currents.

Acetylcholine also has other effects on excitability of neurons. Its presence causes a slow depolarization by blocking a tonically active K+ current, which increases neuronal excitability. Paradoxically, it increases spiking activity in inhibitory interneurons while decreasing strength of synaptic transmission from those cells. This decrease in synaptic transmission also occurs selectively at some excitatory cells: for instance, it has an effect on intrinsic and associational fibers in layer Ib of piriform cortex, but has no effect on afferent fibers in layer Ia. Similar laminar selectivity has been shown in dentate gyrus and region CA1 of the hippocampus. One theory to explain this paradox interprets Acetylcholine neuromodulation in the neocortex as modulating the estimate of expected uncertainty, acting counter to Norepinephrine (NE) signals for unexpected uncertainty. Both would then decrease synaptic transition strength, but ACh would then be needed to counter the effects of NE in learning a signal understood to be noisy.

Muscarinic agonists

A *muscarinic receptor agonist* is an agent that enhances the activity of the muscarinic acetylcholine receptor. The muscarinic receptor has different subtypes, labelled M1-M5, allowing for further differentiation.

In the form of pilocarpine muscarinic receptor agonists have been used medically for a long time.

M1-type muscarinic acetylcholine receptors play a role in cognitive processing. In Alzheimer disease (AD) amyloid formation may decrease the ability of these receptors to transmit their signals leading to decrease cholinergic activity. As these receptors themselves

appear relatively unchanged in the disease process, they have become a potential therapeutic target when trying to improve cognitive function in patients with AD.

A number of muscarinic agonists have been developed and are under investigation to treat AD. These agents show promise as they are neurotrophic, decrease amyloid depositions, and improve damage due to oxidative stress. Tau-phosphorylation is decreased and cholinergic function enhanced. Notably several agents of the AF series of muscarinic agonists have become the focus of such research:. *AF102B, AF150(S), AF267B*. In animal models that are mimicking the damage of AD, these agents appear promising.

Drugs

- M1 agonists
  - *Cevimeline* (AF102B) (Evoxac?) is a muscarinic agonist that is an Food and Drug Administration (FDA)-approved drug and used for the management of dry mouth in Sjogren syndrome.
- M3 agonists
  - *Aceclidine*, for glaucoma.
  - *Arecoline*, an alkaloid present in the Betel nut.
  - *Pilocarpine* is a drug that acts as a muscarinic receptor agonist that is used to treat glaucoma.

Muscarine

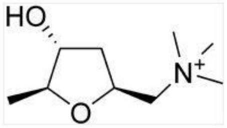
Chemical name (2S,4R,5S)-(4-hydroxy-5-methyl-tetrahydrofuran- 2-ylmethyl)-trimethyl-ammonium

Chemical formula $C_9H_{20}NO_2^+$

Molecular mass 174.26 g/mol

CAS number 300-54-9

SMILES *O[C@@H]1C[C@@H](C[N+](C)(C)C)O[C@H]1C*



Muscarine, L-*(+)-muscarine*, or *muscarin* is a natural product found in certain mushrooms, particularly in Inocybe and Clitocybe species. It was first isolated from Amanita muscaria in 1869. It was the first parasympathomimetic substance ever studied and causes profound activation of the peripheral parasympathetic nervous system that may end in convulsions and death. Muscarine has no effects on the central nervous system because it does not cross the blood-brain barrier due to its positively charged nitrogen atom.

Muscarine mimics the action of the neurotransmitter acetylcholine at metabotropic receptors that are also known under the name muscarinic acetylcholine receptors.

Muscarine poisoning is characterized by increased salivation, sweating (perspiration), and tearflow (lacrimation) within 15 to 30 minutes after ingestion of the mushroom. With large doses, these symptoms may be followed by abdominal pain, severe nausea, diarrhea, blurred vision, and labored breathing. Intoxication generally subsides within 2 hours. Deaths are rare, but may result from cardiac or respiratory failure in severe cases. The specific antidote is atropine.

Muscarine is only a trace compound in the fly agaric Amanita muscaria, the pharmacologically more relevant compound from this mushroom is muscimol.

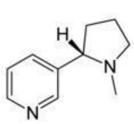
Nicotinic agonists

Nicotine



Chemical name (S)-3-(1-Methyl-2-pyrroli- dinyl)pyridine

Chemical formula $C_{10}H_{14}N_2$

Molecular mass 162.23 g/mol

CAS number 54-11-5

SMILES *[H][C@@]2(N(C)CCC2)c1cccnc1*

Properties

Density 1.01 g/ml

Melting point -79 °C

Boiling point 247 °C (decomposes)

Autoignition temperature 240 °C

Flash point 95 °C

Vapour Pressure 0.006 kPa at 25 °C

Viscosity 2.7 mPa·s at 25 °C, 1.6 mPa·s at 50 °C

Surface Tension 37.5 dyn/cm (37.5 mN/m) at 25.5 °C, 37.0 dyn/cm (37.0 mN/m) at 36.0 °C

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Nicotine is an alkaloid found in the nightshade family of plants (Solanaceae), predominantly in tobacco, and in lower quantities in tomato, potato, eggplant (aubergine), and green pepper. Nicotine alkaloids are also found in the leaves of the coca plant. Nicotine constitutes 0.3 to 5% of the tobacco plant by dry weight, with biosynthesis taking place in the roots, and accumulates in the leaves. It is a potent neurotoxin and is included in many insecticides.

In lower concentrations, the substance acts as a stimulant and is one of the main factors responsible for the dependence-forming properties of tobacco smoking.

Chemistry

Nicotine is a hygroscopic, oily liquid that is miscible with water in its base form. As a nitrogenous base, nicotine forms salts with acids that are usually solid and water soluble. Nicotine easily penetrates the skin. As shown by the physical data, free base nicotine will burn at a temperature below its boiling point, and its vapors will combust at 95 °C in air despite a low vapor pressure. Because of this, most nicotine is burned when a cigarette is smoked; however, enough is inhaled to provide the desired effects.

Pharmacology

Pharmacokinetics: As nicotine enters the body, it is distributed quickly through the bloodstream and can cross the blood-brain barrier. On average it takes about seven seconds for the substance to reach the brain. The half life of nicotine in the body is around 2 hours[1]. The amount of nicotine inhaled with tobacco smoke is a fraction of the amount contained in the tobacco leaves (most of the substance is destroyed by the heat). The amount of nicotine absorbed by the body from smoking depends on many factors, including the type of tobacco, whether the smoke is inhaled, and whether a filter is used. For chewing tobacco, often called dip, snuff, or snus, which is held in the mouth between the lip and gum, the amount released into the body tends to be much greater than smoked tobacco.

Dynamics

Nicotine acts on the nicotinic acetylcholine receptors. In small concentrations it increases the activity of these receptors, among other things leading to an increased flow of adrenaline, a stimulating hormone. The release of adrenaline causes an increase in heart rate, blood pressure and respiration, as well as higher glucose levels in the blood. Cotinine is a break-down product of nicotine which remains in the blood for up to 48 hours and can be used as an indicator of a person's exposure to smoke. In high doses, nicotine will cause a blocking of the nicotinic acetylcholine receptor, which is the reason for its toxicity and its effectiveness as an insecticide.

In addition, nicotine increases dopamine levels in the reward circuits of the brain. Studies have shown that smoking tobacco inhibits monoamine oxidase (MAO), an enzyme responsible for breaking down monoaminergic neurotransmitters such as dopamine, in the brain. It is currently believed that nicotine by itself does not inhibit the production of monoamine oxidase (MAO), but that other ingredients in inhaled tobacco smoke are believed to be responsible for this activity. In this way, it generates feelings of pleasure, similar to that caused by cocaine and heroin, thus causing the addiction associated with the need to sustain high dopamine levels.

Toxicology

The LD50 of nicotine is 50 mg/kg for rats and 3 mg/kg for mice. 40–60 mg can be a lethal dosage for adult human beings. This makes it an extremely deadly poison. It is more toxic than many other alkaloids such as cocaine, which has a lethal dose of 1000 mg.

The carcinogenic properties of nicotine in standalone form, separate from tobacco smoke, have not been evaluated by the IARC, and it has not been assigned to an official carcinogen group. The currently available literature indicates that nicotine, on its own, does not promote the development of cancer in healthy tissue and has no mutagenic properties. Its teratogenic properties have not yet been adequately researched, and while the likelihood of birth defects caused by nicotine is believed to be very small or nonexistent, nicotine replacement product manufacturers recommend consultation with a physician before using a nicotine patch or nicotine gum while pregnant or nursing. However, nicotine and the increased acetylcholinic activity it causes have been shown to impede apoptosis, which is one of the methods by which the body destroys unwanted cells (programmed cell death). Since apoptosis helps to remove mutated or damaged cells that may eventually become cancerous, the inhibitory actions of nicotine creates a more favourable environment for cancer to develop. Thus nicotine plays an indirect role in carcinogenesis. It is also important to note that its addictive properties are often the primary motivating factor for tobacco smoking, contributing to the proliferation of cancer.

At least one study has concluded that exposure to nicotine alone, not simply as a component of cigarette smoke, could be responsible for some of the neuropathological changes observed in infants dying from Sudden Infant Death Syndrome (SIDS).[2]

It has been noted that the majority of people diagnosed with schizophrenia smoke tobacco. Estimates for the number of schizophrenics that smoke range from 75% to 90%. It

was recently argued that the increased level of smoking in schizophrenia may be due to a desire to self-medicate with nicotine. [3][4] More recent research has found the reverse, that it is a risk factor without long-term benefit, used only for its short term effects. [5]However, research on nicotine as administered through a patch or gum is ongoing.

Therapeutic uses

The primary therapeutic use of nicotine is in treating nicotine dependence (smoking). Controlled levels of nicotine are given to a patient through gums, dermal patches, or nasal sprays in an effort to wean them off of their dependence.

Recent studies have indicated that nicotine can be used to help adults suffering from autosomal dominant frontal lobe epilepsy. The same areas that cause seizures in that form of epilepsy are also responsible for processing nicotine in the brain.

Some research has also shown that nicotine can lessen symptoms of mild to moderate ulcerative colitis.

Nicotine and its metabolites are being researched for the treatment of a number of disorders, including ADHD and Parkinson's Disease.

History and name

Nicotine is named after the tobacco plant Nicotiana tabacum, which in turn is named after Jean Nicot, a French ambassador, who sent tobacco and seeds from Portugal to Paris in 1550 and promoted their medicinal use. Nicotine was first isolated from the tobacco plant in 1828 by German chemists, Posselt & Reimann. Its chemical empirical formula was described by Melsens in 1843, and it was first synthesized by A. Pictet and Crepieux in 1893.

Pharmacology

Pharmacology (in Greek: pharmacon (Æ¬Á¼±º¿½) meaning drug, and logos (»Ì³¿Â) meaning science) is the study of how substances interact with living organisms to produce a change in function.[1] If substances have medicinal properties, they are considered *pharmaceuticals*. The field encompasses drug composition and properties, interactions, toxicology, therapy, and medical applications and antipathogenic capabilities.

Development of medication is a vital concern to medicine, but also has strong economical and political implications. To protect the consumer and prevent abuse, many governments regulate the manufacture, sale, and administration of medication. In the United States, the main body that regulates pharmaceuticals is the Food and Drug Administration and they enforce standards set by the United States Pharmacopoeia.

Pharmacology as a chemical science is practiced by pharmacologists. Subdisciplines include clinical pharmacology (the medical field of medication effects on humans), neuro- and psychopharmacology (effects of medication on behavior and nervous system functioning), toxicology and theoretical pharmacology.

Pharmacology is not identical with pharmacy, though in common usage the two are at times confused.

Drug legislation and safety

In the United States, the Food and Drug Administration (FDA) is responsible for creating guidelines for the approval and use of drugs. The FDA requires that all approved drugs fulfill two requirements:

1. The drug must be found to be effective against the disease for which it is seeking approval.
2. The drug must meet safety criteria by being subject to extensive animal and controlled human testing.

Gaining FDA approval usually takes several years to attain. Testing done on animals must be extensive and must include several species to help in the evaluation of both the effectiveness and toxicity of the drug. The dosage of any drug approved for use is intended to fall within a range in which the drug produces a theraputic effect or desired outcome.[1]

The safety and effectiveness of prescription drugs in the U.S. is regulated by the federal Prescription Drug Marketing Act of 1987.

Scientific background

The study of chemicals requires intimate knowledge of the biological system affected. With the knowledge of cell biology and biochemistry increasing, the field of pharmacology has also changed substantially. It has become possible, through molecular analysis of receptors, to design chemicals that act on specific cellular signalling or metabolic pathways by affecting sites directly on cell-surface receptors (which modulate and mediate cellular signalling pathways controlling cellular function).

A chemical has, from the pharmacological point-of-view, various properties. Pharmacokinetics describes the effect of the body on the chemical (e.g. half-life and volume of distribution), and pharmacodynamics describes the chemical's effect on the body (desired or toxic).

When describing the pharmacokinetic properties of a chemical, pharmacologists are often interested in ADME:

- Absorption - How is the medication absorbed (through the skin, the intestine, the oral mucosa)?
- Distribution - How does it spread through the organism?
- Metabolism - Is the medication converted chemically inside the body, and into which substances. Are these active? Could they be toxic?
- Excretion - How is the medication eliminated (through the bile, urine, breath, skin)?

Medication is said to have a narrow or wide therapeutic index or therapeutic window. This describes the ratio of desired effect to toxic effect. A compound with a narrow therapeutic index (close to one) exerts its desired effect at a dose close to its toxic dose. A compound with a wide therapeutic index (greater than five) exerts its desired effect at a dose substantially below its toxic dose. Those with a narrow margin are more difficult to dose and administer, and may require therapeutic drug monitoring (examples are warfarin, some antiepileptics, aminoglycoside antibiotics). Most anti-cancer drugs have a narrow therapeutic margin: toxic side-effects are almost always encountered at doses used to kill tumours.

Drugs used as medicines

Main article: Medication

A *medication* is a licensed drug (chemical) taken to cure or reduce symptoms of an illness or medical condition. Medications are generally divided into two groups -- over-the-counter (OTC) medications, which are available without special restrictions, and Prescription only medicines (POM), which must be prescribed by a physician. Most OTC medication is generally considered to be safe enough that most persons will not hurt themselves accidentally by taking it as instructed. Many countries, such as the UK have a third category of pharmacy medicines which can only be sold in registered pharmacies, by or under the supervision of a pharmacist. However, the precise distinction between OTC and prescription depends on the legal jurisdiction. Medications are typically produced by pharmaceutical companies and are often patented. Those that are not patented are called generic drugs.

Education

The study of pharmacology is typically offered as an advanced degree program.

In the United States, a few institutions have it available as an undergraduate major or concentration that enables graduates to be entry-level lab technicians in the field of drug design and discovery. The following universities offer the undergraduate major:

- Brody School of Medicine at East Carolina University - ECU Pharmacology Department

Duke University - Chemistry degree with Pharmacology concentration
Massachusetts College of Pharmacy and Health Sciences - School of Pharmacy
Purdue University - Bachelor of Science in Pharmaceutical Sciences
University at Buffalo, The State University of New York - Pharmaceutical Sciences Program
State University of New York at Stony Brook - Pharmacological Sciences
University of California, Santa Barbara - Pharmacology major
University of Michigan - B.S. in Pharmaceutical Sciences
University of the Sciences in Philadelphia - Pharmacology and Toxicology Program
University of Wisconsin-Madison - Pharmacology/Toxicology program (PDF)
University of Toledo - B.S. in Pharmaceutical Sciences

Also there is one high school in the United States that offers the Pharmacology course:

- Central High School (Philadelphia) -Pharmacology

Anatomical Therapeutic Chemical Classification System

The *Anatomical Therapeutic Chemical Classification System* is used for the classification of drugs. It is controlled by the WHO Collaborating Centre for Drug Statistics Methodology, and was first published in 1976.

Drugs are divided into different groups according to the organ or system on which they act and/or their therapeutic and chemical characteristics.

Classification

In the system drugs are classified into groups at 5 different levels:

First level

The first level of the code is based on a letter for the anatomical group and consists of one letter; there are 14 main groups:

A Alimentary tract and metabolism

B Blood and blood forming organs

C Cardiovascular system

D Dermatologicals

G Genito-urinary system and sex hormones

H Systemic hormonal preparations, excluding sex hormones and insulins

J Anti-infectives for systemic use

L Antineoplastic and immunomodulating agents

M Musculo-skeletal system

N Nervous system

P Antiparasitic products, insecticides and repellents

Q Veterinary drug

R Respiratory system

S Sensory organs

V Various

Second level

The second level of the code is based on the therapeutic main group and consists of two digits.

Third level

The third level of the code is based on the therapeutic/pharmacological subgroup and consists of one letter.

Fourth level

The fourth level of the code is based on the chemical/therapeutic/pharmacological subgroup and consists of one letter.

Fifth level

The fifth level of the code is based on the chemical substance subgroup and consists of two digits.

Further notes

The actual drug name used is the International Nonproprietary Name (INN) when available.

The ATC/DDD system is the ATC system with the addition of a measure of the assumed average maintenance dose per day for a drug used for its main indication in adults (Defined Daily Doses).

Other ATC classifications are ATCvet (for veterinary medicinal products) and ATC herbal classification (for herbal remedies).

The ATC classification system was based on the Anatomical Classification (AC-system) developed by the European Pharmaceutical Market Research Association (EPhMRA) and the Pharmaceutical Business Intelligence and Research Group (PBIRG).

Biotechnology

Biotechnology is technology based on biology, especially when used in agriculture, food science, and medicine. The UN Convention on Biological Diversity has come up with one of many definitions of biotechnology:[1]

"Biotechnology means any technological application that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use."

This definition is at odds with common usage in the United States, where "biotechnology" generally refers to recombinant DNA based and/or tissue culture based processes that have only been commercialized since the 1970s. Thus, in common usage, modifying plants or animals by breeding, which has been practiced for thousands of years, would not be considered biotechnology. This distinction emphasizes that modern, recombinant DNA based biotechnology is not just a more powerful version of existing technology, but represents something new and different; for instance, theoretically, recombinant DNA biotechnology allows us to take virtually any gene and express it in any organism; we can take the genes that make crimson color in plants and put them into guinea pigs to make pink pets, or, we can take the genes that help arctic fish survive the freezing temperatures and put

them into food to increase the amount of time it can grow before it freezes. This sort of gene transfer was virtually impossible with historical processes.

There has been a great deal of talk - and money - poured into biotechnology with the hope that miracle drugs will appear. While there do seem to be a small number of efficacious drugs, in general the Biotech revolution has not happened in the pharmaceutical sector. However, recent progress with monoclonal antibody based drugs, such as Genentech's Avastin (tm) suggest that biotech may finally have found a role in pharmaceutical sales.

Biotechnology can also be defined as the manipulation of organisms to do practical things and to provide useful products.

One aspect of biotechnology is the directed use of organisms for the manufacture of organic products (examples include beer and milk products). For another example, naturally present bacteria are utilized by the mining industry in bioleaching. Biotechnology is also used to recycle, treat waste, clean up sites contaminated by industrial activities (bioremediation), and produce biological weapons.

There are also applications of biotechnology that do not use living organisms. Examples are DNA microarrays used in genetics and radioactive tracers used in medicine.

Red biotechnology is applied to medical processes. Some examples are the designing of organisms to produce antibiotics, and the engineering of genetic cures through genomic manipulation.

White biotechnology, also known as *grey biotechnology*, is biotechnology applied to industrial processes. An example is the designing of an organism to produce a useful chemical. White biotechnology tends to consume less in resources than traditional processes used to produce industrial goods.

Green biotechnology is biotechnology applied to agricultural processes. An example is the designing of transgenic plants to grow under specific environmental conditions or in the presence (or absence) of certain agricultural chemicals. One hope is that green biotechnology might produce more environmentally friendly solutions than traditional industrial agriculture. An example of this is the engineering of a plant to express a pesticide, thereby eliminating the need for external application of pesticides. An example of this would be Bt corn. Whether or not green biotechnology products such as this are ultimately more environmentally friendly is a topic of considerable debate.

Bioinformatics is an interdisciplinary field which addresses biological problems using computational techniques. The field is also often referred to as computational biology. It plays a key role in various areas, such as functional genomics, structural genomics, and proteomics, and forms a key component in the biotechnology and pharmaceutical sector.

The term *blue biotechnology* has also been used to describe the marine and aquatic applications of biotechnology, but its use is relatively rare.

Biotechnology medical products

Traditional pharmaceutical drugs are small chemicals molecules that treat the symptoms of a disease or illness - one molecule directed at a single target. Biopharmaceuticals are large biological molecules known as proteins and these target the underlying mechanisms and pathways of a malady; it is a relatively young industry. They can deal with targets in humans

that are not accessible with traditional medicines. A patient typically is dosed with a small molecule via a tablet while a large molecule is typically injected.

Small molecules are manufactured by chemistry but large molecules are created by living cells: for example, - bacteria cells, yeast cell,animal cells.

Modern biotechnology is often associated with the use of genetically altered microorganisms such as E. coli or yeast for the production of substances like insulin or antibiotics. It can also refer to transgenic animals or transgenic plants, such as Bt corn. Genetically altered mammalian cells, such as Chinese Hamster Ovary (CHO) cells, are also widely used to manufacture pharmaceuticals. Another promising new biotechnology application is the development of plant-made pharmaceuticals.

Biotechnology is also commonly associated with landmark breakthroughs in new medical therapies to treat diabetes, hepatitis B, Hepatitis C, Cancers, Arthritis, Haemophilia Bone Fractures,Multiple Sclerosis, Cardiovascular as well as molecular diagnostic devices than can be used to define the patient population. Herceptin, is the first drug approved for use with a matching diagnostic test and is used to treat breast cancer in women whose cancer cells express the protein HER2.

History

Early cultures also understood the importance of using natural processes to breakdown waste products into inert forms. From very early nomadic tribes to pre-urban civilizations it was common knowledge that given enough time organic waste products would be absorbed and eventually integrated into the soil. It was not until the advent of modern microbiology and chemistry that this process was fully understood and attributed to bacteria.

The most practical use of biotechnology, which is still present today, is the cultivations of plants to produce food suitable to humans. Agriculture has been theorized to have become the dominant way of producing food since the Neolithic Revolution. The processes and methods of agriculture have been refined by other mechanical and biological sciences since its inception. Through early biotechnology farmers were able to select the best suited and high-yield crops to produce enough food to support a growing population. Other uses of biotechnology were required as crops and fields became increasingly large and difficult to maintain. Specific organisms and organism byproducts were used to fertilize, restore nitrogen, and control pests. Throughout the use of agriculture farmers have inadvertently altered the genetics of their crops through introducing them to new environments, breeding them with other plants, and by using artificial selection. In modern times some plants are genetically modified to produce specific nutritional values or to be economical.

The process of Ethanol fermentation was also one of the first forms of biotechnology. Cultures such as those in Mesopotamia, Egypt, and Iran developed the process of brewing which consisted of combining malted grains with specifics yeasts to produce alcoholic beverages. In this process the carbohydrates in the grains were broken down into alcohols such as ethanol. Later other cultures produced the process of Lactic acid fermentation which allowed the fermentation and preservation of other forms of food. Fermentation was also used in this time period to produce leavened bread. Although the process of fermentation was not fully understood until Louis Pasteur’s work in 1857, it is still the first use of biotechnology to convert a food source into another form.

Combinations of plants and other organisms were used as medications in many early civilizations. Since as early as 200 BC people began to use disabled or minute amounts of infectious agents to immunize themselves against infections. These and similar processes have been refined in modern medicine and have lead to many developments such as antibiotics, vaccines, and other methods of fighting sickness.

A more recent field in biotechnology is that of genetic engineering. Genetic modification has opened up many new fields of biotechnology and allowed the modification of plants, animals, and even humans on a molecular level.

Global biotechnology trends

According to Burrill and Company, an industry investment bank, over $350 billion has been invested in biotech so far, and global revenues have risen from $23 billion in 2000 to to more than $50 billion in 2005. The greatest growth has been in Latin America but all regions of the world have shown strong growth trends.

There has been little innovation in the traditional pharmaceutical industry over the past decade and biopharmaceuticals are now achieving the fastest rates of growth against this background, particularly in breast cancer treatment. Biopharmaceuticals typically treat sub-sets of the total population with a disease whereas traditional drugs are developed to treat the population as a whole. However, one of the great difficulties with traditional drugs are the toxic side effects the incidence of which can be unpredictable in individual patients.

Biotechnology firms

There are around 4,000 biotechnology firms across the globe. Almost 50% of these are in the European Union; 30% in the US and the balance in Asia. The leading biotechnology firms are Amgen, Genentech and Serono.

Key visionaries and personalities in biotechnology sector

- Finland : Leena Palotie
Iceland : Kari Stefansson
Ireland : Timothy O'Brien, Dermot P Kelleher, Pearse Lyons
USA : Kate Jacques, David Botstein, Craig Venter, Sydney Brenner, Eric Lander, Leroy Hood, Robert Langer, Henry I. Miller, Roger Beachy, William Rutter, George Rathmann, Herbert Boyer, Michael West, Thomas Okarma
Europe : Paul D Kemp

Bioinformatics

Bioinformatics and *computational biology* involve the use of techniques including applied mathematics, informatics, statistics, computer science, artificial intelligence, chemistry and biochemistry to solve biological problems usually on the molecular level. Research in computational biology often overlaps with systems biology. Major research efforts in the field include sequence alignment, gene finding, genome assembly, protein structure alignment, protein structure prediction, prediction of gene expression and protein-protein interactions, and the modeling of evolution.

The terms bioinformatics and computational biology are often used interchangeably. However bioinformatics more properly refers to the creation and advancement of algorithms, computational and statistical techniques, and theory to solve formal and practical problems posed by or inspired from the management and analysis of biological data. Computational biology, on the other hand, refers to hypothesis-driven investigation of a specific biological problem using computers, carried out with experimental and simulated data, with the primary goal of discovery and the advancement of biological knowledge. A similar distinction is made by National Institutes of Health in their working definitions of Bioinformatics and Computational Biology, where it is further emphasized that there is a tight coupling of developments and knowledge between the more hypothesis-driven research in computational biology and technique-driven research in bioinformatics. Computational biology also includes lesser known but equally important subdisciplines such as computational biochemistry and computational biophysics.

A common thread in projects in bioinformatics and computational biology is the use of mathematical tools to extract useful information from data produced by high-throughput biological techniques such as genome sequencing. A representative problem in bioinformatics is the assembly of high-quality genome sequences from fragmentary "shotgun" DNA sequencing. Other common problems include the study of gene regulation using data from microarrays or mass spectrometry.

Major Research Areas

Sequence analysis

Since the Phage ¦-X174 was sequenced in 1977, the DNA sequences of hundreds of organisms have been decoded and stored in databases. These data are analyzed to determine genes that code for proteins, as well as regulatory sequences. A comparison of genes within a species or between different species can show similarities between protein functions, or relations between species (the use of molecular systematics to construct phylogenetic trees).

With the growing amount of data, it long ago became impractical to analyze DNA sequences manually. Today, computer programs are used to search the genome of thousands of organisms, containing billions of nucleotides. These programs can compensate for mutations (exchanged, deleted or inserted bases) in the DNA sequence, in order to identify sequences that are related, but not identical. A variant of this sequence alignment is used in the sequencing process itself. The so-called shotgun sequencing technique (which was used, for example, by The Institute for Genomic Research to sequence the first bacterial genome, Haemophilus influenza) does not give a sequential list of nucleotides, but instead the sequences of thousands of small DNA fragments (each about 600-800 nucleotides long). The ends of these fragments overlap and, when aligned in the right way, make up the complete genome. Shotgun sequencing yields sequence data quickly, but the task of assembling the fragments can be quite complicated for larger genomes. In the case of the Human Genome Project, it took several months of CPU time (on a circa-2000 vintage DEC Alpha computer) to assemble the fragments. Shotgun sequencing is the method of choice for virtually all genomes sequenced today, and genome assembly algorithms are a critical area of bioinformatics research.

Another aspect of bioinformatics in sequence analysis is the automatic search for genes and regulatory sequences within a genome. Not all of the nucleotides within a genome are genes. Within the genome of higher organisms, large parts of the DNA do not serve any obvious purpose. This so-called junk DNA may, however, contain unrecognized functional elements. Bioinformatics helps to bridge the gap between genome and proteome projects--for example, in the use of DNA sequences for protein identification.

Genome annotation

In the context of genomics, *annotation* is the process of marking the genes and other biological features in a DNA sequence. The first genome annotation software system was designed in 1995 by Owen White, who was part of the team that sequenced and analyzed the first genome of a free-living organism to be decoded, the bacterium Haemophilus influenzae. Dr. White built a software system to find the genes (places in the DNA sequence that encode a protein), the transfer RNA, and other features, and to make initial assignments of function to those genes. Most current genome annotation systems work similarly, but the programs available for analysis of genomic DNA are constantly changing and improving.

Computational evolutionary biology

Evolutionary biology is the study of the origin and descent of species, as well as their change over time. Informatics has assisted evolutionary biologists in several key ways; it has enabled researchers to:

- trace the evolution of a large number of organisms by measuring changes in their DNA, rather than through physical taxonomy or physiological observations alone,

- more recently, compare entire genomes, which permits the study of more complex evolutionary events, such as gene duplication, lateral gene transfer, and the prediction of bacterial speciation factors,
- build complex computational models of populations to predict the outcome of the system over time
- track and share information on an increasingly large number of species and organisms

Future work endeavours to reconstruct the now more complex tree of life.

The area of research within computer science that uses genetic algorithms is sometimes confused with computational evolutionary biology, but the two areas are unrelated.

Measuring biodiversity

Biodiversity of an ecosystem might be defined as the total genomic complement of a particular environment, from all of the species present, whether it is a biofilm in an abandoned mine, a drop of sea water, a scoop of soil, or the entire biosphere of the planet Earth. Databases are used to collect the species names, descriptions, distributions, genetic information, status and size of populations, habitat needs, and how each organism interacts with other species. Specialized software programs are used to find, visualize, and analyze the information, and most importantly, communicate it to other people. Computer simulations model such things as population dynamics, or calculate the cumulative genetic health of a breeding pool (in agriculture) or endangered population (in conservation). One very exciting potential of this field is that entire DNA sequences, or genomes of endangered species can be preserved, allowing the results of Nature's genetic experiment to be remembered in silico, and possibly reused in the future, even if that species is eventually lost.

Analysis of gene expression

The expression of many genes can be determined by measuring mRNA levels with multiple techniques including microarrays, expressed cDNA sequence tag (EST) sequencing, serial analysis of gene expression (SAGE) tag sequencing, massively parallel signature sequencing (MPSS), or various applications of multiplexed in-situ hybridization. All of these techniques are extremely noise-prone and/or subject to bias in the biological measurement, and a major research area in computational biology involves developing statistical tools to separate signal from noise in high-throughput gene expression studies. Such studies are often used to determine the genes implicated in a disorder: one might compare microarray data from cancerous epithelial cells to data from non-cancerous cells to determine the transcripts that are up-regulated and down-regulated in a particular population of cancer cells.

Analysis of regulation

Regulation is the complex orchestration of events starting with an extra-cellular signal and ultimately leading to an increase or decrease in the activity of one or more protein

molecules. Bioinformatics techniques have been applied to explore various steps in this process. For example, promoter analysis involves the elucidation and study of sequence motifs in the genomic region surrounding the coding region of a gene. These motifs influence the extent to which that region is transcribed into mRNA. Expression data can be used to infer gene regulation: one might compare microarray data from a wide variety of states of an organism to form hypotheses about the genes involved in each state. In a single-cell organism, one might compare stages of the cell cycle, along with various stress conditions (heat shock, starvation, etc.). One can then apply clustering algorithms to that expression data to determine which genes are co-expressed. For example, the upstream regions (promoters) of co-expressed genes can be searched for over-represented regulatory elements.

Analysis of protein expression

Protein microarrays and high throughput (HT) mass spectrometry (MS) can provide a snapshot of the proteins present in a biological sample. Bioinformatics is very much involved in making sense of protein microarray and HT MS data; the former approach faces similar problems as with microarrays targeted at mRNA, the latter involves the problem of matching large amounts of mass data against predicted masses from protein sequence databases, and the complicated statistical analysis of samples where multiple, but incomplete peptides from each protein are detected.

Analysis of mutations in cancer

Massive sequencing efforts are currently underway to identify point mutations in a variety of genes in cancer. The sheer volume of data produced requires automated systems to read sequence data, and to compare the sequencing results to the known sequence of the human genome, including known germline polymorphisms.

Oligonucleotide microarrays, including comparative genomic hybridization and single nucleotide polymorphism arrays, able to probe simultaneously up to several hundred thousand sites throughout the genome are being used to identify chromosomal gains and losses in cancer. Hidden Markov model and change-point analysis methods are being developed to infer real copy number changes from often noisy data. Further informatics approaches are being developed to understand the implications of lesions found to be recurrent across many tumors.

Some modern tools (e.g. Quantum 3.1) provide tool for changing the protein sequence at specific sites through alterations to its amino acids and predict changes in the bioactivity after mutations.

Prediction of protein structure

Protein structure prediction is another important application of bioinformatics. The amino acid sequence of a protein, the so-called primary structure, can be easily determined from the sequence on the gene that codes for it. In the vast majority of cases, this primary

structure uniquely determines a structure in its native environment. (Of course, there are exceptions, such as the bovine spongiform encephalopathy - aka Mad Cow Disease - prion.) Knowledge of this structure is vital in understanding the function of the protein. For lack of better terms, structural information is usually classified as one of secondary, tertiary and quaternary structure. A viable general solution to such predictions remains an open problem. As of now, most efforts have been directed towards heuristics that work most of the time.

One of the key ideas in bioinformatics is the notion of homology. In the genomic branch of bioinformatics, homology is used to predict the function of a gene: if the sequence of gene A, whose function is known, is homologous to the sequence of gene B, whose function is unknown, one could infer that B may share A's function. In the structural branch of bioinformatics, homology is used to determine which parts of a protein are important in structure formation and interaction with other proteins. In a technique called homology modelling, this information is used to predict the structure of a protein once the structure of a homologous protein is known. This currently remains the only way to predict protein structures reliably.

One example of this is the similar protein homology between haemoglobin in humans and the haemoglobin in legumes (leghemoglobin). Both serve the same purpose of transporting oxygen in the organism. Though both of these proteins have completely different amino acid sequences, their protein structures are virtually identical, which reflects their near identical purposes.

Other techniques for predicting protein structure include protein threading and de novo (from scratch) physics-based modeling.

Comparative genomics

The core of comparative genome analysis is the establishment of the correspondence between genes (orthology analysis) or other genomic features in different organisms. It is these intergenomic maps that make it possible to trace the evolutionary processes responsible for the divergence of two genomes. A multitude of evolutionary events acting at various organizational levels shape genome evolution. At the lowest level, point mutations affect individual nucleotides. At a higher level, large chromosomal segments undergo duplication, lateral transfer, inversion, transposition, deletion and insertion. Ultimately, whole genomes are involved in processes of hybridization, polyploidization and endosymbiosis, often leading to rapid speciation. The complexity of genome evolution poses many exciting challenges to developers of mathematical models and algorithms, who have recourse to a spectra of algorithmic, statistical and mathematical techniques, ranging from exact, heuristics, fixed parameter and approximation algorithms for problems based on parsimony models to Markov Chain Monte Carlo algorithms for Bayesian analysis of problems based on probabilistic models.

Many of these studies are based on the homology detection and protein families computation.

Modeling biological systems

Systems biology involves the use of computer simulations of cellular subsystems (such as the networks of metabolites and enzymes which comprise metabolism, signal transduction pathways and gene regulatory networks) to both analyze and visualize the complex connections of these cellular processes. Artificial life or virtual evolution attempts to understand evolutionary processes via the computer simulation of simple (artificial) life forms.

High-throughput image analysis

Computational technologies are used to accelerate or fully automate the processing, quantification and analysis of large amounts of high-information-content biomedical imagery. Modern image analysis systems augment an observer's ability to make measurements from a large or complex set of images, by improving accuracy, objectivity, or speed. A fully developed analysis system may completely replace the observer. Although these systems are not unique to biomedical imagery, biomedical imaging is becoming more important for both diagnostics and research. Some examples are:

- high-throughput and high-fidelity quantification and sub-cellular localization (high-content screening, cytohistopathology)
- morphometrics
- clinical image analysis and visualization
- determining the real-time air-flow patterns in breathing lungs of living animals
- quantifying occlusion size in real-time imagery from the development of and recovery during arterial injury
- making behavioural observations from extended video recordings of laboratory animals
- infrared measurements for metabolic activity determination

Software tools

First generation bioinformatics tools consisted of applications, usually with a text-based interface, which performed a specific task well. The computational biology tool best-known among biologists is probably BLAST, an algorithm for searching large databases of protein or DNA sequences. The NCBI provides a popular web-based implementation that searches their massive sequence databases. Also fairly early on, due to the amassing of sequence and annotation data, keyword search engines which were able to resolve gene and protein synonyms were important. In these early days, computer scripting languages such as Perl and Python were often used to interface with biological databases and parse output from bioinformatics programs written in languages such as C or C++, and much legacy code is still in use today. Today, many other languages are used to author excellent software, and communities of bioinformatics programmers have set up free open source bioinformatics projects to develop and distribute the tools and modules they produce.

As the data sources expanded and diversified, both in content and geography, bioinformatic meta search engines, such as Sequence profiling tools, emerged to help find relevant information from several databases. These meta search engines might index data from a local server or even from a panel of third party services.

More recently, SOAP-based interfaces have been developed for a wide variety of bioinformatics applications allowing an application running on one computer in one part of the world to use algorithms, data and computing resources on servers in other parts of the world. A large availability of these SOAP-based bioinformatics web services, along with the open source bioinformatics collections, lead to the next generation of bioinformatics tools: the integrated bioinformatics platform. These tools range from a collection of standalone tools with a common data format under a single, slick standalone or web-based interface, to integrative and extensible bioinformatics workflow development environments.

An interesting novel direction for bioinformatics applications is illustrated by Q-Pharm's Quantum 3.1, an example of the bioinformatics post-QSAR technology applying quantum and molecular physics instead of statistical methods.

Genetic algorithms

A *genetic algorithm* is a search technique used in computing to find true or approximate solutions to optimization and search problems, and is often abbreviated as GA. Genetic algorithms are categorized as global search heuristics. Genetic algorithms are a particular class of evolutionary algorithms that use techniques inspired by evolutionary biology such as inheritance, mutation, selection, and crossover (also called recombination).

Genetic algorithms are implemented as a computer simulation in which a population of abstract representations (called chromosomes or the genotype or the genome) of candidate solutions (called individuals, creatures, or phenotypes) to an optimization problem evolves toward better solutions. Traditionally, solutions are represented in binary as strings of 0s and 1s, but other encodings are also possible. The evolution usually starts from a population of randomly generated individuals and happens in generations. In each generation, the fitness of every individual in the population is evaluated, multiple individuals are stochastically selected from the current population (based on their fitness), and modified (recombined and possibly mutated) to form a new population. The new population is then used in the next iteration of the algorithm.

Genetic algorithms find application in computer science, engineering, economics,chemistry, physics, mathematics and other fields.

GA procedure

A typical genetic algorithm requires two things to be defined:

1. a genetic representation of the solution domain,
2. a fitness function to evaluate the solution domain.

A standard representation of the solution is as an array of bits. Arrays of other types and structures can be used in essentially the same way. The main property that makes these genetic representations convenient is that their parts are easily aligned due to their fixed size, that facilitates simple crossover operation. Variable length representations were also used, but crossover implementation is more complex in this case. Tree-like representations are explored in Genetic programming and free-form representations are explored in HBGA.

The fitness function is defined over the genetic representation and measures the quality of the represented solution. The fitness function is always problem dependent. For instance, in the knapsack problem we want to maximize the total value of objects that we can put in a knapsack of some fixed capacity. A representation of a solution might be an array of bits, where each bit represents a different object, and the value of the bit (0 or 1) represents whether or not the object is in the knapsack. Not every such representation is valid, as the size of objects may exceed the capacity of the knapsack. The fitness of the solution is the sum of values of all objects in the knapsack if the representation is valid, or 0 otherwise. In some problems, it is hard or even impossible to define the fitness expression; in these cases, interactive genetic algorithms are used.

Once we have the genetic representation and the fitness function defined, GA proceeds to initialize a population of solutions randomly, then improve it through repetitive application of mutation, crossover, and selection operators.

Initialization

Initially many individual solutions are randomly generated to form an initial population. The population size depends on the nature of the problem, but typically contains several hundreds or thousands of possible solutions. Traditionally, the population is generated randomly, covering the entire range of possible solutions (the search space). Occasionally, the solutions may be "seeded" in areas where optimal solutions are likely to be found.

Selection

During each successive epoch, a proportion of the existing population is selected to breed a new generation. Individual solutions are selected through a fitness-based process, where fitter solutions (as measured by a fitness function) are typically more likely to be selected. Certain selection methods rate the fitness of each solution and preferentially select the best solutions. Other methods rate only a random sample of the population, as this process may be very time-consuming.

Most functions are stochastic and designed so that a small proportion of less fit solutions are selected. This helps keep the diversity of the population large, preventing premature convergence on poor solutions. Popular and well-studied selection methods include roulette wheel selection and tournament selection.

Reproduction

The next step is to generate a second generation population of solutions from those selected through genetic operators: crossover (also called recombination), and/or mutation.

For each new solution to be produced, a pair of "parent" solutions is selected for breeding from the pool selected previously. By producing a "child" solution using the above methods of crossover and mutation, a new solution is created which typically shares many of the characteristics of its "parents". New parents are selected for each child, and the process continues until a new population of solutions of appropriate size is generated.

These processes ultimately result in the next generation population of chromosomes that is different from the initial generation. Generally the average fitness will have increased by this procedure for the population, since only the best organisms from the first generation are selected for breeding, along with a small proportion of less fit solutions, for reasons already mentioned above.

Termination

This generational process is repeated until a termination condition has been reached. Common terminating conditions are

- A solution is found that satisfies minimum criteria
- Fixed number of generations reached
- Allocated budget (computation time/money) reached
- The highest ranking solution's fitness is reaching or has reached a plateau such that successive iterations no longer produce better results
- Manual inspection
- Combinations of the above

Pseudo-code algorithm

Choose initial population Evaluate the fitnesses of individuals in the population Repeat Select best-ranking individuals to reproduce Breed new generation through crossover and mutation (genetic operations) and give birth to offspring Evaluate the individual fitnesses of the offspring Replace worst ranked part of population with offspring Until terminating condition

Observations

There are several general observations about the generation of solutions via a genetic algorithm:

- In many problems with sufficient complexity, GAs may have a tendency to converge towards local optima rather than the global optimum of the problem. The likelihood of this occurring depends on the shape of the fitness landscape: certain problems may provide an easy ascent towards a global optimum, others may make it easier for the function to find the local optima. This problem may be alleviated by using a different fitness function, increasing the rate of mutation, or by using selection techniques that maintain a diverse population of solutions.
- Operating on dynamic data sets is difficult, as genomes begin to converge early on towards solutions which may no longer be valid for later data. Several methods have been proposed to remedy this by increasing genetic diversity somehow and preventing early convergence, either by increasing the probability of mutation when the solution quality drops (called triggered hypermutation), or by occasionally introducing entirely new, randomly

generated elements into the gene pool (called random immigrants). Recent research has also shown the benefits of using biological exaptation (or preadaptation) in solving this problem.

- GAs cannot effectively solve problems in which the only fitness measure is right/wrong, as there is no way to converge on the solution. (No hill to climb). In these cases, a random search may find a solution as quickly as a GA.
- Selection is clearly an important genetic operator, but opinion is divided over the importance of crossover versus mutation. Some argue that crossover is the most important, while mutation is only necessary to ensure that potential solutions are not lost. Others argue that crossover in a largely uniform population only serves to propagate innovations originally found by mutation, and in a non-uniform population crossover is nearly always equivalent to a very large mutation (which is likely to be catastrophic).
- Often, GAs can rapidly locate good solutions, even for difficult search spaces.
- For specific optimization problems and problem instantiations, simpler optimization algorithms may find better solutions than genetic algorithms (given the same amount of computation time). Alternative and complementary algorithms include simulated annealing, hill climbing, and swarm intelligence (e.g.: ant colony optimization, particle swarm optimization).
- As with all current machine learning problems it is worth tuning the parameters such as mutation probability, recombination probability and population size to find reasonable settings for the problem class being worked on. A very small mutation rate may lead to genetic drift (which is non-ergodic in nature) or premature convergence of the genetic algorithm in a local optimum. A mutation rate that is too high may lead to loss of good solutions. There are theoretical but not yet practical upper and lower bounds for these parameters that can help guide selection.
- The implementation and evaluation of the fitness function is an important factor in the speed and efficiency of the algorithm.

Variants

The simplest algorithm represents each chromosome as a bit string. Typically, numeric parameters can be represented by integers, though it is possible to use floating point representations. The basic algorithm performs crossover and mutation at the bit level. Other variants treat the chromosome as a list of numbers which are indexes into an instruction table, nodes in a linked list, hashes, objects, or any other imaginable data structure. Crossover and mutation are performed so as to respect data element boundaries. For most data types, specific variation operators can be designed. Different chromosomal data types seem to work better or worse for different specific problem domains.

When bit strings representations of integers are used, Gray coding is often employed. In this way, small changes in the integer can be readily effected through mutations or crossovers. This has been found to help prevent premature convergence at so called

Hamming walls, in which too many simultaneous mutations (or crossover events) must occur in order to change the chromosome to a better solution.

Other approaches involve using arrays of real-valued numbers instead of bit strings to represent chromosomes. Theoretically, the smaller the alphabet, the better the performance, but paradoxically, good results have been obtained from using real-valued chromosomes.

A slight, but very successful variant of the general process of constructing a new population is to allow some of the better organisms from the current generation to carry over to the next, unaltered. This strategy is known as elitist selection.

Parallel implementations of genetic algorithms come in two flavours. Coarse grained parallel genetic algorithms assume a population on each of the computer nodes and migration of individuals among the nodes. Fine grained parallel genetic algorithms assume an individual on each processor node which acts with neighboring individuals for selection and reproduction. Other variants, like genetic algorithms for online optimization problems, introduce time-dependence or noise in the fitness function.

Problem domains

Problems which appear to be particularly appropriate for solution by genetic algorithms include timetabling and scheduling problems, and many scheduling software packages are based on GAs. GAs have also been applied to engineering. Genetic algorithms are often applied as an approach to solve global optimization problems.

As a general rule of thumb genetic algorithms might be useful in problem domains that have a complex fitness landscape as recombination is designed to move the population away from local optima that a traditional hill climbing algorithm might get stuck in.

History

Computer simulations of evolution started with Nils Aall Barricelli in 1954. Barricelli was simulating the evolution of automata that played a simple card game. Starting in 1957, the Australian quantitative geneticist Alex Fraser published a series of papers on simulation of artificial selection of organisms with multiple loci controlling a measurable trait. From these beginnings, computer simulation of evolution by biologists became more common in the early 1960s, and the methods were described in books by Fraser and Burnell (1970) and Crosby (1973). Many early papers are reprinted by Fogel (1998).

Although Barricelli had also used evolutionary simulation as a general optimization method, genetic algorithms became a widely recognized optimization method as a result of the work of John Holland in the early 1970s, and particularly his 1975 book. His work originated with studies of cellular automata, conducted by Holland and his colleagues at the University of Michigan. Research in GAs remained largely theoretical until the mid-1980s, when The First International Conference on Genetic Algorithms was held at The University of Illinois. As academic interest grew, the dramatic increase in desktop computational power allowed for practical application of the new technique. In 1989, The New York Times writer John Markoff wrote about Evolver, the first commercially available desktop genetic algorithm. Custom computer applications began to emerge in a wide variety of fields, and these algorithms are now used by a majority of Fortune 500 companies to solve difficult

scheduling, data fitting, trend spotting and budgeting problems, and virtually any other type of combinatorial optimization problem.

Related techniques

- Ant colony optimization (ACO) uses many ants (or agents) to traverse the solution space and find locally productive areas. While usually inferior to genetic algorithms and other forms of local search, it is able to produce results in problems where no global or up-to-date perspective can be obtained, and thus the other methods cannot be applied.
- Bacteriologic Algorithms (BA) inspired by evolutionary ecology and, more particularly, bacteriologic adaptation. Evolutionary ecology is the study of living organisms in the context of their environment, with the aim of discovering how they adapt. Its basic concept is that in a heterogeneous environment, you can't find one individual that fits the whole environment. So, you need to reason at the population level. BAs have shown better results than GAs on problems such as complex positioning problems (antennas for cell phones, urban planning, and so on) or data mining
- Cross-entropy method The Cross-entropy (CE) method generates candidates solutions via a parameterized probability distribution. The parameters are updated via cross-entropy minimization, so as to generate better samples in the next iteration.
- Evolution strategies (ES) evolve linear individuals by means of mutation. ES algorithms are designed particulary to solve problems in the real-value domain.
- Extremal optimization (EO) Unlike GAs, which work with a population of candidate solutions, EO evolves a single solution and makes local modifications to the worst components. This requires that a suitable representation be selected which permits individual solution components to be assigned a quality measure ("fitness"). The governing principle behind this algorithm is that of emergent improvement through selectively removing low-quality components and replacing them with a randomly selected component. This is decidedly at odds with a GA that selects good solutions in an attempt to make better solutions.
- Genetic programming (GP) is a related technique popularized by John Koza in which computer programs, rather than function parameters, are optimized. Genetic programming often uses tree-based internal data structures to represent the computer programs for adaptation instead of the list structures typical of genetic algorithms.
- Interactive genetic algorithms (IGA) are genetic algorithms that use human evaluation. They are usually applied to domains where it is hard to design a computational fitness function, for example, evolving images, music, artistic designs and forms to fit users' aesthetic preference.
- Memetic algorithm (MA), also called hybrid genetic algorithm among others, is a relatively new evolutionary method where local search is applied

during the evolutionary cycle. The idea of memetic algorithms comes from memes, which–unlike genes–can adapt themselves. In some problem areas they are shown to be more efficient than traditional evolutionary algorithms.

- Simulated annealing (SA) is a related global optimization technique that traverses the search space by testing random mutations on an individual solution. A mutation that increases fitness is always accepted. A mutation that lowers fitness is accepted probabilistically based on the difference in fitness and a decreasing temperature parameter. In SA parlance, one speaks of seeking the lowest energy instead of the maximum fitness. SA can also be used within a standard GA algorithm by starting with a relatively high rate of mutation and decreasing it over time along a given schedule.
- Stochastic optimization is an umbrella set of methods that includes GAs and numerous other approaches.
- Tabu search (TS) is similar to Simulated Annealing in that both traverse the solution space by testing mutations of an individual solution. While simulated annealing generates only one mutated solution, tabu search generates many mutated solutions and moves to the solution with the lowest energy of those generated. In order to prevent cycling and encourage greater movement through the solution space, a tabu list is maintained of partial or complete solutions. It is forbidden to move to a solution that contains elements of the tabu list, which is updated as the solution traverses the solution space.

Building block hypothesis

[Goldberg, 1989, page 41], talking of binary bit string genetic algorithms, says:

Short, low order, and highly fit schemata are sampled, recombined [crossed over], and resampled to form strings of potentially higher fitness. In a way, by working with these particular schemata [the building blocks], we have reduced the complexity of our problem; instead of building high-performance strings by trying every conceivable combination, we construct better and better strings from the best partial solutions of past samplings. Just as a child creates magnificent fortresses through the arrangement of simple blocks of wood [building blocks], so does a genetic algorithm seek near optimal performance through the juxtaposition of short, low-order, high-performance schemata, or building blocks.

Note [Goldberg, 1989] suggests that building blocks are highly fit schemata with only a few defined bits (low order), and that these are close together (short).

Applications

- Artificial Creativity

Automated design, including research on composite material design and multi-objective design of automotive components for crashworthiness, weight savings, and other characteristics.

Automated design of mechatronic systems using bond graphs and genetic

programming (NSF).
Automated design of industrial equipment using catalogs of exemplar lever patterns.
Calculation of Bound states and Local-density approximations.
Chemical kinetics (gas and solid phases)
Configuration applications, particularly physics applications of optimal molecule configurations for particular systems like C60 (buckyballs).
Container loading optimization.
Code-breaking, using the GA to search large solution spaces of ciphers for the one correct decryption.
Design of water distribution systems.
Distributed computer network topologies.
Electronic circuit design, known as Evolvable hardware.
File allocation for a distributed system.
JGAP: Java Genetic Algorithms Package, also includes support for Genetic Programming
Parallelization of GAs/GPs including use of hierarchical decomposition of problem domains and design spaces nesting of irregular shapes using feature matching and GAs.
Game Theory Equilibrium Resolution.
Learning Robot behavior using Genetic Algorithms.
Learning fuzzy rule base using genetic algorithms.
Linguistic analysis, including Grammar Induction and other aspects of Natural Language Processing (NLP) such as word sense disambiguation.
Mobile communications infrastructure optimization.
Molecular Structure Optimization (Chemistry).
Multiple population topologies and interchange methodologies.
Optimisation of data compression systems, for example using wavelets.
Protein folding and protein/ligand docking.
Plant floor layout.
Representing rational agents in economic models such as the cobweb model.
Scheduling applications, including job-shop scheduling. The objective being to schedule jobs in a sequence dependent or non-sequence dependent setup environment in order to maximize the volume of production while minimizing penalties such as tardiness.
Software engineering
Solving the machine-component grouping problem required for cellular manufacturing systems.
Tactical asset allocation and international equity strategies.
Timetabling problems, such as designing a non-conflicting class timetable for a large university.
Training artificial neural networks when pre-classified training examples are not readily obtainable (neuroevolution).
Traveling Salesman Problem.
Robot learning, obstacle avoidance.

Bioluminescence

Bioluminescence is the production and emission of light by a living organism as the result of a chemical reaction during which chemical energy is converted to light energy. The name originates from the Greek bios for "living" and the Latin lumen "light". Bioluminescence may be generated by symbiotic organisms carried within a larger organism. It is generated by an enzyme-catalyzed chemoluminescence reaction, wherein the pigment luciferin is oxidised by the enzyme luciferase. Adenosine triphosphate (ATP) is involved in most instances. The chemical reaction can occur either within or outside of the cell. In bacteria, the expression of genes related to bioluminescence is controlled by an operon called the lux operon.

Characteristics of the phenomenon

Bioluminescence is a form of luminescence, or "cold light" emission; less than 20% of the light generates thermal radiation. It should not be confused with fluorescence, phosphorescence or refraction of light.

Ninety percent of deep-sea marine life is estimated to produce bioluminescence in one form or another. Most marine light-emission belongs in the blue and green light spectrum, the wavelengths that can transmit through water most easily. However, certain loose jawed fish emit red and infrared light.

Non-marine bioluminescence is less widely distributed, but a larger variety in colours is seen. The two best-known forms of land bioluminescence are fireflies and New Zealand glow worms. Other insects, insect larvae, annelids, arachnids and even species of fungi have been noted to possess bioluminescent abilities.

Most forms of bioluminescence are lighter (or only exist) at night, following a circadian rhythm.

Adaptations for bioluminescence

There are four main accepted theories for the evolution of bioluminescent traits:

1. Camouflage
2. Attraction
3. Repulsion
4. Communication

Attraction

Bioluminescence is used as a lure to attract prey by several deep sea fish such as the anglerfish. A dangling appendage that extends from the head of the fish attracts small

animals to within striking distance of the fish. Some fish, however, utilize a non-bioluminescent lure.

The cookiecutter shark uses bioluminescence for camouflage, but a small patch on its underbelly remains dark and appears as a small fish to large predatory fish like tuna and mackerel. When these fish try to consume the "small fish", they are bitten by the shark.

Dinoflagellates have an interesting twist on this mechanism. When a predator of plankton is sensed through motion in the water, the dinoflagellate luminesces. This in turn attracts even larger predators which will consume the would-be predator of the dinoflagellate.

The attraction of mates is another proposed mechanism of bioluminescent action. This is seen actively in fireflies who utilize periodic flashing in their abdomens to attract mates in the mating season. In the marine environment this has only been well-documented in certain small crustacean called ostracod. It has been suggested that pheromones may be used for long-distance communication, and bioluminescent used at close range to "home in" on the target.

The honey mushroom attracts insects using bioluminescence, hoping the insects will help disseminate the fungus' spores into the environment.

Repulsion

Certain squid and small crustaceans utilize bioluminescent chemical mixtures, or bioluminescent bacterial slurries in the same way as many squid use ink. A cloud of luminescence is expulsed, confusing or repelling a potential predator while the squid or crustacean escapes to safety.

Communication

Bioluminescence is thought to play a direct role in communication between bacteria. It promotes the symbiotic induction of bacteria into host species, and may play a role in colony aggregation.

Biotechnology

Bioluminescent organisms are a target for many areas of research. Luciferase systems are widely used in the field of genetic engineering as reporter genes (see picture left). Luciferase systems have also been harnessed for biomedical research using bioluminescence imaging.

Vibrio symbiosis with numerous marine invertebrates and fish, namely the Hawaiian bobtail squid (Euprymna scolopes) is a key experimental model for symbiosis, quorum sensing, and bioluminescence.

The structure of photophores, the light producing organs in bioluminescent organisms, are being investigated by industrial designers.

Some proposed applications of engineered bioluminescence include:

- Christmas trees that don't need lights, reducing dangerous electronics
- glowing trees to line highways to save government electricity bills

- agricultural crops and domestic plants that luminesce when they need watering
- new methods for detecting bacterial contamination of meats and other foods
- bio-identifiers for escaped convicts and mental patients
- detecting bacterial species in suspicious corpses
- novelty pets that bioluminesce (rabbits, mice, fish etc.)

Organisms that bioluminesce

All cells produce some form of bioluminescence within the electromagnetic spectrum, but most is neither visible nor noticeable to the naked eye. Every organism's bioluminescence is unique in wavelength, duration, timing and regularity of flashes. Below follows a list of organisms which have been observed to have visible bioluminescence.

Non-marine organisms

- certain arthropods
  - fireflies
  - glow worms
    - railroad worms
  - certain mycetophilid flies

certain centipedes
certain millipedes

- annelids
- Mushrooms (see Foxfire)
  - Jack O'Lantern mushroom

Honey mushroom
Panellus stipticus
several species of Mycena

Fish

- cookie cutter shark

Marine hatchetfish
Anglerfish
Flashlight fish
Pineconefish
Porichthys
Beebe's monster
Gulper Eel

Marine invertebrates

- many cnidarians
  - Sea pens

coral

Aequorea victoria, a jellyfish

- Ctenophores or "comb jellies"

certain echinoderms

certain nudibranchs

certain clams

- certain crustaceans
  - ostracods

krill

- certain Octopuses
  - Bolitaenidae
- certain squid
  - the order Teuthida

Colossal Squid

Mastigoteuthidae

Sepiolidae

Firefly squid

Plankton and microbes

- Dinoflagellates

Vibrionaceae (e.g. Vibrio fischeri, Vibrio harveyi, Vibrio phosphoreum)

Biotechnology products

Antibiotics | Monoclonal antibodies | Recombinant proteins | Acetone

Recombinant proteins

Recombinant DNA (sometimes *rDNA*) is an artificial DNA sequence resulting from the combining of two other DNA sequences in a plasmid. A *recombinant protein* is a protein produced by an organism after the relevant DNA is inserted into its genome (that is, by a genetically modified organism). This recombines the DNA of two different organisms.

Recombinant DNA technique was discovered by Stanley Cohen and Herbert Boyer in 1973, Nov 1973 publication of “Construction of Biologically Functional Bacterial Plasmids in vitro”, this paper described a technique to isolate and amplify genes, or DNA segments, and insert them into another cell with precision. Recombinant DNA technology was made possible by the discovery of restriction endonucleases by Werner Arber, Daniel Nathans, and Hamilton Smith, for which they received the 1978 Nobel Prize in Medicine.

The term *recombinant DNA* refers to a new combination of DNA molecules that are not found together naturally. Although processes such as crossing over technically produce recombinant DNA, the term is generally reserved for DNA produced by joining molecules derived from different biological sources.

Contents

Uses

Recombinant DNA is used for genetic transformation to produce genetically modified organisms. Some examples of recombinant DNA products are peptide hormone medications including insulin, growth hormone, and oxytocin. Vaccines can also be produced using recombinant processes. The organism most commonly used is Escherichia coli.

Plasmids and recombinant DNA technology

Plasmids are extranuclear fragments of DNA present in some bacteria. A plasmid can transfer genetic material to another bacterium, allowing it to express the transmitted gene(s). Restriction enzymes which cut sequences of DNA at certain spots are used to splice into a plasmid the DNA sequence for the desired gene. The plasmid is then inserted into a bacterium in order to express the gene and produce the protein coded for by the gene. Large amounts of the protein can be produced in a factory with vats of the genetically engineered bacteria.

Most eukaryotes cannot use circular DNA such as that present in a plasmid. Yeasts are the only (known) exception. In the others, other systems, such as transfection with viruses, are used instead.

Green fluorescent protein

The *green fluorescent protein* (*GFP*) is a protein, comprised of 238 amino acids, from the jellyfish Aequorea victoria that fluoresces green when exposed to blue light. This process takes place when the protein aequorin, also produced by A. victoria, interacts with Ca^{2+} ions thus emitting a blue glow.

The wild-type GFP (wtGFP) from A. victoria has a major excitation peak at a wavelength of 395 nm and a minor one at 475 nm. Its emission peak is at 509 nm which is in the lower green portion of the visible spectrum. The GFP from the sea pansy (Renilla reniformis) has a single major excitation peak at 498 nm.

In cell and molecular biology, the GFP gene is frequently used as a reporter of expression. In modified forms it has been used to make biosensors, and many animals have been created

that express GFP as a proof-of-concept that a gene can be expressed throughout a given organism.

One of the most powerful uses of GFP is to express the protein in small sets of specific cells. This allows researchers to optically detect specific types of cells in vitro (in a dish), or even in vivo (in the living organism). The GFP gene can be introduced into organisms and maintained in their genome through breeding, or local injection with a viral vector can be used to introduce the gene.

Due to this widespread usage different mutants of GFP have been engineered over the last few years by the lab of Roger Tsien and others: some mutants have been produced with increased fluorescence and the protein major excitation peak has been shifted to 490 nm with the peak emission kept at 509 nm (EGFP). Color mutants have been obtained from the GFP gene as well: in particular the cyan fluorescent protein (CFP) and the yellow fluorescent protein (YFP) are two colour variants employed for fluorescence resonance energy transfer (FRET) experiments. Genetically-encoded FRET reporters sensitive to cell signaling molecules, such as calcium or glutamate, protein phosphorylation state, protein complementation, receptor dimerization and other processes provide highly specific optical readouts of cell activity in real time.

EGFP is an enhanced green fluorescent protein which is also a commonly used gene reporter.

It is also worth mentioning that the availability of GFP and its derivatives has thoroughly redefined fluorescence microscopy and the way it is used in cell biology and other biological disciplines. While most small fluorescent molecules such as FITC (fluorescein isothiocyanate) are strongly phototoxic when used in live cells, fluorescent proteins such as GFP are usually much less harmful when illuminated in living cells. This has triggered the development of highly automated live cell fluorescence microscopy systems which can be used to observe cells over time expressing one or more proteins tagged with fluorescent proteins. Analysis of such time lapse movies has redefined the understanding of many biological processes which in the past had been studied using fixed (i.e. dead) material.

To date, many bacteria, yeast and other fungal cells, plant, fly, and mammalian cells have been created using GFP as a marker. Research scientists, from National Taiwan University's Department of Animal Science and Technology also reported the production of three fluorescent pigs in early 2006.

Notes

- Alba, a fluorescent bunny, was created by Eduardo Kac using GFP for purposes of art and social commentary

Growth hormone

Growth hormone (*GH* or *somatotropin*) is a polypeptide hormone synthesised and secreted by the anterior pituitary gland which stimulates growth and cell reproduction in humans and other vertebrate animals.

This article describes human growth hormone physiology, with brief mentions of the diseases of GH deficiency, GH excess (acromegaly and pituitary gigantism), as well as GH treatment, and HGH quackery. Each of these topics is treated more fully in separate articles.

Terminology

Growth hormone (GH) is also called somatropin and somatotropin (British: somatotrophin). hGH refers to human growth hormone and is an abbreviation for human GH measured in the extracts from human pituitary glands. In 1985, biosynthetic human growth hormone replaced pituitary-derived human growth hormone for therapeutic use in the U.S. and elsewhere. Biosynthetic human growth hormone, also referred to as recombinant human growth hormone, is also called somatropin and abbreviated as rhGH. Since the mid-1990s the abbreviation HGH has begun to carry paradoxical connotations, and now rarely refers to real GH used for indicated purposes. See articles on GH treatment and hGH quackery for fuller discussions of GH therapy and the HGH issue.

Structure and gene of the human GH molecule

The genes for human growth hormone are localized in the q22-24 region of chromosome 17 and are closely related to human chorionic somatomammotropin (hCS, also known as placental lactogen) genes. GH, human chorionic somatomammotropin (hCS), and prolactin (PRL) are a group of homologous hormones with growth-promoting and lactogenic activity.

The major isoform of the human growth hormone is a protein of 191 amino acids and a molecular weight of about 22,000 daltons. The structure includes four helices necessary for functional interaction with the GH receptor. GH is structurally and apparently evolutionarily homologous to prolactin and chorionic somatomammotropin. Despite marked structural similarities between growth hormone from different species, only human and primate growth hormones have significant effects in humans.

Secretion of GH

GH is secreted into the blood by the somatotrope cells of the anterior pituitary gland, in larger amounts than any other pituitary hormone. Secretion levels are highest during puberty. The transcription factor PIT-1 stimulates both the development of these cells and their production of GH. Failure of development of these cells, as well as destruction of the anterior pituitary gland, results in GH deficiency.

Peptides released by neurosecretory nuclei of the hypothalamus into the portal venous blood surrounding the pituitary are the major controllers of GH secretion by the somatotropes. Growth hormone releasing hormone (GHRH) from the arcuate nucleus and ghrelin promote GH secretion, and somatostatin from the periventricular nucleus inhibits it. GH secretion is also affected by negative feedback from circulating concentrations of GH and IGF-1.

Although the balance of these stimulating and inhibiting peptides determines GH release, this balance is affected by many physiological stimulators and inhibitors of GH secretion. Stimulators of GH secretion include (among others) J B B , exercise, hypoglycemia, dietary

protein, and estradiol. Inhibitors of GH secretion include dietary carbohydrate and glucocorticoids. In addition to control by endogenous processes, a number of foreign compounds (xenobiotics) are now known to influence GH secretion, highlighting the fact that the GH-IGF axis is an emerging target for certain endocrine disrupting chemicals.

Most of the physiologically important GH secretion occurs as several large pulses or peaks of GH release each day. The plasma concentration of GH during these peaks may range from 5 to 30 ng/mL or more. Peaks typically last from 10 to 30 minutes before returning to basal levels. The largest and most predictable of these GH peaks occurs about an hour after onset of sleep. Otherwise there is wide variation between days and individuals. Between the peaks, basal GH levels are low, usually less than 3 ng/mL for most of the day and night.

The amount and pattern of GH secretion change throughout life. Basal levels are highest in early childhood. The amplitude and frequency of peaks is greatest during the pubertal growth spurt. Healthy children and adolescents average about 8 peaks per 24 hours. Adults average about 5 peaks. Basal levels and the frequency and amplitude of peaks decline throughout adult life.

Several molecular forms of GH circulate. Much of the growth hormone in the circulation is bound to a protein (growth hormone binding protein, GHBP) which is derived from the growth hormone receptor.

Functions of GH

Effects of growth hormone on the tissues of the body can generally be described as anabolic (building up). Like most other protein hormones GH acts by interacting with a specific receptor on the surface of cells.

Height growth in childhood is the best known effect of GH action, and appears to be stimulated by at least two mechanisms. 1. GH directly stimulates division and multiplication of chondrocytes of cartilage. These are the primary cells in the growing ends (epiphyses) of children's long bones (arms, legs, digits). 2. GH also stimulates production of insulin-like growth factor 1 (IGF1, formerly known as somatomedin C), a hormone homologous to proinsulin. The liver is a major target organ of GH for this process, and is the principal site of IGF-1 production. IGF-1 has growth-stimulating effects on a wide variety of tissues. Additional IGF-1 is generated within target tissues, making it apparently both an endocrine and an autocrine/paracrine hormone. IGF-1 will also have stimulatory effects on osteoblast and chondrocyte activity to promote bone growth.

Although height growth is the best known effect of GH, it serves many other metabolic functions as well. GH increases calcium retention, and strengthens and increases the mineralization of bone. It increases muscle mass through the creation of new muscle cells (which differs from hypertrophy), and it also promotes lipolysis, which results in the reduction of adipose tissue (body fat). As well, it increases protein synthesis and stimulates the growth of all internal organs excluding the brain. GH plays a role in fuel homeostasis. GH reduces liver uptake of glucose, an effect that opposes that of insulin. GH also contributes to the maintenance and function of pancreatic islets. GH stimulates the immune system.

Clinical problems: too much and too little

Growth hormone excess: (acromegaly and pituitary gigantism)

The most common disease of GH excess is a pituitary tumor comprised of somatotroph cells of the anterior pituitary. These somatotroph adenomas are benign and grow slowly, gradually producing more and more GH. For years, the principal clinical problems are those of GH excess. Eventually the adenoma may become large enough to cause headaches, impair vision by pressure on the optic nerves, or cause deficiency of other pituitary hormones by displacement.

Prolonged GH excess thickens the bones of the jaw, fingers and toes. Resulting heaviness of the jaw and increased thickness of digits is referred to as acromegaly. Accompanying problems can include pressure on nerves (e.g., carpal tunnel syndrome), muscle weakness, insulin resistance or even a rare form of type 2 diabetes, and reduced sexual function.

GH-secreting tumors are typically recognized in the 5th decade of life. It is extremely rare for such a tumor to occur in childhood, but when it does the excessive GH can cause excessive growth, traditionally referred to as pituitary gigantism.

Surgical removal is the usual treatment for GH-producing tumors. In some circumstances focused radiation or a GH antagonist such as bromocriptine or octreotide may be employed to shrink the tumor or block function.

Growth hormone deficiency (GHD)

Deficiency of GH produces significantly different problems at various ages. In children, growth failure and short stature are the major manifestations of GH deficiency. In adults the effects of deficiency are more subtle, and may include deficiencies of strength, energy, and bone mass, as well as increased cardiovascular risk.

There are many causes of GH deficiency, including mutations of specific genes, congenital malformations involving the hypothalamus and/or pituitary gland, and damage to the pituitary from injury, surgery or disease.

Diagnosis of GH deficiency involves a multiple step diagnostic process, usually culminating in GH stimulation test(s) to see if the patient's pituitary gland will release a pulse of GH when provoked by various stimuli.

GH deficiency is treated by replacing GH. All GH in current use is a biosynthetic version of human GH, manufactured by recombinant DNA technology. As GH is a large protein molecule, it must be injected into subcutaneous tissue (or muscle) to get it into the blood. When the patient has had a long-standing deficiency of GH, benefits of treatment are often dramatic and gratifying and side effects of treatment are rare. Increased growth in childhood can result in dramatically improved adult height.

GH is used as replacement therapy in adults with GH deficiency of either childhood-onset (after completing growth phase) or adult-onset (usually as a result of an acquired pituitary tumor). In these patients, benefits have variably included reduced fat mass, increased lean mass, increased bone density, improved lipid profile, reduced cardiovascular risk factors, and improved psychosocial well-being.

This topic is treated more fully in the articles growth hormone deficiency and growth hormone treatment.

Other GH uses and treatment indications

Many other conditions besides GH deficiency cause poor growth, but growth benefits (height gains) are often poorer than when GH deficiency is treated. Examples of other causes of shortness often treated with growth hormone are Turner syndrome, chronic renal failure, Prader-Willi syndrome, intrauterine growth retardation, and severe idiopathic short stature. Higher ("pharmacologic") doses are required to produce significant acceleration of growth in these conditions, producing blood levels well above physiologic. Despite the higher doses, side effects during treatment are rare, and vary little according to the condition being treated.

Sometimes GH is used for other benefits than height. GH treatment improves muscle strength and slightly reduce body fat in Prader-Willi syndrome, benefits more important to these children than increased height. It has also been shown to help maintain muscle mass in AIDS wasting. GH can also be used in patients with short bowel syndrome to lessen the requirement for intravenous parenteral nutrition.

Uses that are controversial include

- GH treatment to reverse effects of aging in older adults

GH treatment to enhance weight loss in obesity
GH treatment for fibromyalgia
GH treatment for Crohn's disease and ulcerative colitis
GH treatment for idiopathic short stature
GH treatment for bodybuilding or athletic enhancement

Risks and side effects of GH treatment

The possible risks and side effects of GH use are varied. They can occur even when used in "pharmacologic doses." They include:

- swelling of the hands and feet(edema)
- thickening of the bones/jaw
- carpal tunnel syndrome/Arthralgia
- tingling in the extremities
- numbness in the hands and feet
- increased organ growth
- decreased insulin reception
- acromegaly
- decreased thyroid output

History

The identification, purification and later synthesis of growth hormone is associated with Choh Hao Li. The history of GH use, from extraction of GH from human pituitary glands to

the limited catastrophe of Creutzfeldt-Jakob Disease to the expanded use and enormous costs of synthetic GH is outlined in the article on GH treatment.

As of 2005, synthetic growth hormones available in the United States (and their manufacturers) included Nutropin (Genentech), Humatrope (Lilly), Genotropin (Pfizer), Norditropin (Novo), and Saizen (Serono). The products are nearly identical in composition, efficacy, and cost, varying primarily in the formulations and delivery devices. In 2005 an Israeli company, Teva, offered Tev-Tropin in the U.S. at a lower price. Lilly and Alkermes are developing an inhalable version that is in phase III clinical trials as of April, 2006.

HGH quackery

Consumers should understand that use of the term "HGH" by marketers since 1990 is a nearly infallible sign that a product so labeled contains no effective amount of growth hormone. Endocrinologists tend to use other terms, and the specific term HGH is often an indicator of questionable claims or information. For fuller discussion, see HGH quackery.

Luteinizing hormone

Luteinizing hormone beta polypeptide *Identifiers*

Luteinizing hormone (*LH*) is a hormone synthesized and secreted by gonadotropes in the anterior lobe of the pituitary gland. In concert with the other pituitary gonadotropin follicle stimulating hormone (FSH) it is necessary for proper reproductive function. In the female, an acute rise of LH – the *LH surge* – triggers ovulation. In the male, where LH had also been called *Interstitial Cell Stimulating Hormone* (*ICSH*), it stimulates Leydig cell production of testosterone.

Structure

LH is a glycoprotein. Each monomeric unit is a protein molecule with a sugar attached to it; two of these make the full, functional protein. Its structure is similar to the other glycoproteins, FSH, TSH, and hCG. The protein dimer contains 2 polypeptide units, labeled

alpha and beta subunits that are connected by two disulfide bridges. The alpha subunits of LH, FSH, TSH, and hCG are identical, and contain 92 amino acids. The beta subunits vary. LH has a beta subunit of 121 amino acids (LHB) that confers its specific biologic action and is responsible for interaction with the LH receptor. This beta subunit contains the same amino acids in sequence as the beta sub unit of hCG and both stimulate the same receptor, however, the hCG beta subunit contains an additional 24 amino acids, and both hormones differ in the composition of their sugar moieties. The different composition of these oligosaccharides affects bioactivity and speed of degradation. The biologic half-life of LH is 20 minutes, shorter than that of FSH (3-4 hours) or hCG (24 hours).

Genes

The gene for the alpha subunit is located on chromosome 6q12.21. The luteinizing hormone beta-subunit gene is localized in the LHB/CGB gene cluster on chromosome 19q13.32. In contrast to the alpha gene activity, beta LH subunit gene activity is restricted to the pituitary gonadotropic cells. It is regulated by the gonadotropin releasing hormone from the hypothalamus. Inhibin, activin, and sex hormones do not affect genetic activity for the beta subunit production of LH.

Activity

In both males and females, LH is essential for reproduction. In females, at the time of menstruation, FSH initiates follicular growth, specifically affecting granulosa cells. With the rise in estrogens, also LH receptors are expressed on the maturing follicle that produces an increasing amount of estradiol. Eventually at the time of the maturation of the follicle, the estrogen rise leads via the hypothalamic interface to the "positive feed-back" effect, a release of LH over a 24-48 hour. This *LH surge* triggers ovulation hereby not only releasing the egg, but also initiating the conversion of the residual follicle into a corpus luteum that, in turn, produces Progesterone to prepare the endometrium for a possible implantation. LH is necessary to maintain luteal function for the first two weeks. In case of a pregnancy luteal function will be further maintained by the action of hCG from the newly established pregnancy. LH supports thecal cells in the ovary that provide androgens and hormonal precursors for estradiol production.

In the male, LH acts upon the Leydig cell of the testis and is responsible for testosterone production that exerts intratesticular activity in terms of the spermatogenesis and endocrine activity as the "male hormone".

The release of LH at the pituitary gland is controlled by pulses of gonadotropin-releasing hormone (GnRH) from the hypothalamus. Those pulses, in turn, are subject to the estrogen feed-back from the gonads.

Normal levels

LH levels are normally low during childhood and, in women, high after menopause. During the reproductive years typical levels are seen between 5-20 mIU/ml. Physiologic high LH levels are seen during the LH surge (v.s.), typically they last 48 hours.

Ovulation predictor kit (LH kit)

The detection of the LH surge has become useful for people who want to know when ovulation occurs. LH can be detected by urinary ovulation predictor kits (OPK, also LH-kit) that are performed daily around the time ovulation may be expected. The conversion from a negative to a positive reading would suggest that ovulation is about to occur within 24-48 hours. Couples who plan to conceive would time intercourse accordingly. As sperms can stay viable in the woman for several days, such tests are not recommended for contraceptive practices.

Disease States

Relative elevations

In children with precocious puberty of pituitary or central origin, LH and FSH levels may be in the reproductive range and not at the low levels typically for their age.

During the reproductive years, relatively elevated LH are frequently seen in patients with the polycystic ovary syndrome, however it would be unusual to have LH levels outside of the normal reproductive range.

High LH levels

Persistently high LH levels are indicative of situations where the normal restricting feedback from the gonad is absent, leading to an unrestricted pituitary production of both, LH and FSH. While this is typical in the menopause, it is abnormal in the reproductive years. There it may be a sign of:

1. Premature menopause

Gonadal dysgenesis, Turner syndrome
Castration
Swyer syndrome
Certain forms of CAH
Testicular failure

Deficient LH activity

Diminished secretion of LH can result in failure of gonadal function (hypogonadism). This condition is typically manifest in males as failure in production of normal numbers of sperm. In females, amenorrhea is commonly observed. Conditions with very low FSH secretions are:

1. Kallmann syndrome

Hypothalamic suppression
Hypopituitarism
Eating disorder
Hyperprolactinemia
Gonadotropin deficiency

2. Gonadal suppression therapy
    1. GnRH antagonist

GnRH agonist (downregulation)

Availability

LH is available mixed with FSH in the form of Pergonal, and other forms of urinary gonadotropins . More purified forms of urinary gonadotropins may reduce the LH portion in relation to FSH. Recombinant LH is available as lutropin alfa (Luveris®)[1]. All these medications have to be given parenterally. They are commonly in infertility therapy to stimulate follicular development, notably in IVF therapy.

Often, hCG medication is used as an LH substitute as it activates the same receptor. Medically used hCG is derived from urine of pregnant women, less costly, and has a longer half-life than LH.

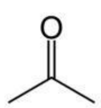
Acetone



Systematic name Propanone

Other names ^{2}-ketopropane, Dimethyl ketone

Molecular formula CH_3COCH_3

SMILES CC(=O)C

Molar mass 58.09 g/mol

Appearance Colorless liquid

CAS number [67-64-1]

Properties

Density and phase 0.79 g/cm^3, liquid

Solubility in water miscible

Melting point 94.9 °C (178.2 K)

Boiling point 56.3 °C (329.4 K)

Viscosity 0.32 cP at 20 °C

Structure

Molecular shape trigonal planar at C=O

Dipole moment 2.91 D

Hazards

MSDS External MSDS

EU classification Flammable (*F*), Irritant (*Xi*), R11, R36, R66, R67
S-phrases S2, S9, S16, S26
Flash point 20 °C
Autoignition temperature 465 °C
RTECS number AL31500000

Supplementary data page

Structure & properties n, μ_r, etc.

Thermodynamic data Phase behaviour, Solid, liquid, gas

Spectral data UV, IR, NMR, MS

Related ketones Butanone

Related solvents water, Ethanol, Isopropanol, Toluene

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

In chemistry, *acetone* (also known as *propanone*, *dimethyl ketone*, *2-propanone*, *propan-2-one* and ^{2}*-ketopropane*) is the simplest representative of the ketones.

Acetone is a colorless mobile flammable liquid with melting point at 95.4 °C and boiling point at 56.53 °C. It has a relative density of 0.819 (at 0 °C). It is readily soluble in water, ethanol, ether, etc., and itself serves as an important solvent. The most familiar household use of acetone is as the active ingredient in nail polish remover. Acetone is also used to make plastic, fibers, drugs, and other chemicals.

Uses

An important industrial use for acetone involves its reaction with phenol for the manufacture of bisphenol A. Bisphenol A is an important component of many polymers such as polycarbonates, polyurethanes and epoxy resins. Acetone is also used extensively for the safe transporting and storing of acetylene. Vessels containing a porous material are first filled with acetone followed by acetylene, which dissolves into the acetone. One liter of acetone can dissolve around 250 litres of acetylene.

Acetone is often the primary (or only) component in nail polish remover. Acetone is also used as a superglue remover. It can be used for thinning and cleaning fiberglass resins and epoxies. It is a strong solvent for most plastics and synthetic fibres.

Acetone has been used in the manufacture of cordite. During World War I a new process of producing acetone through bacterial fermentation was developed by Chaim Weizmann, to help the British war effort.

Acetone can also dissolve many plastics, including those used in consumer-targeted Nalgene bottles.

Acetone is also used as a drying agent, due to the readiness with which it binds to water, and its volatility.

Acetone can also be used on the hair. It can be used as a rinse before shampooing to remove build up, oil and hard water minerals.

Uses in universities and professional laboratories

Due to the nonpolar properties of acetone, it has been used in many university labs as a cleanser for nonpolar substances in testtubes after working with nonpolar organic substances (i.e. cyclohexane, cyclohexene). Acetone is squirted directly from a bottle containing the substance onto the glassware and is drained into a specially marked organic waste bucket.

However, care should be used when cleaning testtubes with acetone as acetone is readily absorbed through vinyl or latex gloves and will come in contact with skin where it is absorbed into the skin. If an excessive amount of acetone is splashed onto gloves, remove gloves immediately and wash hands with water before donning a new pair of gloves.

Acetone is very cool to the touch due to its high volatility and will evaporate quickly, making it very useful in drying lab glassware. Avoid inhaling fumes as acetone is an irritant and inhalation may lead to hepatanic effects (causing liver damage). Always use goggles when handling acetone, it can cause permanent eye damage (corneal clouding).

Health effects

Small amounts of acetone are metabolically produced in the body, mainly from fat. In humans, fasting significantly increases its endogenous production (see ketosis). Acetone can be elevated in diabetes. Exposure to exogenous acetone can be chronic due to acetone contamination of water, food (e.g. milk), or the air (acetone is volatile). A number of acute poisoning cases have been described. Relatively speaking, acetone is not a very toxic compound; it can, however, damage the mucosa of the mouth and can irritate and damage skin. Accidental intake of large amounts of acetone may lead to unconsciousness and death.

The effects of long-term exposure to acetone are known mostly from animal studies. Kidney, liver, and nerve damage, increased birth defects, and lowered reproduction ability of males (only) occurred in animals exposed long-term. It is not known if these same effects would be exhibited in humans.

Interestingly, acetone has been shown to have anticonvulsant effects in animal models of epilepsy, in the absence of toxicity, when administered in millimolar concentrations (see: Likhodii et. al., Ann Neurol. 2003;54(2):219-226). It has been hypothesized that the high fat low carbohydrate ketogenic diet used clinically to control drug-resistant epilepsy in children works by elevating acetone in the brain (see Ibid, p. 219).

Cloning

Cloning is the process of creating an identical copy of an original organism or thing. A cloning in the biological sense, therefore, is a molecule, single cell (like bacteria, lymphocytes etc.) or multi-cellular organism that has been directly copied from and is therefore genetically identical to another living organism. Sometimes this term can refer to "natural" clones made either when an organism is asexually reproduced by chance (as with identical twins), but in common parlance, a clone is an identical copy created intentionally.

The term clone is derived from º»É½, the Greek word for "twig". In horticulture, the spelling clon was used until the twentieth century; the final e came into use to indicate the vowel is a "long o" instead of a "short o". Since the term entered the popular lexicon in a more general context, the spelling clone has been used exclusively.

Molecular cloning

Molecular cloning refers to the procedure of isolating a DNA sequence of interest and obtaining multiple copies of it in an organism. Cloning is frequently employed to amplify DNA fragments containing genes, an essential step in their subsequent analysis. Frequently, the term cloning is misleadingly used to refer to the identification of the chromosomal location of a gene associated with a particular phenotype of interest. In practice, localisation of the gene does not always enable one to amplify the relevant genomic sequence.

Cloning of any DNA sequence involves the following four steps: amplification, ligation, transfection, and screening/selection. Initially, the DNA fragment of interest needs to be

amplified (many copies need to be produced). Amplification is commonly achieved by means of PCR. Subsequently, a ligation procedure is employed whereby the amplified fragment is inserted into a vector. The vector (which is frequently circular) is linearised by means of restriction enzymes, and incubated with the fragment of interest under appropriate conditions that allow for ligation. The yield of the ligation is typically low and depends on the procedure employed. Following ligation the vector with the insert of interest is transfected to cells. Most commonly electroporation is employed, although a number of alternative techniques are available, such as chemical sensitivation of cells. Finally, the transfected cells are cultured. As the aforementioned procedures are of particularly low yield, there is the need to identify the cell colonies that have been transfected with the construct of interest containing the desired insertion sequence. Modern cloning vectors include selectable antibiotic resistance markers, which allow only for cells in which the vector has been transfected to grow. However this selection step does not guarantee that the DNA insert is present in the vector. Further investigation of the resulting colonies is required to confirm that cloning was successful. This can be accomplished by means of blue/white screening (±-factor complimentation) on X-gal medium and/or PCR, possibly followed by DNA sequencing.

Genetic cloning

Cloning a cell means to derive a (clonal) population of cells from a single cell. This is an important in vitro procedure when the expansion of a single cell with certain characteristics is desired, for example in the production of gene-targeted ES cells. Most individuals began as a single cell and are therefore the result of clonal expansion in vivo.

Organism

Cloning means to create a new organism with the same genetic information as a cell from an existing one(identical). It is an asexual method of reproduction, where fertilization or inter-gamete contact does not take place. Asexual reproduction (also known as agamogenesis) is a form of reproduction which does not involve meiosis, gamete formation, or fertilization. In laymen's terms, there is only one "parent" involved. This form of reproduction is common among simple organisms such as amoeba and other single-celled organisms, although most plants reproduce asexually as well.

Horticultural

The term clone is used in horticulture to mean all descendants of a single plant, produced by vegetative reproduction or apomixis. Many horticultural plant cultivars are clones, having been derived from a single individual, multiplied by some process other than sexual reproduction. As an example, some European cultivars of grapes represent clones that have been propagated for over two millennia. Other examples are potato and banana. Grafting can be regarded as cloning, since all the shoots and branches coming from the graft are genetically a clone of a single individual, although the root systems may be genetically

genuine examples of cloning in the broader biological sense, as they create genetically identical organisms by biological means, but this particular kind of cloning has not come under ethical scrutiny and is generally treated as an entirely different kind of operation.

Many trees, shrubs, vines, ferns and other herbaceous perennials form clonal colonies. Parts of a large clonal colony often become detached from the parent, termed fragmentation, to form separate individuals. Some plants also form seeds asexually, termed apomixis, e.g. dandelion.

Animals

Cloning exists in nature in some animal species and is referred to as parthenogenesis. An example is the "Little Fire Ant" (Wasmannia auropunctata), which is native to Central and South America but has spread throughout many *tropical* environments.

Reproductive Cloning

Reproductive cloning is a technology used to generate an animal that has the same nuclear DNA as another currently or previously existing animal. Dolly the sheep, was created by reproductive cloning technology. In a process called "somatic cell nuclear transfer" (SCNT), scientists transfer genetic material from the nucleus of a donor adult cell to an egg whose nucleus, and thus its genetic material, has been removed. The reconstructed egg containing the DNA from a donor cell must be treated with chemicals or electric current in order to stimulate cell division. Once the cloned embryo reaches a suitable stage, it is transferred to the uterus of a female host where it continues to develop until birth.

Dolly or any other animal created using nuclear transfer technology is not truly an identical clone of the donor animal. Only the clone's chromosomal or nuclear DNA is the same as the donor. Some of the clone's genetic materials come from the mitochondria in the cytoplasm of the enucleated egg. Mitochondria, which are organelles that serve as power sources to the cell, contain their own short segments of DNA, although this is only 0.01% of the total DNA. Acquired mutations in mitochondrial DNA are believed to play an important role in the aging process.

Also mutations occur with every cell division so no two cells in an individual are identical, nor are clones. Thus, nuclear transfer clones from different maternal lineages are not clones in the strictest sense because the mitochondrial genome is not the same as that of the nucleus donor cell from which it was produced. This may have important implications for cross-species nuclear transfer in which nuclear-mitochondrial incompatibilities may lead to inviability.

Species cloned

The modern cloning techniques involving nuclear transfer have been successfully performed on several species. Landmark experiments in chronological order:

- Tadpole: (1952) Many scientists questioned whether cloning had actually occurred and unpublished experiments by other labs were not able to reproduce the reported results.
 Carp: (1963) In China, embryologist Tong Dizhou cloned a fish. He published the findings in an obscure Chinese science journal which was never translated into English.[1]
 Mice: (1986) was the first successfully cloned mammal; Soviet scientists Chaylakhyan, Veprencev, Sviridova, Nikitin had mice "Masha" cloned. Research was published in the magazine "Biofizika" volume %%%II, issue 5 of 1987.[2]
 Sheep: (1996) From early embryonic cells by Steen Willadsen. Megan and Morag cloned from differentiated embryonic cells in June 1995 and Dolly the sheep in 1997.
 Rhesus Monkey: Tetra (female, January 2000) from embryo splitting
 Cattle: Alpha and Beta (males, 2001) and (2005) Brazil[3]
 Cat: CopyCat "CC" (female, late 2001), Little Nicky, 2004, was the first cat cloned for commercial reasons
 Mule: Idaho Gem, a john mule born 2003-05-04, was the first horse-family clone.
 Horse: Prometea, a Haflinger female born 2003-05-28, was the first horse clone.

During the first several divisions of a fertilized egg, no differentiation occurs and the cells can be separated without harm, but each will grow into an identical individual. This process has been used on cattle for decades to produce hundreds of identical individuals in some cases. This process is not considered cloning, but is called budding. The new individual is not derived from a differentiated cell, but from an undifferentiated egg. There is no way to determine which are the clones and which is the original.

Health aspects

The success rate of cloning has been low: Dolly the sheep was born after 277 eggs were used to create 29 embryos, which only produced three lambs at birth, only one of which lived, Dolly. Seventy calves have been created from 9,000 attempts and one third of them died young; Prometea took 328 attempts, and, more recently, Paris Texas was created after 400 attempts. Notably, although the first clones were frogs, no adult cloned frog has yet been produced from a somatic adult nucleus donor cell.

There were early claims that Dolly the Sheep had accelerated aging. Aging of this type is thought to be due to shortening of telomeres, regions at the tips of chromosomes which prevent genetic threads fraying every time a cell divides. Over time telomeres get worn down until cell-division is no longer possible — this is thought to be a cause of aging. However, subsequent studies showed that, if anything, Dolly's telomere were longer than normal. Dolly died in the year of 2003. Ian Wilmut said that Dolly's early death had nothing to do with cloning but with a respiratory infection common to lambs raised indoors like Dolly.

Consistent with Dolly's telomeres being longer, analysis of the telomeres from cloned cows showed that they were also longer. This suggests clones could live longer life spans although many died young after excessive growth. Researchers think that this could eventually be developed to reverse aging in humans, provided that this is based chiefly on

the shortening of telomeres. Although some work has been performed on telomeres and aging in nuclear transfer clones, the evidence is at an early stage. [4]

Dolly the Sheep

Dolly (1996-07-05 – 2003-02-14), an ewe, was the first mammal to have been successfully cloned from an adult cell (while the mice in USSR was cloned from embryo cell back in 1986). She was cloned at the Roslin Institute in Scotland and lived there until her death when she was 6. Her birth was announced on 1997-02-22.

The name "Dolly" came from a suggestion by Jesse Haase who helped with her birth, in honor of Dolly Parton, because it was a mammary cell that was cloned. The technique that was made famous by her birth is somatic cell nuclear transfer, in which a non-reproductive cell containing a nucleus is placed in a de-nucleated ovum (which then develops into a fetus). When Dolly was cloned in 1996 from a cell taken from a six-year-old ewe, she became the center of much controversy that still exists today.

Dolly's success is truly remarkable because it proved that the genetic material from a specialized adult cell, such as an udder cell programmed to express only those genes needed by udder cells, could be reprogrammed to generate an entire new organism. Before this demonstration, scientists believed that once a cell became specialized as a liver, heart, udder, bone, or any other type of cell, the change was permanent and other unneeded genes in the cell would become inactive. Some scientists believe that errors or incompleteness in the reprogramming process cause the high rates of death, deformity, and disability observed among animal clones.

On 2003-04-09 her stuffed remains were placed at Edinburgh's Royal Museum, part of the National Museums of Scotland.

Ian Wilmut's role in cloning Dolly the sheep is in doubt. In 2006 he admitted under oath in a Scottish court that he did not clone Dolly the Sheep and was not responsible for the scientific breakthrough which made it all possible. He credited Keith Campbell as being the brains behind Dolly the Sheep.

In August 2006, Iranian scientists oversaw the birth of the Middle East’s first cloned animal – a lamb that died minutes after it was born. However, in September 2006, Iranian scientists successfully cloned a sheep, by somatic cell nuclear transfer, at the Royan research institute in Isfahan, Iran’s second cloned lamb is still alive.

Human cloning

Human cloning is the creation of a genetically identical copy of an existing, or previously existing human, by growing *cloned* tissue from that individual. The term is generally used to refer to artificial human cloning; human clones in the form of identical twins are commonplace, with their cloning occurring during the natural process of reproduction.

Human cloning is amongst the most controversial forms of the practice. There have been numerous demands for all progress in the human cloning fields to be halted. One of the most ethically questionable problems with human cloning is farming of organs from clones. For

example, many believe it is unethical to use a human clone to save the life of another. In this scenario, the cloned human would be euthanized so that the vital organs could be harvested. This process of renewing the body's organs would potentially increase the life expectancy of a human by 50 years.

The cloning described above is reproductive cloning, not to be confused with research cloning in which only parts (such as an organ) are cloned using genetic material from a patient's tissues.

Ethical issues of human cloning

Roman Catholicism and many conservative Christian groups have opposed human cloning and the cloning of human embryos, believing that a human life begins the moment a human egg becomes fertilized. Other Christian denominations such as the United Church of Christ do not believe a fertilized egg constitutes a living being, but still they oppose the cloning of embryonic cells. The World Council of Churches, representing nearly 400 denominations worldwide, opposed cloning of both human embryos and whole humans in February 2006. The United Methodist Church opposed research and reproductive cloning in May 2000 and again in May 2004.

Libertarian views on the subject suggest that the federal government of the United States does not have the power to regulate cloning, as it is not given any such authority by the US constitution. (Similar to abortion rights.)

At present, the main objection to human cloning is that the cloned individual may be biologically damaged, due to the inherent unreliability of its origin: researchers currently are unable to safely and reliably clone non-human primates.

However, many believe that as cloning research and methods improve, concerns of safety and reliability will no longer be an issue. However, it must be pointed out that this has yet to occur, and may never occur. Rudolph Jaenisch, a professor at Harvard, has pointed out that we have become more efficient at producing clones which are still defective (Development Dynamics. Volume 235, pages 2460-2469. 2006). Other arguments against cloning come from various religious orders (believing cloning violates God's will or the natural order of life), and a general discomfort some have with the idea of "meddling" with the creation and basic function of life. This unease often manifests itself in contemporary novels, movies, and popular culture, much like numerous other scientific discoveries and inventions before. Various fictional scenarios portray clones being unhappy, soulless, or unable to integrate into society. Furthermore, clones are often depicted not as unique individuals but as "spare parts," providing organs for the clone's original (or any non-clone that requires replacement organs).

Needless to say, cloning is a poignant and important topic, reflected by its frequent discussion and debate among politicians, scientists, the media, religions, and the general public.

Cloning extinct and endangered species

Cloning, or more precisely, the reconstruction of functional DNA from extinct species has, for decades, been a dream of some scientists. The possible implications of this were dramatized in the best-selling novel by Michael Crichton and high budget Hollywood thriller Jurassic Park. In real life, one of the most anticipated targets for cloning was once the Woolly mammoth, but attempts to extract DNA from frozen mammoths have been unsuccessful, though a joint Russo-Japanese team is currently working toward this goal.[5]

In 2000, a cow named Bessie gave birth to a cloned Asian gaur, an endangered species, but the calf died after two days. In 2003, a banteng was successfully cloned, followed by three African wildcats from a thawed frozen embryo. These successes provided hope that similar techniques (using surrogate mothers of another species) might be used to clone extinct species. Anticipating this possibility, tissue samples from the last bucardo (Pyrenean Ibex) were frozen immediately after it died. Researchers are also considering cloning endangered species such as the giant panda, ocelot, and cheetah. The "Frozen Zoo" at the San Diego Zoo now stores frozen tissue from the world's rarest and most endangered species.[6][7]

In 2002, geneticists at the Australian Museum announced that they had replicated DNA of the Thylacine (Tasmanian Tiger), extinct about 65 years previous, using polymerase chain reaction.[8] However, on 2005-02-15 the museum announced that it was stopping the project after tests showed the specimens' DNA had been too badly degraded by the (ethanol) preservative. Most recently, on 2005-05-15, it was announced that the Thylacine project would be revived, with new participation from researchers in New South Wales and Victoria.

One of the continuing obstacles in the attempt to clone extinct species is the need for nearly perfect DNA. Cloning from a single specimen could not create a viable breeding population in sexually reproducing animals. Furthermore, even if males and females were cloned, the question would remain open if they would be viable at all in the absence of parents that could teach or show them natural behavior. Essentially, if cloning an extinct species succeeded — it must be considered that cloning still is an experimental technology that succeeds only by chance — it is far more likely than not that any resulting animals, even if they were healthy, would be little more than curios or museum pieces.

Cloning endangered species is a highly ideological issue. Many conservation biologists and environmentalists vehemently oppose cloning endangered species — not because they think it won't work but because they think it may deter donations to help preserve natural habitat and wild animal populations. The "rule-of-thumb" in animal conservation is that, if it is still feasible to conserve habitat and viable wild populations, breeding in captivity should not be undertaken in isolation.

In a 2006 review, David Ehrenfeld concludes that cloning in animal conservation is an experimental technology that, at its present state, cannot be expected to work except by pure chance and utterly fails a cost-benefit analysis.[9] Furthermore, he says, it is likely to siphon funds from established and working projects and does not address any of the issues underlying animal extinction (such as habitat destruction, hunting or other overexploitation, and an impoverished gene pool). While cloning technologies are well-established and used on a regular basis in plant conservation, care must be taken to ensure genetic diversity. He concludes:

"Vertebrate cloning poses little risk to the environment, but it can consume scarce conservation resources, and its chances of success in preserving species seem poor. To date, the conservation benefits of transgenics and vertebrate cloning remain entirely theoretical, but many of the risks are known and documented. Conservation biologists should devote their research and energies to the established methods of conservation, none of which require transgenics or vertebrate cloning.[9]"

Embryo

Somatic cell nuclear transfer can also be used to create a clonal embryo. The most likely scenario for this is to produce embryos for use in research, particularly stem cell research. This process is also called "research cloning" or "therapeutic cloning."

Therapeutic cloning, also called "embryo cloning," is the production of human embryos for use in research. The goal of this process is not to create cloned human beings, but rather to harvest stem cells that can be used to study human development and to treat disease. Stem cells are important to biomedical researchers because they can be used to generate virtually any type of specialized cell in the human body. Stem cells are extracted from the egg after it has divided for 5 days. The egg at this stage of development is called a blastocyst. The extraction process destroys the embryo, which raises a variety of ethical concerns. Many researchers hope that one day stem cells can be used to serve as replacement cells to treat heart disease, Alzheimer's, cancer, and other diseases.

Scientists believe that cloning may be used to create stem cells genetically compatible with the somatic cell donor. Cloning in stem cell research, called research cloning or therapeutic cloning, has not yet been successful: no embryonic stem cell lines have been derived from clonal embryos. The process might provide a way to grow organs in host carrier, which become completely compatible with the original. Host carrier growing poses a risk of trans-species diseases if the host is of a different species (e.g., a pig).

In human beings, this is a highly controversial issue for several reasons. It involves creating human embryos in vitro and then destroying them, attempting to obtain embryonic stem cells. But proposals to use cloning techniques in human stem cell research raise a set of concerns beyond the moral status of the embryo. These have led a number of individuals and organizations who are not opposed to human embryonic stem cell research to be concerned about, or opposed to, human research cloning. One concern is that cloning in human stem cell research will lead to the reproductive cloning of humans. A second concern is the appropriate sourcing of the eggs that are needed. Research cloning requires a large number of human eggs, which can only be obtained from women. A third concern is the feasibility of developing stem cell therapies from cloning.

In November 2001, scientists from Advanced Cell Technologies (ACT), a biotechnology company in Massachusetts, announced that they had cloned the first human embryos for the purpose of advancing therapeutic research. To do this, they collected eggs from women's ovaries and then removed the genetic material from these eggs with a needle less than 2/10,000th of an inch wide. A skin cell was inserted inside the enucleated egg to serve as a new nucleus. The egg began to divide after it was stimulated with a chemical called ionomycin. The results were limited in success. Although this process was carried out with

eight eggs, only three began dividing, and only one was able to divide into six cells before stopping.

Genetic engineering

Genetic engineering, *genetic modification* (*GM*) and *gene splicing* are terms for the process of manipulating genes, usually outside the organism's normal reproductive process.

It involves the isolation, manipulation and reintroduction of DNA into cells or model organisms, usually to express a protein. The aim is to introduce new characteristics or attributes physiologically or physically, such as making a crop resistant to a herbicide, introducing a novel trait, or producing a new protein or enzyme. Examples can include the production of human insulin through the use of modified bacteria, the production of erythropoietin in Chinese Hamster Ovary cells, and the production of new types of experimental mice such as the OncoMouse (cancer mouse) for research, through genetic redesign.

Since a protein is specified by a segment of DNA called a gene, future versions of that protein can be modified by changing the gene's underlying DNA. One way to do this is to isolate the piece of DNA containing the gene, precisely cut the gene out, and then reintroduce (splice) the gene into a different DNA segment. Daniel Nathans and Hamilton Smith received

the 1978 Nobel Prize in physiology or medicine for their isolation of restriction endonucleases, which are able to cut DNA at specific sites. Together with ligase, which can join fragments of DNA together, restriction enzymes formed the initial basis of recombinant DNA technology.

Applications

The first Genetically Engineered drug was human insulin approved by the USA's FDA in 1982. Another early application of genetic engineering was to create human growth hormone as replacement for a drug that was previously extracted from human cadavers. In 1986 the FDA approved the first genetically engineered vaccine for humans, for hepatitis B. Since these early uses of the technology in medicine, the use of GE has expanded to supply many drugs and vaccines.

One of the best known applications of genetic engineering is that you can probilize the outcome of offspring. There are potentially momentous biotechnological applications of GM, for example oral vaccines produced naturally in fruit, at very low cost.

A radical ambition of some groups is human enhancement via genetics, eventually by molecular engineering.

Genetic engineering and research

Although there has been a tremendous revolution in the biological sciences in the past twenty years, there is still a great deal that remains to be discovered. The completion of the sequencing of the human genome, as well as the genomes of most agriculturally and scientifically important plants and animals, has increased the possibilities of genetic research immeasurably. Expedient and inexpensive access to comprehensive genetic data has become a reality with billions of sequenced nucleotides already online and annotated. Now that the rapid sequencing of arbitrarily large genomes has become a simple, if not trivial affair, a much greater challenge will be elucidating function of the extraordinarily complex web of interacting proteins, dubbed the proteome, that constitutes and powers all living things. Genetic engineering has become the gold standard in protein research, and major research progress has been made using a wide variety of techniques, including:

- Loss of function, such as in a knockout experiment, in which an organism is engineered to lack the activity of one or more genes. This allows the experimenter to analyze the defects caused by this mutation, and can be considerably useful in unearthing the function of a gene. It is used especially frequently in developmental biology. A knockout experiment involves the creation and manipulation of a DNA construct in vitro, which, in a simple knockout, consists of a copy of the desired gene which has been slightly altered such as to cripple its function. The construct is then taken up by embryonic stem cells, where the engineered copy of the gene replaces the organism's own gene. These stem cells are injected into blastocysts, which are implanted into surrogate mothers. Another method, useful in organisms such as Drosophila (fruit fly), is to

induce mutations in a large population and then screen the progeny for the desired mutation. A similar process can be used in both plants and prokaryotes.

- Gain of function experiments, the logical counterpart of knockouts. These are sometimes performed in conjunction with knockout experiments to more finely establish the function of the desired gene. The process is much the same as that in knockout engineering, except that the construct is designed to increase the function of the gene, usually by providing extra copies of the gene or inducing synthesis of the protein more frequently.
- 'Tracking' experiments, which seek to gain information about the localization and interaction of the desired protein. One way to do this is to replace the wild-type gene with a 'fusion' gene, which is a juxtaposition of the wild-type gene with a reporting element such as Green Fluorescent Protein (GFP) that will allow easy visualization of the products of the genetic modification. While this is a useful technique, the manipulation can destroy the function of the gene, creating secondary effects and possibly calling into question the results of the experiment. More sophisticated techniques are now in development that can track protein products without mitigating their function, such as the addition of small sequences which will serve as binding motifs to monoclonal antibodies.

Molecular genetics

Molecular genetics is the field of biology which studies the structure and function of genes at a molecular level. Molecular genetics employs the methods of genetics and molecular biology. It is so-called to differentiate it from other sub fields of genetics such as ecological genetics and population genetics. An important area within molecular genetics is the use of molecular information to determine the patterns of descent, and therefore the correct scientific classification of organisms: this is called molecular systematics.

Forward genetics

One of the first tools available to molecular geneticists is the forward genetic screen. The aim of this technique is to identify mutations that produce a certain phenotype. A mutagen is very often used to accelerate this process. Once mutants have been isolated, the mutated gene can be molecularly identified.

Reverse genetics

While forward genetic screens are productive, a more straightforward approach would be to determine the phenotype that results from mutating a given gene. This is called reverse genetics. In some organisms, such as yeast and mice, it is possible to induce the deletion of a particular gene, creating a gene knockout. Alternatives include the random induction of DNA deletions and subsequent selection for deletions in a gene of interest, the application of RNA interference and the creation of transgenic organisms that do not express a gene of interest.

DNA repair

DNA repair refers to a collection of processes by which a cell identifies and corrects damage to the DNA molecules that encode its genome. In human cells, both normal metabolic activities and environmental factors such as UV light can cause DNA damage, resulting in as many as 1 million individual molecular lesions per cell per day.[1] Many of these lesions cause structural damage to the DNA molecule and can alter or eliminate the cell's ability to transcribe the gene that the affected DNA encodes. Other lesions induce potentially harmful mutations in the cell's genome, which affect the survival of its daughter cells after it undergoes mitosis. Consequently, the DNA repair process must be constantly active so it can respond rapidly to any damage in the DNA structure.

The rate of DNA repair is dependent on many factors, including the cell type, the age of the cell, and the extracellular environment. A cell that has accumulated a large amount of DNA damage, or one that no longer effectively repairs damage incurred by its DNA, can enter one of three possible states:

1. an irreversible state of dormancy, known as senescence
2. cell suicide, also known as apoptosis or programmed cell death
3. unregulated cell division, which can lead to the formation of a tumor that is cancerous

The DNA repair ability of a cell is vital to the integrity of its genome and thus to its normal functioning and that of the organism. Many genes that were initially shown to influence lifespan have turned out to be involved in DNA damage repair and protection.[2] Failure to correct molecular lesions in cells that form gametes can introduce mutations into the genomes of the offspring and thus influence the rate of evolution.

DNA damage

DNA damage, due to environmental factors and normal metabolic processes inside the cell, occurs at a rate of 1,000 to 1,000,000 molecular lesions per cell per day.[1] While this constitutes only 0.000165% of the human genome's approximately 6 billion bases (3 billion base pairs), unrepaired lesions in critical genes (such as tumor suppressor genes) can impede a cell's ability to carry out its function and appreciably increase the likelihood of tumor formation.

The vast majority of DNA damage affects the primary structure of the double helix; that is, the bases themselves are chemically modified. These modifications can in turn disrupt the molecules' regular helical structure by introducing non-native chemical bonds or bulky adducts that do not fit in the standard double helix. Unlike proteins and RNA, DNA usually lacks secondary structure and therefore damage or disturbance does not occur at that level. DNA is, however, supercoiled and wound around "packaging" proteins called histones, and both superstructures are vulnerable to the effects of DNA damage.

Sources of damage

DNA damage can be subdivided into two main types:

1. endogenous damage such as attack by reactive oxygen species produced from normal metabolic byproducts (spontaneous mutation), especially the process of oxidative deamination;
2. exogenous damage caused by external agents such as
   - ultraviolet [UV 200-300nm] radiation from the sun
   - other radiation frequencies, including x-rays and gamma rays
   - hydrolysis or thermal disruption
   - certain plant toxins
   - human-made mutagenic chemicals, especially aromatic compounds that act as DNA intercalating agents
   - cancer chemotherapy and radiotherapy

The replication of damaged DNA before cell division can lead to the incorporation of wrong bases opposite damaged ones. Daughter cells that inherit these wrong bases carry mutations from which the original DNA sequence is unrecoverable (except in the rare case of a back mutation, for example, through gene conversion).

Types of damage

There are four main types of damage to DNA due to endogenous cellular processes:

- oxidation of bases [e.g. 8-oxo-7,8-dihydroguanine (8-oxoG)] and generation of DNA strand interruptions from reactive oxygen species,
- alkylation of bases (usually methylation), such as formation of 7-methylguanine
- hydrolysis of bases, such as deamination, depurination and depyrimidination.
- mismatch of bases, due to DNA replication in which the wrong DNA base is stitched into place in a newly forming DNA strand.

Damage caused by exogenous agents comes in many forms. Some examples are:

- UV light causes crosslinking between adjacent cytosine and thymine bases creating pyrimidine dimers
- Ionizing radiation such as that created by radioactive decay or in cosmic rays causes breaks in DNA strands
- Industrial chemicals such as vinyl chloride and hydrogen peroxide, and environmental chemicals such as polycyclic hydrocarbons found in smoke, soot and tar create a huge diversity of DNA adducts- ethenobases, oxidized bases and alkylated phosphotriesters, just to name a few.

Nuclear versus mitochondrial DNA damage

In human, and eukaryotic cells in general, DNA is found in two cellular locations - inside the nucleus and inside the mitochondria. Nuclear DNA (nDNA) exists as chromatin during non-replicative stages of the cell cycle and is condensed into aggregate structures known as chromosomes during cell division. In either state the DNA is highly compacted and wound up around bead-like proteins called histones. Whenever a cell needs to express the genetic information encoded in its nDNA the required chromosomal region is unravelled, genes located therein are expressed, and then the region is condensed back to its resting conformation. Mitochondrial DNA (mtDNA) is located inside mitochondria organelles, exists in multiple copies, and is also tightly associated with a number of proteins to form a complex known as the nucleoid. Inside mitochondria, reactive oxygen species (ROS), or free radicals, byproducts of the constant production of adenosine triphosphate (ATP) via oxidative phosphorylation, create a highly oxidative environment that is known to damage mtDNA. A critical enzyme in counteracting the toxicity of these species is superoxide dismutase, which is present in both the mitochondria and cytoplasm of eukaryotic cells.

Senescence and apoptosis

Senescence, an irreversible state in which the cell no longer divides (mitosis), is a protective response to the shortening of the chromosome ends (telomeres). The telomeres are long regions of repetitive noncoding DNA that cap chromosomes and undergo partial degradation each time a cell undergoes division (see Hayflick limit).[3] In contrast, quiescence is a reversible state of cellular dormancy that is unrelated to genome damage (see cell cycle). Senescence in cells may serve as a functional alternative to apoptosis in cases where the physical presence of a cell for spatial reasons is required by the organism,[4] which serves as a "last resort" mechanism to prevent a cell with damaged DNA from replicating inappropriately in the absence of pro-growth cellular signaling. Unregulated cell division can lead to the formation of a tumor (see cancer), which is potentially lethal to an organism. Therefore the induction of senescence and apoptosis is considered to be part of a strategy of protection against cancer.

DNA repair mechanisms

Cells cannot function if DNA damage corrupts the integrity and accessibility of essential information in the genome (but cells remain superficially functional when so-called "non-essential" genes are missing or damaged). Depending on the type of damage inflicted on the DNA's double helical structure, a variety of repair strategies have evolved to restore lost information. If possible, cells use the unmodified complementary strand of the DNA or the sister chromatid as a template to losslessly recover the original information. Without access to a template, cells use an error-prone recovery mechanism known as translesion synthesis as a last resort.

Damage to DNA alters the spatial configuration of the helix and such alterations can be detected by the cell. Once damage is localized, specific DNA repair molecules are summoned to, and bind at or near the site of damage, inducing other molecules to bind and form a complex that enables the actual repair to take place. The types of molecules involved and the mechanism of repair that is mobilized depend on the type of damage that has occurred and the phase of the cell cycle that the cell is in.

Direct reversal

Cells are known to eliminate three types of damage to their DNA by chemically reversing it. These mechanisms do not require a template, since the types of damage they counteract can only occur in one of the four bases. Such direct reversal mechanisms are specific to the type of damage incurred. The formation of thymine dimers (a common type of cyclobutyl dimer) upon irradiation with UV light results in an abnormal covalent bond between adjacent thymidine bases. The photoreactivation process in bacteria directly reverses this damage by the action of the enzyme photolyase, which uses energy absorbed from UV light to promote catalysis. Another type of damage, methylation of guanine bases, is directly reversed by the protein methyl guanine methyl transferase (MGMT). This is an expensive process because each MGMT molecule can only be used once; that is, the reaction is stoichiometric rather than catalytic.[5] A generalized response to methylating agents in bacteria is known as the adaptive response and confers a level of resistance to alkylating agents upon sustained exposure.[6]The third type of DNA damage reversed by cells is certain methylation of the bases cytosine and adenine.

Single strand damage

When only one of the two strands of a double helix has a defect, the other strand can be used as a template to guide the correction of the damaged strand. In order to repair damage to one of the two paired molecules of DNA, there exist a number of excision repair mechanisms that remove the damaged nucleotide and replace it with an undamaged nucleotide complementary to that found in the undamaged DNA strand.[5]

- Base excision repair (BER), which repairs damage due to a single nucleotide caused by oxidation, alkylation, hydrolysis, or deamination;
 Nucleotide excision repair (NER), which repairs damage affecting longer strands of 2-30 bases. This process recognizes bulky, helix-distorting changes such as thymine dimers as well as single-strand breaks (repaired with enzymes

such UvrABC endonuclease). A specialized form of NER known as Transcription-Coupled Repair (TCR) deploys high-priority NER repair enzymes to genes that are being actively transcribed;

Mismatch repair (MMR), which corrects errors of DNA replication and recombination that result in mispaired nucleotides following DNA replication.

Double strand breaks

A type of DNA damage particularly hazardous to dividing cells is a break to both strands in the double-helix. Two mechanisms exist to repair this damage. They are generally known as non-homologous end-joining (NHEJ) and recombinational repair (also known as template-assisted repair or homologous recombination repair).[5]

The NHEJ pathway operates when the cell has not yet replicated the region of DNA on which the lesion has occurred. The process directly joins the two ends of the broken DNA strands without a template, losing sequence information in the process. Thus this repair mechanism is necessarily mutagenic. However, if the cell is not dividing and has not replicated its DNA, the NHEJ pathway is the cell's only option. NHEJ relies on chance pairings, or microhomologies, between the single-stranded tails of the two DNA fragments to be joined. There are multiple independent "failsafe" pathways for NHEJ in higher eukaryotes.[7]

Recombinational repair requires the presence of an identical or nearly identical sequence to be used as a template for repair of the break. The enzymatic machinery responsible for this repair process is nearly identical to the machinery responsible for chromosomal crossover during meiosis. This pathway allows a damaged chromosome to be repaired using the newly created sister chromatid as a template, i.e. an identical copy that is also linked to the damaged region via the centromere. Double-stranded breaks repaired by this mechanism are usually caused by the replication machinery attempting to synthesize across a single-strand break or unrepaired lesion, both of which result in collapse of the replication fork.

It should be noted that topoisomerases sometimes introduce both single and double strand breaks in the course of changing the DNA's state of supercoiling, which is especially common in regions near an open replication fork. Such breaks are not considered DNA damage because they serve a biochemical purpose and are immediately repaired by the enzymes that created them.

A team of French researchers bombarded Deinococcus radiodurans to study the mechanism of double-strand break DNA repair in that organism. At least two copies of the genome, with random DNA breaks, can form DNA fragments through annealing. Partially overlapping fragments are then used for synthesis of homologous regions through a moving D-loop that can continue extension until they find complementary partner strands. In the final step there is crossover by means of RecA-dependent homologous recombination[8].

Translesion synthesis

Translesion synthesis is an error-prone (almost error-guaranteeing) last-resort method of repairing a DNA lesion that has not been repaired by any other mechanism. The DNA

replication machinery cannot continue replicating past a site of DNA damage, so the advancing replication fork will stall on encountering a damaged base. The translesion synthesis pathway is mediated by specific DNA polymerases that insert extra bases at the site of damage and thus allow replication to bypass the damaged base to continue with chromosome duplication. From the cell's perspective, it is "better" to introduce mutations around a single site than to continue the cell cycle with an incompletely replicated chromosome. The bases inserted by the translesion synthesis machinery are template-independent, but not arbitrary; for example, one human polymerase inserts adenine bases when synthesizing past a thymine dimer.[5]

DNA repair and aging

Poor DNA repair induces pathology

Experimental animals with genetic deficiencies in DNA repair often show decreased lifespan and increased cancer incidence. For example, mice deficient in the dominant NHEJ pathway and in telomere maintenance mechanisms get lymphoma and infections more often, and consequently have shorter lifespans than wild-type mice.[9] Similarly, mice deficient in a key repair and transcription protein that unwinds DNA helices have premature onset of aging-related diseases and consequent shortening of lifespan.[10] However, not every DNA repair deficiency creates exactly the predicted effects; mice deficient in the NER pathway exhibited shortened lifespan without correspondingly higher rates of mutation.[11]

If the rate of DNA damage exceeds the capacity of the cell to repair it, the accumulation of errors can overwhelm the cell and result in early senescence, apoptosis or cancer. Inherited diseases associated with faulty DNA repair functioning result in premature aging, increased sensitivity to carcinogens, and correspondingly increased cancer risk (see below). On the other hand, organisms with enhanced DNA repair systems, such as Deinococcus radiodurans, the most radiation-resistant known organism, exhibit remarkable resistance to the double strand break-inducing effects of radioactivity, likely due to enhanced efficiency of DNA repair and especially NHEJ.[12] It is noteworthy that some workers suguest that if a DNA damage event occurs during the self repair process then the combination of the two events will exert an effect greater than the sum of the individual events (if they occured with a long time delay between them), this is the basis of the second event theory favoured by C. Busby (The Low Level Radiation Campaign).

Longevity and caloric restriction

A number of individual genes have been identified as influencing variations in lifespan within a population of organisms. The effects of these genes is strongly dependent on the environment, particularly on the organism's diet. Caloric restriction reproducibly results in extended lifespan in a variety of organisms, likely via nutrient sensing pathways and decreased metabolic rate. The molecular mechanisms by which such restriction results in lengthened lifespan are as yet unclear (see [13] for some discussion); however, the behavior

of many genes known to be involved in DNA repair is altered under conditions of caloric restriction.

For example, increasing the gene dosage of the gene SIR-2, which regulates DNA packaging in the nematode worm Caenorhabditis elegans, can significantly extend lifespan.[14] The mammalian homolog of SIR-2 is known to induce downstream DNA repair factors involved in NHEJ, an activity that is especially promoted under conditions of caloric restriction.[15] Caloric restriction has been closely linked to the rate of base excision repair in the nuclear DNA of rodents,[16] although similar effects have not been observed in mitochondrial DNA.[17]

Interestingly, the C. elegans gene AGE-1, an upstream effector of DNA repair pathways, confers dramatically extended lifespan under free-feeding conditions but leads to a decrease in reproductive fitness under conditions of caloric restriction.[18] This observation supports the pleiotropy theory of the biological origins of aging, which suggests that genes conferring a large survival advantage early in life will be selected for even if they carry a corresponding disadvantage late in life.

Medicine and DNA repair modulation

Hereditary DNA repair disorders

Defects in the NER mechanism are responsible for several genetic disorders, including:

- xeroderma pigmentosum: hypersensitivity to sunlight/UV, resulting in increased skin cancer incidence and premature aging
- Cockayne syndrome: hypersensitivity to UV and chemical agents
- trichothiodystrophy: sensitive skin, brittle hair and nails

Mental retardation often accompanies the latter two disorders, suggesting increased vulnerability of developmental neurons.

Other DNA repair disorders include:

- Werner's syndrome: premature aging and retarded growth
- Bloom's syndrome: sunlight hypersensitivity, high incidence of malignancies (especially leukemias).
- ataxia telangiectasia: sensitivity to ionizing radiation and some chemical agents

All of the above diseases are often called "segmental progerias" ("accelerated aging diseases") because their victims appear elderly and suffer from aging-related diseases at an abnormally young age.

Other diseases associated with reduced DNA repair function include Fanconi's anemia, hereditary breast cancer and hereditary colon cancer.

DNA repair and cancer

Inherited mutations that affect DNA repair genes are strongly associated with high cancer risks in humans. Hereditary nonpolyposis colorectal cancer (HNPCC) is strongly associated with specific mutations in the DNA mismatch repair pathway. BRCA1 and BRCA2, two famous mutations conferring a hugely increased risk of breast cancer on carriers, are

both associated with a large number of DNA repair pathways, especially NHEJ and homologous recombination.

Cancer therapy procedures such as chemotherapy and radiotherapy work by overwhelming the capacity of the cell to repair DNA damage, resulting in cell death. Cells that are most rapidly dividing - most typically cancer cells - are preferentially affected. The side effect is that other non-cancerous but rapidly dividing cells such as stem cells in the bone marrow are also affected. Modern cancer treatments attempt to localize the DNA damage to cells and tissues only associated with cancer, either by physical means (concentrating the therapeutic agent in the region of the tumor) or by biochemical means (exploiting a feature unique to cancer cells in the body).

DNA repair and evolution

An Ancient and Conserved Mechanism

The basic processes of DNA repair are highly conserved among both prokaryotes and eukaryotes and even among bacteriophage (viruses that infect bacteria); however, more complex organisms with more complex genomes have correspondingly more complex repair mechanisms.[19] The ability of a large number of protein structural motifs to catalyze relevant chemical reactions has played a significant role in the elaboration of repair mechanisms during evolution. For an extremely detailed review of hypotheses relating to the evolution of DNA repair, see [20].

The fossil record indicates that single celled life began to proliferate on the planet at some point during the Precambrian period, although exactly when recognizably modern life first emerged is unclear. Nucleic acids became the sole and universal means of encoding genetic information, requiring DNA repair mechanisms that in their basic form have been inherited by all extant life forms from their common ancestor. The emergence of Earth's oxygen-rich atmosphere (known as the "oxygen catastrophe") due to photosynthetic organisms, as well as the presence of potentially damaging free radicals in the cell due to oxidative phosphorylation, necessitated the evolution of DNA repair mechanisms that act specifically to counter the types of damage induced by oxidative stress.

Evolutionary rate as a function of DNA repair rate

When DNA damage is not repaired properly, or is repaired by an error-prone mechanism, mutations are introduced into the genomes of the cell's progeny. When this occurs in a germ line cell that will eventually produce a gamete, the mutation is passed on to the affected organism's offspring. The rate of evolution in a particular species (or, more narrowly, in a particular gene) is a function of the rate of mutation and thus of the accuracy and the rate of the DNA repair pathway and factors that can influence it.[21]

DNA replication

DNA replication or *DNA synthesis*, it is the process of copying a double-stranded DNA strand. Since DNA strands are antiparallel and complementary, each strand can serve as a template for the reproduction of the opposite strand. The template strand is preserved as a whole piece and the new strand is assembled from nucleotide triphosphates. This process is called semiconservative replication. Ideally, the two resulting strands are identical, although in reality there are always errors, though proofreading and error-checking mechanisms exist to ensure a very high level of fidelity.

In a cell, this step is obligatory prior to cell division. Prokaryotes persistently replicate their DNA and creating a whole, new chromosome is a limiting step in cell division. In eukaryotes, timings are highly regulated and this occurs during the S phase of the cell cycle, preceding mitosis or meiosis I. The process may also be performed in vitro using reconstituted or completely artificial components, in a process known as PCR.

DNA may be synthesized artificially, but this process is not fundamentally a replicative process, and only produces one strand of DNA.

Introduction

DNA replication or DNA synthesis, it is the process of copying a double-stranded DNA strand. Since DNA strands are antiparallel and complementary, each strand can serve as a

template for the reproduction of the opposite strand. The template strand is preserved as a whole piece and the new strand is assembled from nucleotide triphosphates. This process is called semiconservative replication. Ideally, the two resulting strands are identical, although in reality there are always errors, though proofreading and error-checking mechanisms exist to ensure a very high level of fidelity.

In a cell, this step is obligatory prior to cell division. Prokaryotes persistently replicate their DNA and creating a whole, new chromosome is a limiting step in cell division.The large size of eukaryotic chromosomes and the limits of nucleotide incorporation during DNA synthesis, make it necessary for multiple origins of replication to exist in order to complete replication in a reasonable period of time. However, it is clear that at a replication origin the strands of DNA must dissociate and unwind in order to allow access to DNA polymerase.

The process may also be performed in vitro using reconstituted or completely artificial components, in a process known as PCR. DNA may be synthesized artificially, but this process is not fundamentally a replicative process, and only produces one strand of DNA.

3 Steps for DNA polymerization

This is a description of DNA polymerization using an enzyme. This is not the synthetic, purely chemical, laboratory method of artificially synthesizing oligos in a laboratory or oligo factory. Artificially synthesized oligos are a key aspect of the Polymerase Chain Reaction (PCR).

Initiation

In the initiation step, several key factors are recruited to an origin of replication. This origin of replication is unwound (i.e., the two strands are pulled apart at that site) and the partially unwound strands form a "replication bubble", with one replication fork on either end. Each group of enzymes at the replication fork moves away from the origin, unwinding and replicating the original DNA strands as they proceed. Primers mark the individual sequences and the starting points to be replicated.

The factors involved are collectively called the pre-replication complex. It consists of the following:

- A topoisomerase, which introduces negative supercoils into the DNA in order to minimize tortional strain induced by the unwinding of the DNA by helicase ahead of the replicational complex. The topoisomerase reversibly breaks the DNA strand, allowing the DNA to swivel, preventing the DNA from knotting up.
- A helicase, which unwinds and splits the DNA ahead of the fork. Thereafter, single-strand binding proteins (SSB) swiftly bind to the separated DNA, preventing the strands from reuniting.
- A primase (DnaG or RNA polymerase in prokaryotes, DNA polymerase ± in eukaryotes), which generates an RNA primer to be used in DNA replication.

- A DNA holoenzyme, which in reality is a complex of proteins that together perform the "actual" replication, i.e., the polymerization of nucleotides complementary to the template strand.
  - DNA polymerase III in prokaryotes DNA polymerase ´ and DNA pol µ in eukaryotes.

Elongation

5' _ _ _ _ _ _ _ _ _ _ _3' <--DNA template Primer-DNA-Primer-DNA <--Okazaki fragments 3' _ _ _ _ _ _ _ _ _ _ _5' <--complimentary DNA strand

At the beginning of elongation, an enzyme called DNA polymerase binds to the DNA and synthesizes DNA from the RNA primer, which indicates the starting point for the elongation. DNA polymerases can only synthesize the new DNA in the 5' to 3' direction. Because of this these enzymes can only travel on one side of the original strand without any interruption. This new strand, which proceeds from 5' to 3', is the leading strand. The other new strand, which procedes from 3' to 5', is the lagging strand.

In prokaryotes RNA primers are removed by DNA polymerase I, which also synthesizes DNA in their place, in eukaryotes they are removed by RNase H or FER1 and replaced with DNA by DNA polymerase ´ or µ.

Since DNA synthesis only occurs in the 5' to 3' direction, the DNA of the lagging strand is replicated in pieces known as Okazaki Fragments. Each time DNA polymerase reaches the 5' end of the RNA primer for the next Okazaki fragment, it dissociates and reassociates at the 3' end of the primer. Another enzyme, DNA ligase, is necessary to connect the Okazaki fragments.

In prokaryotes, leading strand and lagging strand synthesis are coupled by the action of the DNA polymerase III holoenzyme. One complex replicates the leading and lagging strands simultaneously. During this stage helicase continues to unwind the DNA into two single strands while topoisomerases relieves the supercoiling caused by this.

Both prokaryotes and eukaryotes have DNA polymerases with proof-reading and 3' exonuclease activities. These functions increase the fidelity of replication. Prokaryotes tend to have fewer or weaker proof-reading mechanisms due to the nature of their natural selection of their gene pools.

Termination

Termination occurs when DNA replication forks meet one another or run to the end of a linear DNA molecule. Also, termination may occur when a replication fork is deliberately stopped by a special protein, called a replication terminator protein, that binds to specific sites on a DNA molecule.

When the polymerase reaches the end of a linear DNA molecule, there is a potential problem due to the antiparallel structure of DNA. Because an RNA primer must be regularly laid down on the lagging strand, the last section of the lagging-strand DNA cannot be

replicated because there is no DNA template for the primer to be synthesized on. To solve this problem, the ends of most chromosomes consist of noncoding DNA that contains repeat sequences. The end of a linear chromosome is called the telomere. Cells can endure the shortening of the chromosome at the telomere to a degree, since it's necessary for chromosome stability. Many cells use an enzyme called telomerase that adds the repeat units to the end of the chromosome so the ends do not become too short after multiple rounds of DNA replication. Many simple, single-celled organisms overcome the whole problem by having circular chromosomes.

Before the DNA replication is finally complete, enzymes are used to proofread the sequences to make sure the nucleotides are paired up correctly in a process called DNA repair. If mistake or damage occurs, enzymes such as a nuclease will remove the incorrect DNA. DNA polymerase will then fill in the gap.

Equation

A chemical equation can be written that represents the process:

$(DNA)_{\boldsymbol{n}}$ + dNTP ’ $(DNA)_{\boldsymbol{n+1}}$ + $PP_{\boldsymbol{i}}$

Nucleotides (dNTP) used by DNA replications contain three phosphates attached to the sugar, like ATP and are named accordingly CTP, TTP, and GTP. However, in contrast to most other processes of the cell in which only one phosphate group ($P_{\boldsymbol{i}}$), the last two phosphate groups ($PP_{\boldsymbol{i}}$) (pyrophosphate group) are detached.

Organization of multiple replication sites

A diploid human cell contains 6 billion nucleotide pairs (arrayed in 46 linear chromosomes) that are copied at about 50 base pairs per second by each replication fork. Yet in a typical cell the entire replication process takes only about 8 hours. This is because there are many replication origin sites on a eukaryotic chromosome. Therefore, replication can begin at some origins earlier than at others. As replication nears completion, "bubbles" of newly replicated DNA meet and fuse, forming two new molecules.

There must be some form of regulation and organization of these multiple replication sites to prevent conflict. To date, two replication control mechanisms have been identified: one positive and one negative. For DNA to be replicated, each replication origin site must be bound by a set of proteins called the origin recognition complex. These remain attached to the DNA throughout the replication process. Specific accessory proteins, called licensing factors, must also be present for initiation of replication. Destruction of these proteins after initiation of replication prevents further replication cycles from occurring. This is because licensing factors are only produced when the nuclear membrane of a cell breaks down during mitosis.

- Immortal DNA strand hypothesis

DNA polymerase

A *DNA polymerase* is an enzyme that assists in DNA replication. Such enzymes catalyze the polymerization of deoxyribonucleotides alongside a DNA strand, which they "read" and use as a template. The newly-polymerized molecule is complementary to the template strand and identical to the template's partner strand.

All DNA polymerases synthesize DNA in the 5' to 3' direction. No known DNA polymerase is able to begin a new chain (de novo). They can only add a nucleotide onto a preexisting 3'-OH group. For this reason, DNA polymerase needs a primer at which it can add the first nucleotide. Primers consist of RNA and DNA bases with the first two bases always being RNA, and are synthesized by another enzyme called primase. An enzyme known as a helicase is required to unwind DNA from a double-strand structure to a single-strand structure to facilitate replication of each strand consistent with the semiconservative model of DNA replication.

DNA polymerases have highly-conserved structure, which means that their overall catalytic subunits vary, on a whole, very little from species to species. Conserved structures usually indicate evolutionary advantages. DNA polymerase is considered to be a holoenzyme since it requires a Magnesium ion as a co-factor to function properly. In the absence of the Magnesium ion, it is referred to as an apoenzyme.

Error correction is a property of some, but not all, DNA polymerases. This process corrects mistakes in newly-synthesized DNA. When an incorrect base pair is recognized, DNA polymerase reverses its direction by one base pair of DNA. The 3'->5' exonuclease activity of the enzyme allows the incorrect base pair to be excised (this activity is known as proofreading). Following base excision, the polymerase can re-insert the correct base and replication can continue.

Some viruses also encode special DNA polymerases which may selectively replicate viral DNA through a variety of mechanisms. Retroviruses encode an unusual DNA polymerase called reverse transcriptase, which is an RNA-dependent DNA polymerase (RdDp). It polymerizes DNA from a template of RNA.

DNA polymerase families

Based on sequence homology, DNA polymerases can be further subdivided into seven different families A, B, C, D, X, Y, and RT.

Family A

Family A polymerases contain both replicative and repair polymerases. Replicative members from this family include the extensively studied T7 DNA polymerase as well as the eukaryotic mitochondrial DNA Polymerase [3]. Among the repair polymerases are E. coli DNA pol I, Thermus aquaticus pol I, and Bacillus stearothermophilus pol I. These repair polymerases are involved in excision repair and processing of Okazaki fragments generated during lagging strand synthesis.

Family B

Family B polymerases mostly contain replicative polymerases and include the major eukaryotic DNA polymerases ±, ´, μ, and also DNA polymerase ¶. Family B also includes DNA polymerases encoded by some bacteria and bacteriophages, of which the best characterized are from T4, Phi29 and RB69 bacteriophages. These enzymes are involved in both leading and lagging strand synthesis. A hallmark of the B family of polymerases is remarkable accuracy during replication and many have strong 3'-5' exonuclease activity (except DNA polymerase ± and ¶ which have no proofreading activity).

Family C

Family C polymerases are the primary bacterial chromosomal replicative enzymes and thus have polymerase and 3'-5' exonuclease activity.

Family D

Family D polymerases are still not very well characterized. All known examples are found in the Euryarchaeota subdomain of Archaea and are thought to be replicative polymerases.

Families X

Family X contains the well known eukaryotic polymerase pol ² as well as other eukaryotic polymerases such as pol Ã, pol », pol ¼, and terminal deoxynucleotidyl transferase (TdT). Pol ² is required for short-patch base excision repair, a DNA repair pathway that is essential for repairing abasic sites. Pol » and Pol ¼ are involved in non-homologous end joining, a mechanism for rejoining DNA double-strand breaks. TdT is only expressed in lymphoid tissue and adds "n nucleotides" to double-strand breaks formed during V(D)J recombination to promote immunological diversity.

Families Y

The Y-family polymerases differ from others in having a low fidelity on undamaged templates and in their ability to replicate through damaged DNA. Members of this family are hence called translesion sythesis (TLS) polymerases. Depending on the lesion TLS polymerases can bypass the damage in an error-free or error-prone fashion, the latter resulting in elevated mutagenesis. Xeroderma pigmentosum variant (XPV) patients for instance have mutations in the gene encoding Pol · (eta), which is error-free for UV-lesions. In XPV patients alternative error-prone polymerases e.g. Pol¶ (zeta) (polymerase ¶ is a B Family polymerase), are thought to be involved in mistakes which result in the cancer predisposition of these patients. Other members in humans are Pol ¹ (iota), Pol º (kappa) and Rev1 (terminal deoxycytidyl transferase). In E.coli two TLS polymerases, Pol IV (DINB) and PolV (UMUC), are known.

Family RT

Finally, the reverse transcriptase family contain examples both from retroviruses and eukaryotic polymerases. The eukaryotic polymerases are usually restricted to telomerases. These polymerases use a RNA template to synthesize the DNA strand.

Prokaryotic DNA polymerases

Bacteria have 5 known DNA polymerases:

- *Pol I*: Is implicated in DNA repair and has both 5'->3'(Nick translation) and 3'->5' (Proofreading) exonuclease activity.
- *Pol II*: Pol II is involved in replication of damaged DNA and has both 5'->3'chain extension ability and 3'->5' exonuclease activity.
- *Pol III*: is the main polymerase in bacteria (elongates in DNA replication), as such it has 3'->5' exonuclease proofreading ability.
- *Pol IV*: is a Y-family DNA polymerase
- *Pol V*: is a Y-family DNA polymerase and participates in bypassing DNA damage

Eukaryotic DNA polymerases

Eukaryotes have at least 15 DNA Polymerases[1]:

- *Pol ±*: acts as a primase (synthesizing a RNA primer), and then as a DNA Pol elongating that primer with DNA nucleotides. After a few hundred nucleotides elongation is taken over by Pol ´ and µ.
- *Pol ²*: is implicated in repairing DNA.
- *Pol ³*: replicates mitochondrial DNA.
- *Pol ´*: is the main polymerase in eukaryotes, it is highly processive and has 3'->5' exonuclease activity.
- *Pol µ*: may substitute for *Pol ´* in lagging strand synthesis, however the exact role is uncertain.
- ·, ¹, º, and *Rev1* are Y-family DNA polymerases and *Pol ¶* is a B-family DNA polymerase. These polymerases are involved in the bypass of DNA damage.[2]
- There are also other eukaryotic polymerases known, which are not as well characterized: *¸*, *»*, *Æ*, *Ã*, and *¼*. There are also others, but the nomenclature has become quite jumbled. See the External Links or do a quick search of PubMed to get the most up-to-date information.

None of the eukariotic polymerases can remove primers (5'->3' exonuclease activity), that function is carried out by other enzymes. Only the polymerases that deal with the elongation (³, ´ and µ) have proofreading ability (3'->5' exonuclease).

Gene expression

Gene expression, or simply *expression*, is the process by which a gene's DNA sequence is converted into the structures and functions of a cell. Non-protein coding genes (e.g. rRNA genes, tRNA genes) are not translated into protein.

Gene expression is a multi-step process that begins with transcription of DNA, which genes are made of, into messenger RNA. It is then followed by post transcriptional modification and translation into a gene product, followed by folding, post-translational modification and targeting. The amount of protein that a cell expresses depends on the tissue, the developmental stage of the organism and the metabolic or physiologic state of the cell.

Patterns of gene expression

Numerous terms are used to describe patterns of gene expression, including:

- A *constitutive gene* is a gene that is transcribed continually compared to a facultative gene which is only transcribed when needed.
- A *housekeeping gene* is typically a constitutive gene that is transcribed at a relatively constant level. The housekeeping gene's products are typically needed for maintenance of the cell. It is generally assumed that their expression is unaffected by experimental conditions. Examples include actin, GAPDH and ubiquitin.
- A *facultative gene* is a gene which is only transcribed when needed compared to a constitutive gene.
- An *inducible gene* is a gene whose expression is either responsive to environmental change or dependent on the position of the cell cycle.

Measurement

Indirectly, the expression of particular genes may be assessed with DNA microarray technology, which can provide a rough measure of the cellular concentration of different messenger RNAs; often thousands at a time. While the name of this type of assessment is actually a misnomer, it is often referred to as expression profiling. The expression of many genes is known to be regulated after transcription, so an increase in mRNA concentration need not always increase expression. A more sensitive and more accurate method of relative gene expression measurement is real-time polymerase chain reaction. With carefully constructed standard curve it can even produce an absolute measurement such as in number of copies of mRNA per nanolitre of homogenized tissue, or in number of copies of mRNA per total poly-adenosine RNA. Protein expression levels can be measured by fusing the desired protein to another reporter protein, such as the green fluorescent protein or the enzyme beta-galactosidase. The expression level of these reporter proteins can be directly quantified using standard techniques.

Regulation of gene expression

Regulation of gene expression is the cellular control of the amount and timing of appearance of the functional product of a gene. Any step of gene expression may be modulated, from the DNA-RNA transcription step to post-translational modification of a protein. Gene regulation gives the cell control over structure and function, and is the basis for cellular differentiation, morphogenesis and the versatility and adaptability of any organism.

Overexpression

The protein encoded for by a gene can be expressed in increased quantity. This can come about by increasing the number of copies of the gene or increasing the binding strength of the promoter region.

Often, the DNA sequence for a protein of interest will be cloned or subcloned into a plasmid containing the lac promoter, which is then transformed into the bacterium Escherichia coli. Addition of IPTG (a lactose analog) causes the bacteria to express the protein of interest. However, this strategy does not always yield functional protein, in which case, other organisms or tissue cultures may be more effective. As for example the yeast, Saccharomyces cerevisiae, is often preferred to bacteria for proteins that undergo extensive Posttranslational modification. Nonetheless, bacterial expression has the advantage of easily producing large amounts of protein, which is required for X-ray crystallography or nuclear magnetic resonance experiments for structure determination.

Gene networks and expression

Genes have sometimes been regarded as nodes in a network, with inputs being proteins such as transcription factors, and outputs being the level of gene expression. The node itself performs a function, and the operation of these functions have been interpreted as performing a kind of information processing within cell and determine cellular behaviour.

Techniques

- Primer: Used to facilitate expression
- Shuttle Vector

Posttranslational modification

Posttranslational modification is the chemical modification of a protein after its translation. It is one of the later steps in protein biosynthesis for many proteins.

A protein (also called a polypeptide) is a chain of amino acids. During protein synthesis, 20 different amino acids can be incorporated in proteins. After translation, the posttranslational modification (PTM) of amino acids extends the range of functions of the

protein by attaching to it other biochemical functional groups such as acetate, phosphate, various lipids and carbohydrates, by changing the chemical nature of an amino acid (e.g. citrullination) or by making structural changes, like the formation of disulfide bridges.

Also, enzymes may remove amino acids from the amino end of the protein, or cut the peptide chain in the middle. For instance, the peptide hormone insulin is cut twice after disulfide bonds are formed, and a propeptide is removed from the middle of the chain; the resulting protein consists of two polypeptide chains connected by disulfide bonds.

Other modifications, like phosphorylation, are part of common mechanisms for controlling the behavior of a protein, for instance activating or inactivating an enzyme.

PTMs involving addition of functional groups

PTMs involving addition include:

- acetylation, the addition of an acetyl group, usually at the N-terminus of the protein
- alkylation, the addition of an alkyl group (e.g. methyl, ethyl)
  - methylation the addition of a methyl group, usually at lysine or arginine residues. (This is a type of alkylation.)
- biotinylation, acylation of conserved lysine residues with a biotin appendage

glutamylation, covalent linkage of glutamic acid residues to tubulin and some other proteins.
glycylation, covalent linkage of one to more than 40 glycine residues to the tubulin C-terminal tail
glycosylation, the addition of a glycosyl group to either asparagine, hydroxylysine, serine, or threonine, resulting in a glycoprotein
isoprenylation, the addition of an isoprenoid group (e.g. farnesol and geranylgeraniol)
lipoylation, attachment of a lipoate functionality
phosphopantetheinylation, the addition of a 4'-phosphopantetheinyl moiety from coenzyme A, as in fatty acid, polyketide, non-ribosomal peptide and leucine biosynthesis
phosphorylation, the addition of a phosphate group, usually to serine, tyrosine, threonine or histidine
sulfation, the addition of a sulfate group to a tyrosine.
Selenation
C-terminal amidation

PTMs involving addition of other proteins or peptides

- ISGylation, the covalent linkage to the ISG15 protein (Interferon-Stimulated Gene 15) (2)

SUMOylation, the covalent linkage to the SUMO protein (Small Ubiquitin-related

MOdifier) (1)
ubiquitination, the covalent linkage to the protein ubiquitin.

PTMs involving changing the chemical nature of amino acids

- citrullination, or deimination the conversion of arginine to citrulline deamidation, the conversion of glutamine to glutamic acid or asparagine to aspartic acid

PTMs involving structural changes

- disulfide bridges, the covalent linkage of two cysteine amino acids proteolytic cleavage, cleavage of a protein at a peptide bond

Case examples

- cleavage and formation of disulfide bridges during the production of insulin
PTM of histones as regulation of transcription: RNA polymerase control by chromatin structure
PTM of RNA polymerase II as regulation of transcription: RNA polymerase II

Protease

Proteases (proteinases, peptidases, or proteolytic enzymes) are enzymes that break peptide bonds between amino acids of proteins. The process is called peptide cleavage, a common mechanism of activation or inactivation of enzymes, especially those involved in blood coagulation or digestion. They use a molecule of water for this and are thus classified as hydrolases.

Classification

There are currently six classes of proteases:

- Serine proteases
Threonine proteases
Cysteine proteases
Aspartic acid proteases (e. g., plasmepsin)
Metalloproteases
Glutamic acid proteases

the threonine and glutamic acid proteases were not described until 1995 and 2004, respectively. The mechanism used to cleave a peptide bond involves making an amino acid residue that has the character of a polarized peptide bond (serine, cysteine and threonine peptidases) or a water molecule (aspartic acid, metallo- and glutamic acid peptidases)

nucleophilic so that it can attack the peptide carbonyl group. One way to make a nucleophile is by a catalytic triad, where a histidine residue is used to activate serine, cysteine or threonine as a nucleophile.

Occurrence

Proteases occur naturally in all organisms and constitute 1-5% of the gene content. These enzymes are involved in a multitude of physiological reactions from simple digestion of food proteins to highly regulated cascades (e.g., the blood clotting cascade, the complement system, apoptosis pathways, and the invertebrate prophenoloxidase activating cascade). Peptidases can break either specific peptide bonds (limited proteolysis), depending on the amino acid sequence of a protein, or break down a complete peptide to amino acids (unlimited proteolysis). The activity can be a destructive change abolishing a protein's function or digesting it to its principal components; it can be an activation of a function or it can be a signal in a signalling pathway.

Inhibitors

The function of peptidases is inhibited by protease inhibitor enzymes. Examples of protease inhibitors are the class of serpins (serine protease or peptidase inhibitors), incorporating alpha 1-antitrypsin. Other serpins are complement 1-inhibitor, antithrombin, alpha 1-antichymotrypsin, plasminogen activator inhibitor 1 (coagulation, fibrinolysis) and the recently discovered neuroserpin.

The natural protease inhibitors are not to be confused with the protease inhibitors used in antiretroviral therapy. Some viruses, with HIV among them, depend on proteases in their reproductive cycle. Thus, protease inhibitors are developed as antiviral means.

Degradation

Proteases, being themselves proteins, are known to be cleaved by other protease molecules, sometimes of the same variety. This may be an important method of regulation of peptidase activity.

Protease research

The field of protease research is enormous. Barrett and Rawlings estimated that approximately 8000 papers related to this field are published each year.

Ubiquitin

Ubiquitin is a small regulatory protein that is ubiquitous in eukaryotes. *Ubiquitination* (or *Ubiquitylation*) refers to the post-translational modification of a protein by the covalent attachment (via an isopeptide bond) of one or more ubiquitin monomers. Ubiquitin (originally, *Ubiquitous Immunopoietic Polypeptide*) was first identified in 1975 as an 8.5 kDa protein of unknown function expressed universally in living cells. The basic functions of ubiquitin and the components of the ubiquitination pathway were elucidated in the early 1980s in groundbreaking work performed by Aaron Ciechanover, Avram Hershko and Irwin Rose for which the Nobel Prize in Chemistry was awarded in 2004.

Poly-ubiquitination, the process in which a chain of at least four ubiquitin peptides are attached to a lysine on a substrate protein, most commonly results in the degradation of the substrate protein via the proteasome. Apparently, at least four ubiquitins are required on a substrate protein in order for the proteasome to bind and therefore degrade the substrate (though there are examples of non-ubiquitinated proteins being targeted to the proteasome).

Mono-ubiquitination, the process in which a single ubiquitin peptide is bound to a substrate, initiates cell signaling by allowing other proteins that contain ubiquitin binding domains to interact with the mono-ubiquitinated substrate. Mono-ubiquitination has been associated with targeting of membrane proteins to the lysosome, for example.

The ubiquitylation system was initially characterised as an ATP-dependent proteolytic system present in cellular extracts. A heat-stable polypeptide present in these extracts, ATP-dependent proteolysis factor 1 (APF-1), was found to become covalently attached to the model protein substrate lysozyme in an ATP and Mg2+-dependent process. Multiple APF-1 molecules were linked to a single substrate molecule by an isopeptide linkage and conjugates were found to be rapidly degraded with the release of free APF-1. Soon after APF-1-protein conjugation was characterised, APF-1 was identified as ubiquitin. The carboxyl group of the C-terminal glycine residue of ubiquitin (Gly76) was identified as the moiety conjugated to substrate lysine residues.

The protein

Ubiquitin properties (human)

Number of residues 76

Molecular mass 8564.47 Da

Isoelectric point (pI) 6.79

Gene names RPS27A (UBA80, UBCEP1), UBA52 (UBCEP2), UBB, UBC

Ubiquitin is a small protein that occurs in all eukaryotic cells. Its main function is to mark other proteins for destruction, known as proteolysis. Several ubiquitin molecules attach to the condemned protein (polyubiquitination), and it then moves to a proteasome, a barrel-shaped structure where the proteolysis occurs. Ubiquitin can also mark transmembrane proteins (for example, receptors) for removal from membranes and fulfill several signalling roles within the cell.

Ubiquitin consists of 76 amino acids and has a molecular mass of about 8500 Da. It is highly conserved among eukaryotic species: Human and yeast ubiquitin share 96 % sequence identity. The human ubiquitin sequence is:

MQIFVKTLTGKTITLEVEPSDTIENVKAKIQDKEGIPPDQQRLIFAGKQLEDGRTLSDYNIQKESTL
HLVLRLRGG

Ubiquitylation

The process of marking a protein with ubiquitin (ubiquitylation or ubiquitination) consists of a series of steps:

1. Activation of ubiquitin - Ubiquitin is activated in a two-step reaction by an E1 ubiquitin-activating enzyme in a process requiring ATP as an energy source. The initial step involves production of an ubiquitin-adenylate intermediate. The second step transfers ubiquitin to the E1 active site cysteine residue, with release of AMP. This step results in a thioester linkage between the C-terminal carboxyl group of ubiquitin and the E1 cysteine sulfhydryl group.
2. Transfer of ubiquitin from E1 to the active site cysteine of an ubiquitin-conjugating enzyme E2 via a trans(thio)esterification reaction. Mammalian genomes contain 20-30 UBCs.
3. The final step of the ubiquitylation cascade generally requires the activity of one of the hundreds of E3 ubiquitin-protein ligases (often termed simply ubiquitin ligase). E3 enzymes function as the substrate recognition modules of the system and are capable of interaction with both E2 and substrate. E3 enzymes possess one of two domains:
    - The *HECT* (Homologous to the E6-AP Carboxyl Terminus) domain
    - The *RING* domain (or the closely related *U-box* domain)

Transfer can occur in two ways:

- Directly from E2, catalysed by RING domain E3s.
- Via an E3 enzyme, catalysed by HECT domain E3s. In this case, a covalent E3-ubiquitin intermediate is formed before transfer of ubiquitin to the substrate protein.

In many cases, ubiquitin molecules are further added on to previously-conjugated ubiquitin molecules to form a polyubiquitin chain. If the chain is longer than 3 ubiquitin molecules, the tagged protein is rapidly degraded by the 26S-proteasome into small peptides (usually 3-24 amino acid residues in length). Ubiquitin moieties are cleaved off the protein by deubiquitinating enzymes and are recycled for further use.

Cell-surface transmembrane molecules that are tagged with ubiquitin are often mono-ubiquitinated, and this modification alters the subcellular localization of the protein, often targeting the protein for destruction in lysosomes.

The ubiquitin pathway is thought to be the method of cellular egress for a number of retroviruses, including HIV and Ebola, but the exact mechanism by which this occurs has yet to be deduced.

The Anaphase-promoting complex (APC) and the SCF complex (for Skp1-Cullin-F-box protein complex) are two examples of multi-subunit E3s involved in recognition and ubiquitination of specific target proteins for degradation by the proteasome.

Disease association

Genetic disorders

- The gene whose disruption causes Angelman syndrome, UBE3A, encodes an ubiquitin ligase (E3) enzyme termed E6-AP.
- The gene disrupted in Von Hippel-Lindau syndrome encodes an ubiquitin E3 ligase termed the VHL tumor suppressor or VHL gene.
- The gene disrupted in Liddle's Syndrome results in disregulation of an epithelial Na+ channel (ENaC) and causes hypertension.

Immunohistochemistry

Antibodies to ubiquitin are used in histology to identify abnormal accumulations of protein inside cells that are markers of disease. These accumulations are called inclusion bodies. Examples of such abnormal inclusions in cells are

- Neurofibrillary tangles in Alzheimer's disease

Lewy body in Parkinson's disease
Pick bodies in Pick's disease
Inclusions in motor neuron disease
Mallory's Hyalin in alcoholic liver disease
Rosenthal fibres in astrocytes

Protein biosynthesis

Within the nucleus of the cell (light blue), genes (DNA, dark blue) are transcribed into RNA. This RNA is then subject to post-transcriptional modification and control, resulting in a mature mRNA (red) that is then transported out of the nucleus and into the cytoplasm (peach), where it undergoes translation into a protein. mRNA is translated by ribosomes (purple) that match the three-base codons of the mRNA to the three-base anti-codons of the appropriate tRNA. Newly synthesized proteins (black) are often further modified, such as by binding to an effector molecule (orange), to become fully active.

Protein biosynthesis (Synthesis) is the process in which cells build proteins. The term is sometimes used to refer only to protein translation but more often it refers to a multi-step process, beginning with amino acid synthesis and transcription which are then used for translation. Protein biosynthesis, although very similar, differs between prokaryotes and eukaryotes.

Amino acid synthesis

Amino acids are the monomers which are polymerized to produce proteins. Amino acid synthesis is the set of biochemical processes (metabolic pathways) which build the amino acids from carbon sources like glucose. Not all amino acids may be synthesised by every organism, for example adult humans have to obtain 8 of the 20 amino acids from their diet.

The amino acids are then loaded onto tRNA molecules for use in the process of translation.

Transcription

Transcription is the process by which an mRNA template, carrying the sequence of the protein, is produced for the translation step from the genome. Transcription makes the template from one strand of the DNA double helix, called the template strand. Transcription takes place in 3 stages.

1. Transcription starts with the process of initiation. RNA polymerase, the enzyme which produced RNA from a DNA template, binds to a specific region on DNA that designates the starting point of transcription. This binding region is called the promoter. As the RNA polymerase binds on to the promoter, the DNA strands are beginning to unwind.
2. The second process is elongation. RNA polymerase travels along the template (noncoding) strand, synthesizing a ribonucleotide polymer. RNA

polymerase does not use the coding strand as a template because a copy of any strand produces a base sequence *complementary* to the strand which is being copied. Therefore DNA from the noncoding strand is used as a template to copy the coding strand.

3. The third stage is termination. As the polymerase reaches the termination stage, modifications are required for the newly transcribed mRNA to be able to travel to the other parts of the cell, including cytoplasm and endoplasmic reticulum for translation. A 5' cap is added to the mRNA to protect it from degradation. In eukaryotes a poly-A tail is added on the 3' end for protection and as a template for further process. Also in eukaryotes (higher organisms) the vital process of splicing occurs at this stage.

Translation

During translation, mRNA previously transcribed from DNA is decoded by specialized cellular structures called ribosomes to make proteins. Protein biosynthesis is divided into initiation, elongation and termination phases.

The ribosome has sites, which allow another specialized RNA molecule, known as tRNA, to bind to the mRNA. Binding of the correct tRNA to the mRNA on the ribosome is accomplished by an "anticodon" that is part of the tRNA. Thus, the correct tRNA, chemically linked to a specific amino acid, is directed to the ribosome to be added to a growing (nascent) polypeptide. The chemical process of connecting two amino acids is shown in the picture below.

The chemical process of connecting two amino acids resulting in a dipeptide and a water molecule

As the ribosome travels down the mRNA one codon at a time, another tRNA is attached to the mRNA at one of the ribosome sites. The first tRNA is released, but the amino acid that is attached to the first tRNA is now moved to the second tRNA, and binds to its amino acid. This translocation continues on, and a long chain of amino acid (protein), is formed.

When the entire unit reaches the stop codon on the mRNA, it falls apart and a newly formed protein is released. This is termination. It is important to know that during this process, many enzymes are used to either assist or facilitate the whole procedure.

Events following biosynthesis (Protein Synthesis)

The events following biosynthesis include post-translational modification and protein folding. During and after synthesis, polypeptide chains often fold to assume, so called, native secondary and tertiary structures. This is known as protein folding.

Many proteins undergo post-translational modification. This may include the formation of disulfide bridges or attachment of any of a number of biochemical functional groups, such as acetate, phosphate, various lipids and carbohydrates. Enzymes may also remove one or more amino acids from the leading (amino) end of the polypeptide chain, leaving a protein consisting of two polypeptide chains connected by disulfide bonds.

- Genetic code

Genetic code

The *genetic code* is the set of rules by which information encoded in genetic material (DNA or RNA sequences) is translated into proteins (amino acid sequences) by living cells. Specifically, the code defines a mapping between tri-nucleotide sequences called *codons* and amino acids; every triplet of nucleotides in a nucleic acid sequence specifies a single amino acid. Most organisms use a nearly universal code that is referred to as the *standard genetic code*. Even viruses, which are not cellular and do not synthesize proteins themselves, have proteins made using this standard code. For a time, therefore, the code was thought to be universal. However, there are notable exceptions. It is also possible for a single organism to translate different parts of the genome in different ways. For example, in humans, protein synthesis in mitochondria relies on a modified genetic code that varies from the standard one.

Cracking the genetic code

After the structure of DNA was deciphered by James Watson, Francis Crick and Rosalind Franklin, serious efforts to understand the nature of the encoding of proteins began. George Gamov postulated that a three-letter code must be employed to encode the 20 different amino acids used by living cells to encode proteins. The first elucidation of a codon was done by Marshall Nirenberg and Heinrich J. Matthaei in 1961 at the National Institutes of Health. They used a cell-free system to translate a poly-uracil RNA sequence (or UUUUU... in biochemical terms) and discovered that the polypeptide they had synthesized consisted of only the amino acid phenylalanine. They, thereby deduced from this poly-phenylalanine that the codon UUU specified the amino-acid phenylalanine. Extending this work, Nirenberg and his coworkers were able to determine the nucleotide makeup of each codon. In order to determine the order of the sequence, trinucleotides were bound to ribosomes and radioactivaly labeled aminoacyl-tRNA was used to determine, which amino acid corresponded to the codon. Nirenberg's group was able to determine the the sequences of 54 out of 64 codons. Subsequent work by Har Gobind Khorana identified the rest of the code, and shortly thereafter Robert W. Holley determined the structure transfer RNA, the adapter molecule that facilitates translation. In 1968, Khorana, Holley and Nirenberg shared the Nobel Prize in Physiology or Medicine for their work.

Transfer of information via the genetic code

The genetic information carried by an organism, its genome, is inscribed in one or more DNA, or in some cases RNA, molecules. Each functional portion of a DNA or RNA molecule is referred to as a gene. The gene sequence inscribed in DNA, and in RNA, is composed of tri-

nucleotide units called codons, each coding for a single amino acid. Each nucleotide sub-unit consists of a phosphate, deoxyribose sugar and one of the 4 nitrogenous nucleotide bases grouped into 2 categories, purine and pyrimidine. The purine bases adenine (A) and guanine (G) are larger and consist of two aromatic rings. The pyrimidine bases cytosine (C) and thymine (T) are smaller and consist of only one aromatic ring. In RNA, however, thymine (T) is substituted by uracil (U), and the deoxyribose is substituted by ribose.

Each protein-coding gene is transcribed into a short template molecule of the related polymer RNA, known as messenger RNA or mRNA. This in turn is translated on the ribosome into an amino acid chain or polypeptide, which will then fold, resulting in secondary and tertiary structures. The process of translation requires transfer RNAs specific for individual amino acids with the amino acids covalently attached to them, guanosine triphosphate as an energy source, and a number of translation factors. tRNAs have anticodons complementary to the codons in mRNA and can be "charged" covalently with amino acids at their 3' terminal CCA ends. Individual tRNAs are charged with specific amino acids by enzymes known as aminoacyl tRNA synthetases which have high specificity for both their cognate amino acids and tRNAs. The high specificity of these enzymes is a major reasons why the fidelity of protein translation is maintained.

Theoretically, there are $4^3 = 64$ different codon combinations possible with a triplet codon of three nucleotides. In reality, all 64 codons of the standard genetic code are assigned for either amino acids or stop signals during translation. If, for example, an RNA sequence, UUUAAACCC is considered and the *reading-frame* starts with the first U (by convention, 5' to 3'), there are three codons, namely, UUU, AAA and CCC, each of which specifies one amino acid. This RNA sequence will be translated into an amino acid sequence, three amino acids long.

The standard genetic code is shown in the following tables. Table 1 shows what amino acid each of the 64 codons specifies. Table 2 shows what codons specify each of the 20 standard amino acids involved in translation. These are called forward and reverse codon tables, respectively. For example, the codon AAU represents the amino acid asparagine, and UGU and UGC represent cysteine {standard three-letter designations, Asn and Cys respectively).

Table 1: RNA codon table

This table shows the 64 codons and the amino acid each codon codes for. The direction is 5' to 3'.

Salient features

Reading frame of a sequence

Note that a codon is defined by the inital nucleotide from which translation starts. For example, the string GGGAAACCC, if read from the first position, contains the codons GGG, AAA and CCC;and if read from the second position, it contains the codons GGA and AAC; if read starting from the third position, GAA and ACC. Partial codons have been ignored in this example. Every sequence can thus be read in three *reading frames*, each of which will produce a different amino acid sequence (in the given example, Gly-Lys-Pro, Gly-Asp, or Glu-Thr, respectively). With double-stranded DNA there are six possible reading frames, three in the forward orientation on one strand and three reverse, or on the opposite strand.

The actual frame a protein sequence is translated in is defined by a *start codon*, usually the first AUG codon in the mRNA sequence. Mutations that disrupt the reading frame by insertions or deletions of one or two nucleotide bases are known as frameshift mutations. These mutations may impair the function of the resulting protein, if it is formed, and are thus rare in in vivo protein-coding sequences. Often such misformed proteins are targeted for proteolytic degradation. One reason for the rareness of frame-shifted mutations being inherited is that if the protein being translated is essential for growth under the selective pressures the organism faces, absence of a functional protein may cause lethality before the organism is viable.

Start/stop codons

Translation starts with a chain initiation codon (start codon). Unlike stop codons, the codon alone is not sufficient to begin the process. Nearby sequences and initiation factors are also required to start translation. The most common start codon is AUG, which also codes for methionine, but other start codons are also used.

The three stop codons have been given names: UAG is amber, UGA is opal (sometimes also called umber), and UAA is ochre. "Amber" was named after its discoverer Harris Bernstein, whose last name means "amber" in German. The other two stop codons were named 'ochre" and "opal" in order to keep the "color names" theme. Stop codons are also called termination codons and they signal release of the nascent polypeptide from the ribosome due to binding of release factors in the absence of cognate tRNAs with anticodons complementary to these stop signals.[2]

Degeneracy of the genetic code

Many codons are *redundant*, meaning that two or more codons can code for the same amino acid. Degenerate codons may differ in their third positions; e.g., both GAA and GAG code for the amino acid glutamic acid. A codon is said to be *four-fold degenerate* if any nucleotide at its third position specifies the same amino acid; it is said to be *two-fold degenerate* if only two of four possible nucleotides at its third position specify the same amino acid. In two-fold degenerate codons, the equivalent third position nucleotides are always either two purines (A/G) or two pyrimidines (C/T). Only two amino acids are specified by a single codon; one of these is the amino-acid methionine, specified by the codon AUG, which also specifies the start of translation; the other is tryptophan, specified by the

codon UGG. The degeneracy of the genetic code is what accounts for the existence of silent mutations.

Degeneracy results because a triplet code designates 20 amino acids and a stop codon. Because there are four bases, triplet codons are required to produce at least 21 different codes. For example, if there were two bases per codon, then only 16 amino acids could be coded for (4^2=16). Because at least 21 codes are required, then 4^3 gives 64 possible codons, meaning that some degeneracy must exist.

These properties of the genetic code make it more fault-tolerant for point mutations. For example, in theory, four-fold degenerate codons can tolerate any point mutation at the third position, although codon usage bias restricts this in practice in many organisms; two-fold degenerate codons can tolerate one out of the three possible point mutations at the third position. Since transition mutations (purine to purine or pyrimidine to pyrimidine mutations) are more likely than transversion (purine to pyrimidine or vice-versa) mutations, the equivalence of purines or that of pyrimidines at two-fold degenerate sites adds a further fault-tolerance.

A practical consequence of redundancy is that some errors in the genetic code only cause a silent mutation or an error that would not affect the protein because the hydrophilicity or hydrophobicity is maintained by equivalent substitution of amino acids; for example, a codon of NUN (where N = any nucleotide) tends to code for hydrophobic amino acids. Even so, it is a single point mutation that causes a modified hemoglobin molecule in sickle-cell disease. The hydrophilic glutamate (Glu) is substituted by the hydrophobic valine (Val), which reduces the solubility of ß-globin. In this case, this mutation causes hemoglobin to form linear polymers linked by the hydrophobic interaction between the valine groups causing sickle-cell deformation of erythrocytes. Sickle-cell disease is generally not caused by a de novo mutation. Rather it is selected for in malarial regions (in a similar way to thalassemia), as heterozygous people have some resistance to the malarial Plasmodium parasite (heterozygote advantage).

These variable codes for amino acids are allowed because of modified bases in the first base of the anticodon of the tRNA, and the base-pair formed is called a wobble base pair. The modified bases include inosine and the Non-Watson-Crick U-G basepair.

Variations

Numerous variations of the standard genetic code are found in mitochondria, which are energy-producing organelles that are found inside eukaryotic cells. Mycoplasma translate the codon UGA as tryptophan. Ciliate protozoa also have some variation in the genetic code: UAG and often UAA code for glutamine (a variant also found in some green algae), or UGA codes for cysteine. Another variant is found in some species of the yeast, Candida, where CUG codes for serine. In addition in some rare cases certain proteins may also use alternate initiation (start) codons.

In certain proteins, non-standard amino acids are substituted for standard stop codons, depending upon associated signal sequences in the messenger RNA: UGA can code for selenocysteine and UAG can code for pyrrolysine as discussed in the relevant articles. A detailed description of variations in the genetic code can be found at the NCBI web site. However, there may be other non-standard interpretations that are not yet known.

Sequencing of genomes may reveal unique genetic codes that allow the incorporation of other novel amino acids into proteins.

Origin of the genetic code

Despite the variations that exist, the genetic codes used by all known forms of life on Earth are very similar. Since there are many possible genetic codes that are thought to have similar utility to the one used by Earth life, the theory of evolution suggests that the genetic code was established very early in the history of life.

One can ask the question: is the genetic code completely random, just one set of codon-amino acid correspondences that happened to establish itself and be "frozen in" early in evolution, although functionally any of the many other possible transcription tables would have done just as well? Already a cursory look at the table shows patterns that suggest that this is not the case.

There are three themes running through the many theories that seek to explain the evolution of the genetic code (and hence the origin of these patterns).[3] One is illustrated by recent aptamer experiments which show that some amino acids have a selective chemical affinity for the base triplets that code for them.[4] This suggests that the current, complex transcription mechanism involving tRNA and associated enzymes may be a later development, and that originally, protein sequences were directly templated on base sequences. Another is that the standard genetic code that we see today grew from a simpler, earlier code through a process of "biosynthetic expansion". Here the idea is that primordial life 'invented' new amino acids (e.g. as by-products of metabolism) and later back-incorporated some of these into the machinery of genetic coding. Although much circumstantial evidence has been found to indicate that originally the number of different amino acids used may have been considerably smaller than today,[5] precise and detailed hypotheses about exactly which amino acids entered the code in exactly what order has proved far more controversial.[6][7] A third is that natural selection organized the codon assignments of the genetic code to minimize the effects of genetic errors (mutations).[8]

Transcription factor

In molecular biology, a *transcription factor* is a protein that acts as a regulator of gene expression, specifically regulating the activation or inhibition of transcription in the eukaryotic nucleus. Transcription factors localise to regions of promoter and enhancer sequence elements either through direct binding to DNA or through binding other DNA-bound proteins. They act by promoting or inhibiting the formation of the preinitiation complex (PIC) that recruits and activates RNA polymerase.

The regulation of transcription factors is a highly complex process as it is dependent upon a number of events, most notable of which are the presence of other DNA binding proteins (including other transcription factors) as well as local chromatin structure. Initial models, based on in vitro exprriments suggested that there is a definite assembly sequence of transcription factors dictated by the DNA sequence. It is, however, becoming incresingly obvious that the events leading to activation of transcription are dependent on a large number of factors and are highly intertwined. Furthermore epigenetic information present on DNA appears to play an important role in transcriptional activation.

Classes

There are three classes of transcription factors:

- General transcription factors are involved in the formation of a preinitiation complex. The most common are abbreviated as TFIIA, TFIIB, TFIID, TFIIE, TFIIF, TFIIH. They are ubiquitous and interact with the core promoter region surrounding the transcription start site(s) of all class II genes.

- *Upstream transcription factors* are proteins that bind somewhere upstream of the initiation site to stimulate or repress transcription.
- *Inducible transcription factors* are similar to upstream transcription factors but require activation or inhibition.

General Definition- Protein involved in recognition by RNA polymerases of specific regulatory sequences in eukaryotic genes.

DNA motifs found in transcription factors

- Helix-turn-helix (HTH) bind the major groove of the DNA. Zinc fingers function as structural platforms for DNA binding. Leucine zippers function in associating the transcription factors with each other. Basic-helix-loop-helix (bHLH) bind DNA with two alpha helices containing basic amino acid residues which are linked by a loop and are typically dimeric. G-quadruplex Motifs are a focus for current studies in their role as a TF binding site.

Examples of transcription factors

STAT

The Signal Transducers and Activator of Transcription (STAT) proteins regulate many aspects of cell growth, survival and differentiation. The transcription factors of this family are activated by the Janus Kinase JAK and dysregulation of this pathway is frequently observed in primary tumors and leads to increased angiogenesis and enhanced survival of tumors. Knockout studies have provided evidence that STAT proteins are involved in the development and function of the immune system and play a role in maintaining immune tolerance and tumor surveillance.

Function of STAT proteins

STAT proteins were originally described as latent cytoplasmic transcription factors that require phosphorylation for nuclear retention. The unphosphorylated STAT proteins shuttle between the cytosol and the nucleus waiting for its activation signal. Once the activated transcription factors reach the nucleus, they bind to a consensus DNA-recognition motif called gamma activated sites (GAS) in the promoter region of cytokine-inducible genes and activate transcription of these genes.

Activation of STAT proteins

Extracellular binding of Cytokines induces activation of the intracellular Janus kinase that phosphorylates a specific tyrosine residue in the STAT protein which promotes the dimerization of STAT monomers via their SH2 domain. The phosphorylated dimer is then

actively transported in the nucleus via importin a/b and RanGDP complex. Once inside the nucleus the active STAT dimer binds to cytokine inducible promoter regions of genes containing gamma activated site (GAS) motif and activate transcription of this proteins. The STAT protein can be dephosphorylated by nuclear phosphatases which leads to inactivation of STAT and the transcription factor becomes transported out of the nucleus by exportin crm1/RanGTP.

Stem cells

Stem cells are primal cells that retain the ability to renew themselves through cell division and can differentiate into a wide range of specialized cell types. Research in the stem cell field grew out of findings by Canadian scientists Ernest A. McCulloch and James E. Till in the 1960s.

The two categories of stem cells include embryonic stem cells and adult stem cells and possibly a third, cord-blood-derived embryonic-like stem cells (CBEs). In a blastocyst of a developing embryo, stem cells differentiate into all of the specialised embryonic tissues. In adult organisms, stem cells and progenitor cells act as a repair system for the body, replenishing specialized cells. As stem cells can be readily grown and transformed into specialized tissues such as muscles or nerves through cell culture, their use in medical therapies has been proposed.

Stem cell properties

Defining properties

The rigorous definition of a *stem cell* requires that it possesses two properties:

- *Self-renewal* - the ability to go through numerous cycles of cell division while maintaining the undifferentiated state.
- *Unlimited potency* - the capacity to differentiate into any mature cell type. In a strict sense, this makes stem cells either *totipotent* or *pluripotent*, although some *multipotent* and/or *unipotent* progenitor cells are sometimes referred to as stem cells.

These properties can be illustrated in vitro, using methods such as clonogenic assays, where the progeny of single cell is characterized. However, in vitro culture conditions can alter the behavior of cells, making it unclear whether the cells will behave in a similar manner in vivo. Considerable debate exists whether some proposed adult cell populations are truly stem cells.

Potency definitions

Potency specifies the differentiation potential (the potential to differentiate into different cell types) of the stem cell.

- *Totipotent* stem cells are produced from the fusion of an egg and sperm cell. Cells produced by the first few divisions of the fertilized egg cell are also totipotent. These cells can differentiate into embryonic and extraembryonic cell types.
- *Pluripotent* stem cells are the descendants of totipotent cells and can differentiate into cells derived from the three germ layers.
- *Multipotent* stem cells can produce only cells of a closely related family of cells (e.g. hematopoietic stem cells differentiate into red blood cells, white blood cells, platelets, etc.).
- *Unipotent* cells can produce only one cell type, but have the property of self-renewal which distinguishes them from non-stem cells.

Embryonic stem cells

Embryonic stem cells (ES cells) are stem cells derived from the inner cell mass of a blastocyst. A blastocyst is an early stage embryo - approximately 4 to 5 days old in humans and consisting of 50-150 cells. ES cells are pluripotent, and give rise during development all derivatives of the three primary germ layers: ectoderm, endoderm and mesoderm. In other words, they can develop into each of the more than 200 cell types of the adult body when given sufficient and necessary stimulation for a specific cell type. They do not contribute to the extra-embryonic membranes or the placenta.

When given no stimuli for differentiation, ES cells will continue to divide in vitro and each daughter cell will remain pluripotent. The pluripotency of ES cells has been rigorously demonstrated in vitro and in vivo, thus they can be indeed classified as stem cells.

Because of their unique combined abilities of unlimited expansion and pluripotency, embryonic stem cells are a potential source for regenerative medicine and tissue replacement after injury or disease. To date, no approved medical treatments have been derived from embryonic stem cell research. This is not surprising considering that many nations currently have a moratorium on either ES cell research or the production of new ES cell lines.

Adult stem cells

Adult stem cells are undifferentiated cells found throughout the body that divide to replenish dying cells and regenerate damaged tissues. Also known as *somatic* (from Greek £É¼±Ä¹ºóÂ, of the body) stem cells, they can be found in children, as well as adults.

A great deal of adult stem cell research has focused on clarifying their capacity to divide or self-renew indefinitely and their differentiation potential. Many adult stem cells may be better classified as progenitor cells, due to their limited capacity for cellular differentiation.

Nevertheless, specific multipotent or even unipotent adult progenitors may have potential utility in regenerative medicine. The use of adult stem cells in research and therapy is not as controversial as embryonic stem cells, because the production of adult stem cells does not require the destruction of an embryo. In contrast with the embryonic stem cell research, more US government funding has been provided for adult stem cell research. Adult

stem cells can be isolated from a tissue sample obtained from an adult. They have mainly been studied in humans and model organisms such as mice and rats.

Lineage

To ensure self-renewal, stem cells undergo two types of cell division (see Stem cell division and differentiation diagram). Symmetric division gives rise to two identical daughter cells both endowed with stem cell properties. Asymmetric division, on the other hand, produces only one stem cell and a progenitor cell with limited self-renewal potential. Progentiors can go through several rounds of cell division before terminally differentiating into a mature cell. It is believed that the molecular distinction between symmetric and asymmetric divisions lies in differential segregation of cell membrane proteins (such as receptors) between the daughter cells.

Treatments

Medical researchers believe that stem cell research has the potential to change the face of human disease. A number of current treatments already exist, although the majority of them are not commonly used because they tend to be experimental and not very cost-effective. Medical researchers anticipate being able to use technologies derived from stem cell research to treat cancer, parkinson's disease, spinal cord injuries, and muscle damage, amongst a number of other diseases, impairments and conditions. However, there still exists a great deal of social and scientific uncertainty surrounding stem cell research, which could possibly be overcome through public debate and future research.

Stem cells, however, are already used extensively in research, and some scientists do not see cell therapy as the first goal of the research, but see the investigation of stem cells as a goal worthy in itself.

Controversy surrounding stem cell research

There exists a widespread controversy over stem cell research that emanates from the techniques used in the creation and usage of stem cells. Embryonic stem cell research is particularly controversial because, with the present state of technology, starting a stem cell line requires the destruction of a human embryo and/or therapeutic cloning. Opponents of the research argue that this practice is a slippery slope to reproductive cloning and tantamount to the instrumentalization of a human being. Contrarily, medical researchers in the field argue that it is necessary to pursue embryonic stem cell research because the resultant technologies are expected to have significant medical potential, and that the embryos used for research are only those slated for destruction anyway. The ensuing debate has prompted authorities around the world to seek regulatory frameworks and highlighted the fact that stem cell research represents a social and ethical challenge.

Key events in stem cell research

- 1960s - Joseph Altman and Gopal Das present evidence of adult neurogenesis, ongoing stem cell activity in the brain; their reports contradict Cajal's "no new neurons" dogma are largely ignored
1963 - McCulloch and Till illustrate the presence of self-renewing stem cells in mouse bone marrow
1968 - bone marrow transplant between two siblings successfully treats SCID
1978 - haematopoietic stem cells are discovered in human cord blood
1981 - mouse embryonic stem cells are derived from the inner cell mass
1992 - neural stem cells are cultured in vitro as neurospheres
1995 - President Bill Clinton signs into law the Dickey Amendment which makes it illegal for Federal money to be used for research where stem cells are derived from the destruction of the embryo.
1997 - leukemia is shown to originate from a haematopoietic stem cell, the first direct evidence for cancer stem cells
1998 - James Thomson and coworkers derive the first human embryonic stem cell line at the University of Wisconsin-Madison.
2000s - several reports of adult stem cell plasticity are published
2003 - Dr. Songtao Shi of NIH discovers new source of adult stem cells in children's primary teeth[1]
2004-2005 - Hwang Woo-Suk claims to have created several human embryonic stem cell lines from unfertilised human oocytes. The lines are later shown to be fabricated
2005 - Researchers at Kingston University in England claim to have discovered a third category of stem cell, dubbed cord-blood-derived embryoniclike stem cells (CBEs), derived from umbilical cord blood. The group claims these cells are able to differentiate into more types of tissue than adult stem cells.
2001-2006 - President George W. Bush is the first president to provide federal funding for embryonic stem cell research totaling approximately $100 Million.
July 19, 2006 - President George W. Bush vetoes H.R. 810, a bill that would have reversed the Clinton-era law which made it illegal for Federal money to be used for research where stem cells are derived from the destruction of an embryo.

Vaccination

Vaccination is the process of administering weakened or dead pathogens to a healthy person or animal, with the intent of conferring immunity against a targeted form of a related disease agent. It succeeded and is distinct from inoculation.

The term was coined by Edward Jenner and adapted by Louis Pasteur for his pioneering work in vaccination. Vaccination (Latin: vacca—cow) is so named because the first vaccine was derived from a virus affecting cows: the cowpox virus, a relatively benign virus that provides a degree of immunity to smallpox, a contagious and deadly disease. In common speech, 'vaccination' and 'immunization' generally have the same colloquial meaning.

Vaccination efforts have been met with some resistance since its inception. Early success and compulsion brought widespread acceptance and mass vaccination campaigns were undertaken which have greatly reduced the incidence of many diseases in many areas. The eradication of smallpox, which was last seen in a natural case in 1977, is considered the most spectacular success of vaccination. Currently some people assert that childhood vaccination causes some autoimmune disease and autism. Scientific studies have not demonstrated a link, however, the assertion found space in a United States House of Representatives report in 2003 which included the suggestion that mercury derivatives in vaccines might have been a cause of autism.

Triggering immune sensitization

In the generic sense, the process of artificial induction of immunity, in an effort to protect against infectious disease, works by 'priming' the immune system with an 'immunogen'. Stimulating immune response, via use of an infectious agent, is known as immunization. Vaccinations involve the administration of one or more immunogens, in the form of live, but weakened (attenuated) infectious agents, which normally are either weaker, but closely-related species (as with smallpox and cowpox), or strains weakened by some process. In such cases, an immunogen is called a vaccine.

Some modern vaccines are administered after the patient already has contracted a disease, as in the cases of experimental AIDS, cancer and Alzheimer's disease vaccines. Vaccinia given after exposure to smallpox, within the first four days, is reported to attenuate the disease considerably, and vaccination within the first week is known to be beneficial to a degree. The first Rabies immunisation was given by Pasteur to a child bitten by a rabid dog, and then and subsequently post-exposure immunisation to Rabies has generally been followed by survival. The essential empiricism behind such immunizations is that the vaccine triggers an immune response more rapidly than the natural infection itself.

Most vaccines are given by hypodermic injection as they are not absorbed reliably through the gut. Live attenuated Polio, some Typhoid and Cholera Vaccines are given orally in order to produce immunity based in the bowel.

History of vaccinations

Vaccination campaigns have spread throughout the globe since Jenner's smallpox vaccine of 1796, sometimes prescribed by law or regulations. Vaccines are now used to fight a wide variety of disease threats besides smallpox. Louis Pasteur further developed the technique during the 19th century, extending its use to protecting against bacterial anthrax and viral rabies. The method Pasteur used entailed treating the infectious agents for those diseases so they lost the ability to cause serious disease. Pasteur adopted the name vaccine as a generic term in honor of Jenner's discovery, which Pasteur's work built upon.

Prior to vaccination with cowpox, the only known protection against smallpox was inoculation or variolation (Variola - the Smallpox viruses) where a small amount of live smallpox virus was administered to the patient; this carried the serious risk that the patient would be killed or seriously ill. The death rate from variolation was reported to be around a tenth of that from natural infection with Variola, and the immunity provided was considered quite reliable. Factors contributing to the efficacy of variolation probably include the choices of Variola Minor strains used, the relatively low number of cells infected in the first phase of multiplication following initial exposure, and the exposure route used, via the skin or nasal lining rather than inhalation of droplets into the lungs.

Consistency would suggest the activity should have predated Jenner's description of an effective vaccination system, and there is some history relating to opposition to the older and more hazardous procedure of variolation.

In modern times, the first vaccine-preventible disease targeted for eradication was smallpox. The World Health Organization coordinated the global effort to eradicate this disease. The last naturally occurring case of smallpox occurred in Somalia in 1977.

In 1988, the governing body of W.H.O. targeted polio for eradication by the year 2000. Although the target was missed, eradication is very close. The next eradication target would most likely be measles, which has declined since the introduction of measles vaccination in 1963.

In 2000, the Global Alliance for Vaccines and Immunization was established to strengthen routine vaccinations and introduce new and under-used vaccines in countries with a per capita GDP of under US$1000. GAVI is now entering its second phase of funding, which extends through 2014.

Compulsory vaccination and opposition to vaccination

In an attempt to eliminate the risk of outbreaks of some diseases, several governments and other institutions have instituted policies requiring vaccination for all people. For example, an 1853 law required universal vaccination against smallpox in England and Wales, with fines levied on people who did not comply. In the United States, the Supreme Court ruled in the 1905 case Jacobson v. Commonwealth of Massachusetts that the state could require individuals to be vaccinated for the common good. Common contemporary vaccination policies require that children receive common vaccinations before entering school. Compulsory vaccination is believed to have greatly reduced the rates of some infectious diseases.[1]

Beginning with early vaccination in the nineteenth century, these policies led to resistance from a variety of groups, collectively called anti-vaccinationists, who objected on ethical, political, medical safety, religious, and other grounds. Common objections are that compulsory vaccination represents excessive government intervention in personal matters, or that the proposed vaccinations are not sufficiently safe. Many modern vaccination policies allow exemptions for people who have compromised immune systems, allergies to the components used in vaccinations or strongly-held objections.[1]

In 1904 in the city of Rio de Janeiro, Brazil a government program of mandatory smallpox vaccination resulted in the so-called Vaccine Revolt, several days of rioting with considerable property damage and a number of deaths.

Herd immunity and medical risk management issues

Vaccination campaigns are generally accepted as having contributed to the worldwide elimination of smallpox, through herd immunity, and to the restriction of polio to isolated pockets in countries where healthcare access is difficult. The risk management practices of government health agencies' promoting widespread vaccination campaigns has prompted increasing controversy in recent years, despite the fact that many once-common childhood diseases, such as mumps, measles and rubella, are now relatively rare in developed countries.

Nevertheless, vaccination campaigns may have unfortunate co-evolutionary side-effects, particularly if they produce a selective pressure in favor of certain strains against which there are no vaccines or treatment. Another problem related to co-evolution is that vaccines that may eliminate one infectious diseases or another may, in turn, allow others to thrive in the ecological niche that has been vacated. For example, it has been postulated that (the less-often-fatal) serogroup-B meningitis strains may expand into the niche provided if serogroup-C is largely eradicated through vaccination. However, while there has been a rise in serogroup-B meningitis, there is as yet no evidence to link this to the meningitis-C vaccination.

An incompletely-successful attempt at eradication of a disease through vaccination might increase the average age of contraction of the disease. In diseases such as measles, where there is a higher rate of complication in older people, the overall effect might, in theory, be to cause more deaths than before the vaccination was introduced. Potentially, this could be a 'perverse effect' of vaccination campaigns. Observation of immunity levels in a population over many years has been followed by booster immunization programs, for instance, in the United Kingdom, with measles and mumps.

Adjuvants and preservatives

Vaccines typically contain one or more adjuvants, used to boost the immune response. Tetanus toxoid for instance is usually adsorbed onto Alum. This presents the antigen in such a way as to produce a greater action than the simple aqueous tetanus toxoid. People who get an excessive reaction to adsorbed tetanus toxoid may be given the simple vaccine when time for a booster occurs.

In the preparation for the 1990 Gulf campaign, Pertussis vaccine (not acellular) was used as an adjuvant for Anthrax vaccine. This produces a more rapid immune response than giving only the Anthrax, which is of some benefit if exposure might be imminent.

They may also contain preservatives, which are used to prevent contamination with bacteria or fungi. Until recent years, the preservative thiomersal was used in many vaccines that did not contain live virus. As of 2005, the only childhood vaccine in the U.S.A. that contains thiomerosal is the influenza vaccine [2], which is currently recommended only for children with certain risk factors.[2] The UK is considering Influenza immunisation in children perhaps as soon as in 2006-7. Single-dose Influenza vaccines supplied in the UK do not list Thiomersal (its UK name) in the ingredients. Preservatives may be used at various stages of production of vaccines, and the most sophisticated methods of measurement might

detect traces of them in the finished product, as they may in the environment and population as a whole[3].

Vaccine research

Some major contemporary research in vaccination focuses on development of vaccinations for diseases including HIV and malaria.

Vaccine is an international peer-reviewed journal for vaccination researchers, indexed in Medline pISSN: 0264-410X.

Vaccines

A *vaccine* is an antigenic preparation used to establish immunity to a disease. The term derives from Edward Jenner's use of cowpox ("vacca" means cow in Latin), which, when administered to humans, provided them protection against smallpox, which Pasteur and others perpetuated. The process of distributing and administrating vaccines is referred to as vaccination.

Vaccines can be prophylactic (e.g. to prevent or ameliorate the effects of a future infection by any natural or "wild" pathogen), or therapeutic (e.g. vaccines against cancer are also being investigated).

Types of vaccines

Vaccines may be living, weakened strains of viruses or bacteria that intentionally give rise to unapparent-to-trivial infections. Vaccines may also be killed or inactivated organisms or purified products derived from them.

There are four types of traditional vaccines:

- Inactivated - these are previously virulent micro-organisms that have been killed with chemicals or heat. Examples are vaccines against flu, cholera, bubonic plague, and hepatitis A. Most such vaccines may have incomplete or short-lived immune responses and are likely to require booster shots.
- Live, attenuated - these are live micro-organisms that have been cultivated under conditions that disable their virulent properties. They typically provoke more durable immunological responses and are the preferred type for healthy adults. Examples include yellow fever, measles, rubella, and mumps.
- Toxoids - these are inactivated toxic compounds from micro-organisms in cases where these (rather than the micro-organism itself) cause illness. Examples of toxoid-based vaccines include tetanus and diphtheria.
- Subunit - rather than introducing a whole inactivated or attenuated micro-organism to an immune system, a fragment of it can create an immune

response. Characteristic example is the subunit vaccine against HBV that is composed of only the surface proteins of the virus (produced in yeast)

The live tuberculosis vaccine is not the contagious TB strain, but a related strain called "BCG"; it is used in the United States very infrequently.

A number of innovative vaccines are also in development and in use:

- Conjugate - certain bacteria have polysaccharide outer coats that are poorly immunogenic. By linking these outer coats to proteins (e.g. toxins), the immune system can be led to recognize the polysaccharide as if it were a protein antigen. This approach is used in the Haemophilus influenzae type B vaccine.
- Recombinant Vector - by combining the physiology of one micro-organism and the DNA of the other, immunity can be created against diseases that have complex infection processes
- DNA vaccination - in recent years a new type of vaccine, created from an infectious agent's DNA called DNA vaccination, has been developed. It works by insertion (and expression, triggering immune system recognition) into human or animal cells, of viral or bacterial DNA. Some cells of the immune system that recognize the proteins expressed will mount an attack against these proteins and cells expressing them. Because these cells live for a very long time, if the pathogen that normally expresses these proteins is encountered at a later time, they will be attacked instantly by the immune system. One advantage of DNA vaccines is that they are very easy to produce and store. As of 2006, DNA vaccination is still experimental, but shows some promising results.

Note that while most vaccines are created using inactivated or attenuated compounds from micro-organisms, synthetic vaccines are composed mainly or wholly of synthetic peptides, carbohydrates or antigens.

Developing immunity

The immune system recognizes vaccine agents as foreign, destroys them, and 'remembers' them. When the virulent version of an agent comes along, the immune system is thus prepared to respond, by (1) neutralizing the target agent before it can enter cells, and (2) by recognizing and destroying infected cells before that agent can multiply to vast numbers.

Vaccines have contributed to the eradication of smallpox, one of the most contagious and deadly diseases known to man. Other diseases such as rubella, polio, measles, mumps, chickenpox, and typhoid are nowhere near as common as they were just a hundred years ago. As long as the vast majority of people are vaccinated, it is much more difficult for an outbreak of disease to occur, let alone spread. This effect is called herd immunity. Polio, which is transmitted only between humans, is targeted by an extensive eradication campaign that has seen endemic polio restricted to only parts of four countries. The difficulty of reaching all children, however, has caused the eradication date to be missed twice by 2006.

Vaccination schedule

In order to provide best protection, children are recommended to receive vaccinations as soon as their immune systems are sufficiently developed to respond to particular vaccines, with additional 'booster' shots often required to achieve 'full immunity'. This has led to the development of complex vaccination schedules. In the United States, the Advisory Committee on Immunization Practices, which recommends schedule additions for the Center for Disease Control, recommends routine vaccination of children against: hepatitis A, hepatitis B, polio, mumps, measles, rubella, diphtheria, pertussis, tetanus, HiB, chicken pox, rotavirus, influenza, meningococcal disease and pneumonia. The large number of vaccines and boosters recommended (up to 24 injections by age two) has led to problems with achieving full compliance. In order to combat declining compliance rates, various notification systems have been instituted and a number of combination injections are now marketed (e.g., Prevnar and ProQuad vaccines), which provide protection against multiple diseases. Complete scheduled vaccinations may be a requirement for school admission at various grades. In the US, there are varying exemptions that may be claimed by parents, for religious or other reasons.

Besides recommendations for infant vaccination boosters, many specific vaccines are recommended for repeated injections throughout life -- most commonly for measles, tetanus, influenza, and pneumonia. Pregnant women are often screened for continued resistance to rubella. In 2006, a vaccine was introduced against shingles, a disease caused by the chicken pox virus, which usually affects the elderly. Vaccine recommendations for the elderly concentrate on pneumonia and influenza, which are more deadly to that group.

Vaccine Controversies

Main article: Vaccine controversy

Opposition to vaccination, from a wide array of vaccine critics, has existed since the earliest vaccination campaigns:

A number of vaccines, including those given to very young children, have contained thimerosal, a preservative that metabolizes into ethylmercury. It has been used in some influenza, DTP (diphtheria, tetanus and pertussis) vaccine formulations. Since 1997, use of thimerosal has been gradually diminishing in western industrialized countries after recommendations by medical authorities, but trace amounts of thimerosal remain in many vaccines and in some vaccines, thimerosal has not yet been phased out despite recommendations. Some states in USA have enacted laws banning the use of thimerosal in childhood vaccines.

In the late 1990s, controversy over vaccines escalated in both the US and the United Kingdom when a study, published in the respected journal Lancet, by Dr. Andrew Wakefield suggested a possible link between bowel disorders, autism and MMR vaccine, and urged further research. His report, which focused upon a novel syndrome he described as autistic enterocolitis, garnered significant media attention, leading to a drop in the uptake of the MMR vaccine in the UK and some other countries. The study garnered criticism for its small sample size, and for failing to use healthy controls. In response to the controversies, a

number of studies with larger sample sizes were conducted, and failed to confirm the findings. In 2004, 10 of the 13 authors of the original Wakefield study retracted the paper's interpretation, without disputing the central finding of a consistent set of bowel disorders among the autistic study subjects, stating the data were insufficient to establish a causal link between MMR vaccine and autism. Wakefield was also later found to have received a substantial sum from trial lawyers to fund this research further calling into question the validity of its findings. Also in 2004, the United States' Institute of Medicine reported that evidence "favors rejection" of any link between vaccines containing thimerosal, or MMR, and the development of autism.

In 2004 and 2005, England and Wales experienced an increase in the incidence of mumps infections among adolescents and young adults. The age group affected were too old to have received the routine MMR immunisations around the time Wakefield et al's paper was published, and too young to have contracted natural mumps as a child, and thus to achieve a herd immunity effect. With the decline in mumps that followed the introduction of the MMR vaccine, these individuals had not been exposed to the disease, but still had no immunity, either natural or vaccine induced. Therefore, when the disease re-emerged as immunization rates declined following the controversy, they were susceptible to infection. This and similar examples indicate the importance of:

1. careful modelling to anticipate the impact that an immunisation campaign will have on the epidemiology of the disease in the medium to long term
2. ongoing surveillance for the relevant disease following introduction of a new vaccine and
3. maintaining high immunisation rates, even when a disease has become rare.

There is opposition to vaccination (of any type) from some sectors of the community, particularly those who favour 'alternative' health care. Often this opposition is not based on specific data or details but rather a general leaning against conventional medicine and science. Naturopaths and other alternative health care practitioners sometimes offer their own, alternative treatments to conventional vaccination.

In Australia, a massive increase in vaccination rates was observed when the federal government made certain benefits (such as the universal 'Family Allowance' welfare payments for parents of children) dependent on vaccination. As well, children were not allowed into school unless they were either vaccinated or their parents completed a statutory declaration refusing to immunize them, after discussion with a doctor, and other bureaucracy. (Similar school-entry vaccination regulations have been in place in some parts of Canada for several years.) It became easier and cheaper to vaccinate one's children than not to. When faced with the annoyance, many more casual objectors simply gave in.

Potential for adverse side effects in general

Some refuse to immunize themselves or their children, because they believe certain vaccines' adverse side effects outweigh their benefits. A variation of this reasoning is that not enough is known of the adverse effects to determine whether the potential benefits make

the risks worthwhile. Since most people are vaccinated against contagious and potentially fatal diseases, the chances of someone who is not vaccinated becoming ill is a good deal smaller than it might be if their opinion was held by more people. Therefore, they acquire some of the benefits of vaccines through herd immunity without assuming the risks those who choose to vaccinate do.

Advocates of recommended routine vaccination argue that side effects of most approved vaccines are either far less serious than actually catching the disease, or are very rare, and argue that the calculus of risk/benefit ratio should be based on benefit to humanity rather than simply on the benefit to the immunized individual. The main risk of rubella, for example, is to the fetuses of pregnant women, but this risk can be effectively reduced by the immunization of children to prevent transmission to pregnant women.

Efficacy of vaccines

Vaccines do not guarantee complete protection from a disease. Even after a vaccination, there is still a possibility that a vaccinated person may get the disease. Sometimes this is because the host's immune system simply doesn't respond adequately or at all. This is known in medical jargon as a 'low titre of antibodies'. This may be due to a lowered immunity in general (diabetes, steroid use, HIV infection) or just bad luck (the host's immune system does not have a B-cell capable of generating antibodies to that antigen).

Even if the host develops antibodies, the human immune system is not perfect. Some germs can mutate (the common cold and influenza viruses are highly efficient at this), and in any case the immune system might still not be able to defeat the infection.

Adjuvants are typically used to boost immune response. The efficacy or performance of the vaccine is dependent on a number of factors:

- the disease itself (for some diseases vaccination performs better than for other diseases)
- the strain of vaccine (some vaccinations are for different strains of the disease)
- whether one kept to the timetable for the vaccinations
- some individuals are 'non-responders' to certain vaccines, meaning that they do not generate antibodies even after being vaccinated correctly
- other factors such as ethnicity or genetic predisposition

In cases where a vaccinated individual does develop the disease vaccinated against, the disease is likely to be milder than without vaccination.

Adverse effects (known and suspected)

Some autoimmune diseases like Acute disseminated encephalomyelitis, Guillain-Barré syndrome, Transverse myelitis and multiple sclerosis are known to be connected to vaccines, which suggests other autoimmune disorders might also be vaccine-related **[1]** **[2]**

Economics of vaccine development

One challenge in vaccine development is economic: many of the diseases most demanding a vaccine, including HIV, malaria and tuberculosis, exist principally in poor countries. Although some contend pharmaceutical firms and biotech companies have little incentive to develop vaccines for these diseases, because there is little revenue potential, the number of vaccines actually administered has risen dramatically in recent decades. This increase, particularly in the number of different vaccines administered to children before entry into schools may be due to government mandates, rather than economic incentive. Most vaccine development to date has relied on 'push' funding by government and non-profit organizations, of government agencies, universities and non-profit organizations.

Many researchers and policymakers are calling for a different approach, using 'pull' mechanisms to motivate industry. Mechanisms such as prizes, tax credits, or advance market commitments could ensure a financial return to firms that successfully developed an HIV vaccine. If the policy were well-designed, it might also ensure people have access to a vaccine if and when it is developed.

Preservatives

In order to extend shelf life and reduce production and storage costs, thimerosal, a mercury-containing organic compound, was used routinely until recent years as a preservative. Thimerosal was gradually being phased out in the U.S. (it has been phased out in other countries, e.g. Denmark in 1992), but may be used in stages of manufacture. Parents wishing to avoid this preservative, most common in multi-dose containers of influenza vaccine, may specifically ask for thimerosal-free alternatives that contain only trace amounts. The mercury-free vaccines are, however, extremely difficult for parents to find. Often health care workers have insufficient knowledge needed to discuss the issue with parents, and often they will report to parents that vaccines are mercury free when in fact that is not the case. Recently, the Bush Administration has taken measures to drastically ease many regulations preventing mercury from being put into vaccines, and also has taken measures to permit industrial producers to use levels of mercury in vaccines much higher than previously permitted. Mercury is the leading candidate for the widely discussed autism epidemic currently afflicting children, and, as has been noted by many researchers, children who are unvaccinated (such as some Amish groups), have drastically reduced autism rates as compared to children who are vaccinated.

Chickenpox, also spelled *chicken pox*, is the common name for Varicella simplex, classically one of the childhood infectious diseases caught and survived by most children.

Chickenpox is caused by the varicella-zoster virus (VZV), also known as human herpes virus 3 (HHV-3), one of the eight herpes viruses known to affect humans. It starts with conjunctival and catarrhal symptoms, moderate fever and then characteristic spots appearing in two or three waves, mainly on the body and head rather than the hands and becoming itchy raw pox (pocks), small open sores which heal mostly without scarring.

Chickenpox has a two-week incubation period and is highly contagious by air transmission two days before symptoms appear. Following primary infection there is usually lifelong protective immunity from further episodes of chickenpox. Recurrent chickenpox is fairly rare but more likely in people with compromised immune systems.

Symptomatic treatment, with calamine lotion to ease itching and paracetamol (known in the U.S. as acetaminophen) to reduce fever, is widely used.

Chickenpox is rarely fatal (usually from varicella pneumonia), with pregnant women and those with depressed immune systems being more at risk. Pregnant women not known to be immune and who come into contact with chickenpox may need urgent treatment as the virus can cause serious problems for the fetus.

Later in life, viruses remaining dormant in the nerves can reactivate causing localised eruptions of shingles. This occurs particularly in people with compromised immune systems,

such as the elderly, and perhaps even those suffering sunburn. Unlike chickenpox which normally fully settles, shingles may result in persisting post-herpetic neuralgia pain.

A chickenpox vaccine has been available since 1995, and is now required in some countries for children to be admitted into elementary school unless the parent/guardian submits an exemption. In addition, effective medications (e.g. aciclovir) are available to treat chickenpox in healthy adults and immunocompromised persons.

Symptoms and signs

Chickenpox is highly infectious and spreads from person to person by direct contact or through the air from an infected person's coughing or sneezing. Touching the fluid from a chickenpox blister can also spread the disease. A person with chickenpox is contagious 1–2 days before the rash appears and until all blisters have formed scabs. This may take between 5–10 days.[1] It takes from 10–21 days after contact with an infected person for someone to develop chickenpox.[2]

The chickenpox lesions (blisters) start as a 2–4 mm red papule which develops an irregular outline (rose petal). A thin-walled, clear vesicle (dew drop) develops on top of the area of redness. This "dew drop on a rose petal" lesion is very characteristic for chickenpox. After about 8–12 hours the fluid in the vesicle gets cloudy and the vesicle breaks leaving a crust. The fluid is highly contagious, but once the lesion crusts over, it is not considered contagious. The crust usually falls off after 7 days sometimes leaving a crater-like scar. Although one lesion goes through this complete cycle in about 7 days, another hallmark of chickenpox is the fact that new lesions crop up every day for several days. Therefore, it may take about a week until new lesions stop appearing and existing lesions crust over. Children are not sent back to school until all lesions have crusted over.[3]

Second infections with chickenpox occur in immunocompetent individuals, but are uncommon. Such second infections are rarely severe. A soundly-based conjecture being carefully assessed in countries with low prevalence of chickenpox due to immunisation, low birth rates, and increased separation is that immunity has been reinforced by subclinical challenges and this is now less common. This is more dangerous with shingles. There have been reported cases of repeat infections.[4][5]

Congenital defects in babies

These may occur if the child's mother was exposed to VZV during pregnancy. Effects to the fetus may be minimal in nature but physical deformities range in severity from under developed toes and fingers, to severe anal and bladder malformation. Possible problems include:

- Damage to brain: encephalitis, microcephaly, hydrocephaly, aplasia of brain
- Damage to the eye (optic stalk, optic cup, and lens vesicles), microphthalmia, cataracts, chorioretinitis, optic atrophy.

- Other neurological disorder: damage to cervical and lumbosacral spinal cord, motor/sensory deficits, absent deep tendon reflexes, anisocoria/Horner's syndrome
- Damage to body: hypoplasia of upper/lower extremities, anal and bladder sphincter dysfunction
- Skin disorders: zig zag (cicatricial) skin lesions, hypopigmentation

Prognosis and treatment

Chickenpox infection tends to be milder the younger a child is and symptomatic treatment for itch (e.g. calamine lotion and/or antihistamines) and fever (with paracetamol or ibuprofen) is usually all that is required. Infection in otherwise healthy adults tends to more severe and active; treatment with antiviral drugs (e.g. aciclovir) is generally advised. Patients of any age with depressed immune systems or extensive eczema are at risk of more severe disease and should also be treated with antiviral medication. In the U.S., 55 percent of chickenpox deaths were in the over-20 age group.

Screening and prevention

In the UK Varicella antibodies are measured as part of the routine of prenatal care, and by 2005 all NHS healthcare personnel had determined their immunity and been immunised if they were non-immune and have direct patient contact.

History

One history of medicine book credits Giovanni Filippo (1510–1580) of Palermo with the first description of varicella (chickenpox). Subsequently in the 1600s, an English physician named Richard Morton described what he thought a mild form of smallpox as "chicken pox." Later, in 1767, a physician named William Heberden, also from England, was the first physician to clearly demonstrate that chickenpox was different from smallpox. However, it is believed the name chickenpox was commonly used in earlier centuries before doctors identified the disease.

There are many explanations offered for the origin of the name chickenpox:

- the specks that appear looked as though the skin was pecked by chickens;
- the disease was named after chick peas, from a supposed similarity in size of the seed to the lesions;
- Samuel Johnson suggested that the disease was "no very great danger," thus a "chicken" version of the pox;
- the term reflects a corruption of the Old English word, "giccin", which meant "itching".

As "pox" also means curse, in medieval times some believed it was a plague brought on to curse children by the use of black magic.

During the medieval era, oatmeal was discovered to soothe the sores, and oatmeal baths are today still commonly given to relieve itching.

Vaccination

Japan was among the first countries to routinely vaccinate for chickenpox. Routine vaccination against varicella zoster virus is also performed in the United States, and the incidence of chickenpox has been dramatically reduced there (from 4 million cases per year in the pre-vaccine era to approximately 400,000 cases per year as of 2005). In Europe most countries do not currently vaccinate against varicella, though the vaccine is gaining wider acceptance. Australia, Canada, and other countries have now adopted recommendations for routine immunization of children and susceptible adults against chickenpox. Other countries, such as Germany and the United Kingdom, have targeted recommendations for the vaccine, e.g., for susceptible health care workers at risk of varicella exposure.

Chickenpox is most often a mild disease, especially for children. Prior to the introduction of vaccine, there were around 4,000,000 cases per year in the U.S., mostly children, with typically 100 or fewer deaths. Though mostly children caught it, the majority of deaths (by as much as 80%) were among adults. Additionally, chickenpox involved the hospitalization of about 10,000 people each year.[6]

During 2003 and the first half of 2004, the CDC reported eight deaths from varicella, six of whom were children or adolescents. These deaths and hospitalizations have substantially declined in the U.S. due to vaccination,[7][8] though the rate of shingles infection has increased for the same reason. The vaccine has more recently been determined to be effective at preventing shingles (zoster) in persons 60 years of age and older, if administered regularly.[9]

The long-term duration of protection from varicella vaccine is unknown, but there are now persons vaccinated more than thirty years ago with no evidence of waning immunity, while others have become vulnerable in as few as 6 years. Assessments of duration of immunity are complicated in an environment where natural disease is still common, which typically leads to an overestimation of effectiveness, and we are only now entering an era in the U.S. where the long-term efficacy of varicella vaccine can be accurately gauged.[10]

The vaccine is exceedingly safe: approximately 5% of children who receive the vaccine develop a fever or rash, but there have been no deaths yet (as of 1 May 2006) attributable to the vaccine despite more than 40 million doses being administered.[11] Cases of vaccine-related chicken pox have been reported in patients with a weakened immune system,[11][12] but no deaths.

The literature contains several reports of adverse reactions following varicella vaccination,[13][14][15][16][17][18][19][20][21][22][23][24][25] including vaccine-strain zoster in children and adults.[26][27] A mean of 2,350 reports per year are attributed to varicella vaccine based on 20,004 cases reported to the Vaccine Adverse Event Reporting System (VAERS) database from May, 1995 through December, 2003. Minor events are known to be under-reported to VAERS.

Controversy

Mortality due to primary varicella has declined significantly in countries which make wide use of the varicella vaccine.[7][11] Zoster (shingles) occurs decades after varicella and unsurprisingly zoster incidence has not declined in multiple studies. It is too early to observe the effect on postherpetic neuralgia (PHN).

It has been claimed that shingles may increase after introduction of varicella vaccine.[28][29] There is yet no evidence this has occurred, and it might occur in the absence of immunisation due to a general decrease in childhood infection for other reasons.[30]

Vaccination is common in the United States, with 41 of the 50 states require immunization for children attending government-run schools. All 50 states offer a medical exemption, and 48 of those states also offering philosophical and/or religious exemptions. The vaccination is not routine in the United Kingdom. Debate continues in the UK on the time when it will be desirable to adopt routine chickenpox vaccination, and in the U.S. opinions that it should be dropped, individually, or along with all immunizations, are also voiced.

Additional controversy has arisen because cell lines derived from aborted fetal tissue were used in its development, and thus violates the ethics and beliefs of people who oppose the use of aborted fetal tissue in medical research.CDC

Duration of immunity

Some vaccinated children have been found to lose their protective antibody in as little as five to eight years; however, according to the World Health Organization: "After observation of study populations for periods of up to 20 years in Japan and 10 years in the United States, more than 90% of immunocompetent persons who were vaccinated as children were still protected from varicella."[6] As time goes on, boosters may be determined to be necessary, and introduced. Persons infected after vaccine experience milder cases of chicken pox.[2]

Catching wild chickenpox as a child has been thought to commonly result in lifelong immunity, indeed parents have deliberately ensured this in the past with "pox parties" (and similarly for some other diseases such as rubella. See below.) Historically, exposure of adults to contagious children has boosted their immunity, reducing the risk of shingles.[29] Second episodes of chickenpox have been rare, but occur and probably more frequently in the UK latterly and definitely more frequently in the vaccine group. In one study, 30% of children had lost the antibody after five years, and 8% had already caught "wild" chickenpox in that five year period.[31]

The CDC and corresponding national organisations are carefully observing the failure rate which may be high compared with other modern vaccines - large outbreaks of chickenpox having occurred at schools which required their children to be vaccinated.

Immunocompromise

The mortality rate in immunocompromised patients with disseminated herpes zoster is 5-15%, with most deaths from pneumonia. Vaccines, unfortunately are less effective among these high-risk patients, as well as being more dangerous because it is an attenuated live virus (see last footnote), but clearly immunisation before immunocompromise would be desirable.

Pox parties

A "pox party" is a party held by parents for the purpose of infecting their children with childhood diseases. Similar ideas have applied to other diseases, e.g. measles, but are now discouraged by doctors and health services. The rationale behind such parties is that guests exposed to the varicella virus will contract the disease and develop strong and persistent immunity, at an age before disaster is likely particularly from chickenpox or rubella.

The first reference to such a practice is the letter of Lady Montagu to Sarah Chiswell describing the parties people in Istanbul made for the purpose of variolation - an effective technique for gaining immunity to smallpox, which she imported to England.

Pox parties have been portrayed in TV cartoons, including South Park ("Chickenpox") and The Simpsons ("Milhouse of Sand and Fog").

Flu vaccine

The *flu vaccine* is a vaccine to protect against the highly variable influenza virus.

The annual flu kills an estimated 36,000 people in the United States each year. The annually updated trivalent flu vaccine for the 2006-2007 season consists of hemagglutinin (HA) surface glycoprotein components from influenza H3N2, H1N1, and B influenza viruses.[1]

Each year the influenza virus changes and different strains become dominant. Due to the high mutability of the virus a particular vaccine formulation usually only works for about a year. The World Health Organization co-ordinates the contents of the vaccine each year to contain the most likely strains of the virus to attack the next year. The flu vaccine is usually recommended for anyone in a high-risk group who would be likely to suffer complications from influenza.

History of the flu vaccine

Vaccines are used in both humans and nonhumans. Human vaccine is meant unless specifically identified as a veterinary or poultry or livestock vaccine.

Vaccines prior to flu vaccines

A vaccine is an antigenic preparation used to produce active immunity to a disease, in order to prevent or ameliorate the effects of infection by any natural or "wild" strain of the organism. The process of distributing and administrating vaccines is referred to as vaccination. Smallpox is the first disease people tried to prevent by purposely inoculating themselves with other types of infections. Smallpox inoculation is believed to have started in India or China before 200 BC. In 1718, Lady Mary Wortley Montague reported that the Turks have a habit of deliberately inoculating themselves with fluid taken from mild cases of smallpox and she inoculated her own children. In 1796 Edward Jenner inoculated using cowpox (a mild relative of the deadly smallpox virus). Pasteur and others built on this.[2]

Influenza

Influenza commonly known as the flu, is an infectious disease that infects birds and mammals (primarily of the upper airways and lungs in mammals) and is caused by an RNA virus of the Orthomyxoviridae family (the influenza viruses). The most common and characteristic symptoms of influenza in humans are fever, pharyngitis (sore throat), myalgia (muscle pains), severe headache, coughing, and malaise (weakness and fatigue).[3] Hippocrates first described the symptoms of influenza in 412 B.C.. Since then, the virus has undergone mutations and shifts and has caused numerous pandemics. The first influenza pandemic was recorded in 1580, since this time, various methods have been employed to eradicate its cause.[4] The etiological cause of influenza, the orthomyxoviridae was finally discovered by the Medical Research Council (MRC) of the United Kingdom in 1933.[5]

Known flu pandemics:[6]

- 1889-90 - Asiatic (Russian) Flu, mortality rate said to be 0.75-1 death per 1000 possibly H2N2

1900 - possibly H3N8
1918–20 – Spanish Flu, 500 million ill, at least 40 million died of H1N1
1957–58 – Asian Flu, 1 to 1.5 million died of H2N2
1968–69 – Hong Kong Flu, 3/4 to 1 million died of H3N2

Flu vaccine origins

In the world wide Spanish flu pandemic of 1918, "Physicians tried everything they knew, everything they had ever heard of, from the ancient art of bleeding patients, to administering oxygen, to developing new vaccines and sera (chiefly against what we now call Hemophilus influenzae—a name derived from the fact that it was originally considered the etiological agent—and several types of pneumococci). Only one therapeutic measure, transfusing blood from recovered patients to new victims, showed any hint of success."[7]

"In 1931, viral growth in embryonated hens' eggs was discovered, and in the 1940s, the US military developed the first approved inactivated vaccines for influenza, which were used in the Second World War".[2]

Flu vaccine acceptance

The current egg-based technology for producing influenza vaccine was created in the 1950s.[8]

"The WHO Global Influenza Surveillance Network was established in 1952. The network comprises 4 WHO Collaborating Centres (WHO CCs) and 112 institutions in 83 countries, which are recognized by WHO as WHO National Influenza Centres (NICs). These NICs collect specimens in their country, perform primary virus isolation and preliminary antigenic characterization. They ship newly isolated strains to WHO CCs for high level antigenic and genetic analysis, the result of which forms the basis for WHO recommendations on the composition of influenza vaccine for the Northern and Southern Hemisphere each year."[9]

In the U.S. swine flu scare of 1976 President Gerald Ford was confronted with a potential swine flu pandemic. The vaccination program was plagued by delays and public relations problems, but about 24% of the population was vaccinated by the time the program was cancelled with much concern and doubt about flu vaccination.[10]

According to the CDC: "Influenza vaccination is the primary method for preventing influenza and its severe complications. [...] Vaccination is associated with reductions in influenza-related respiratory illness and physician visits among all age groups, hospitalization and death among persons at high risk, otitis media among children, and work absenteeism among adults. Although influenza vaccination levels increased substantially during the 1990s, further improvements in vaccine coverage levels are needed".[11]

Current status

"Vaccination in the veterinary world pursues four goals: (i) protection from clinical disease, (ii) protection from infection with virulent virus, (iii) protection from virus excretion, and (iv) serological differentiation of infected from vaccinated animals (so-called DIVA principle). In the field of influenza vaccination, neither commercially available nor experimentally tested vaccines have been shown so far to fulfil all of these requirements."[12]

Flu research includes molecular virology, molecular evolution, pathogenesis, host immune responses, genomics, and epidemiology. These help in developing influenza countermeasures such as vaccines, therapies and diagnostic tools. Improved influenza countermeasures require basic research on how viruses enter cells, replicate, mutate, evolve into new strains and induce an immune response. The Influenza Genome Sequencing Project is creating a library of influenza sequences that will help us understand what makes one strain more lethal than another, what genetic determinants most affect immunogenicity, and how the virus evolves over time. Solutions to limitations in current vaccine methods are being researched.

"Today, we have the capability to produce 300 million doses of trivalent vaccine per year - enough for current epidemics in the Western world, but insufficient for coping with a pandemic."[2][13]

Clinical trials of vaccines

A vaccine is assessed in terms of the reduction of the risk of disease produced by vaccination, its efficacy. In contrast, in the field, the effectiveness of a vaccine is the practical reduction in risk for an individual when they are vaccinated under real-world conditions.[14] Measuring efficacy of influenza vaccines is relatively simple, as the immune response produced by the vaccine can be assessed in animal models, or the amount of antibody produced in vaccinated people can be measured,[15] or most rigorously, by immunising adult volunteers and then challenging with virulent influenza virus.[16] In studies such as these, influenza vaccines showed high efficacy and produced a protective immune response. For ethical reasons, such challenge studies cannot be performed in the population most at risk from influenza - the elderly and young children. However, studies on the effectiveness of flu vaccines in the real world are uniquely difficult. The vaccine may not be matched to the virus in circulation, virus prevalence varies widely between years and influenza is often confused with other flu-like illnesses.[17]

Nevertheless, multiple clinical trials of both live and inactivated influenza vaccines have been performed and their results pooled and analyzed in several recent meta-analyzes. Studies on live vaccines have very limited data, but these preparations may be more effective than inactivated vaccines.[16] The meta-analyses examined the efficacy and effectiveness of inactivated vaccines in adults,[18] children,[19] and the elderly.[20][21] In adults, vaccines show high efficacy against the targeted strains, but low effectiveness overall, so the benefits of vaccination are small, with a one-quarter reduction in risk of contracting influenza but no effect on the rate of hospitalization.[18] In children, vaccines again showed high efficacy, but low effectiveness in preventing "flu-like illness", in children under two the data are extremely limited, but vaccination appeared to confer no measurable benefit.[19] In the elderly, vaccination does not reduce the frequency of influenza, but may reduce pneumonia, hospital admission and deaths from influenza or pneumonia.[20][21] The measured effectiveness of the vaccine in the elderly varies depending on whether the population studies is in residential care homes, or in the community, with the vaccine appearing more effective in an institutional environment. This apparent effect may be due to selection bias or differences in diagnosis and surveillance.

Overall, the benefit of influenza vaccination is clearest in the elderly, with vaccination in children of questionable benefit. Vaccination of adults is not predicted to produce significant improvements in public health. The apparent contradiction between vaccines with high efficacy, but low effectiveness, may reflect the difficulty in diagnosing influenza under clinical conditions and the large number of strains circulating in the population.[17]

Who should get it

Yearly influenza vaccination should be routinely offered to patients at risk of complications of influenza:

- the elderly (UK recommendation is those aged 65 or above)
- patients with chronic lung diseases (asthma, COPD, etc.)
- patients with chronic heart diseases (congenital heart disease, chronic heart failure, ischaemic heart disease)
- patients with chronic liver diseases (including liver cirrhosis)

- patients who are immunosuppressed (those with HIV or who are receiving drugs to suppress the immune system such as chemotherapy and long-term steroids) and their household contacts
- healthcare workers (both to prevent sickness and to prevent spread to patients)[22]

The only contraindication is known anaphylaxis to the vaccine or its component.

In the United States a person aged 50-64 is nearly ten times more likely to die an influenza-associated death as a person under age 50 and a person over age 65 is over ten times more likely to die an influenza-associated death as a person in the 50-64 age group.[23] Vaccination of those over age 65 reduces influenza-associated death by about 50%.[24][25] However, it is unlikely that the vaccine completely explains the results since elderly people who get the vaccine are likely more healthy and health-conscious than those who don't.[26]

Flu vaccine virus selection

Selecting viruses for the vaccine manufacturing process is very difficult.

At the U.S.'s Food and Drug Administration's (FDA) Center for Biologics Evaluation and Research's Vaccines and Related Biological Products Advisory Committee's 101st meeting of February 16, 2005, an extensive discussion and vote was held concerning next year's flu vaccine virus selection; but began with a summary of the previous year:

Influenza B

"For Influenza B, the question was asked: are there new strains present? And the answer was yes, and in 2004, the majority of the viruses were similar to a strain called B/Shanghai/361/2002, which is from the so-called B/Yamagata/1688 hemagglutinin lineage. That lineage was not the one that was being used in the vaccine that was current last year. In a minority of the strains that were found during the epidemiologic studies were similar to the strain that was in the vaccine for last year, which was B/Hong Kong/330/2001, which belongs to the HA lineage that we represent with the strain B/Victoria/287. In answer to the question were these new viruses spreading, the answer, of course, is definitely yes. The Fujian-like viruses had become widespread around the world and were predominant everywhere, and these B/Shanghai-like strains at the time we were holding this meeting in February were predominant not only in North America and the United States, but also in Asia and Europe."

New viruses

"Were the new viruses that were identified and spreading, were those inhibited by the current vaccines? And this question, as it sometimes is, was not a very definite no or yes. It was a little bit difficult to interpret, but it seemed like many of the A/Fujian-like viruses were not well inhibited by the current vaccines, although some of them were. For the B/Shanghai-like strains, of course, we've known for a long time that these two divergent hemagglutinin lineages are not that well inhibited one by the other, and as time has gone on and antigenic drift has occurred in these strains, that has become truer. Generally we also know that for the B/Yamagata-like strains and the B/Victoria-like strains, that very young children and people who haven't been immunologically primed, exposure to one of these does not seem to immediately give antibodies that cross-react with the other HA lineage."

Manufacturing issues

"So were there strains that were suitable for manufacturing? And the answer was yes. Of course, we all know that for inactivated vaccines and for live attenuated vaccines manufacturing depends on having egg adapted strains, either the wild-type or reassortant, and in the case of the live vaccine, of course, it has to be a reassortant for the attenuation phenotype. But there were A/Fujian-like strains that were available, and there was a high growth reassortant that was being used in manufacturing for the Southern Hemisphere

already, the A/Wyoming/3/2003 X 147 reassortant. For the B strain, there were a number of wild-type isolates that seemed to be suitable for manufacturing, including B/Jilin/20/2003 and B/Jiangsu/10/2003, in addition to the B/Shanghai/361 strain itself."

Strains selected

"So based on that, the strains that were selected for this year include A/New Caledonia/20/99-like strain, which in this case really is A/New Caledonia/20/99. For the B/Shanghai/361/2002-like recommendation that was made, there were all three of these strains, B/Shanghai, B/Jilin, and B/Jiangsu. And for the A/Fujian/411/2002-like recommendation that was made and the A/Wyoming/3/2003 strain was chosen or is the one that has become widely used for vaccine preparation. Now, the implications of the strain selection were that preparation of the vaccines was on schedule throughout the year. All of the strains seemed to be typical and easy to adapt for manufacturing purposes, and going into the summer, the supply of vaccine was expected to match the demand predicted by previous years' experiences."

Unexpected difficulties

"But what happened was that we ended up with a vaccine shortage at the end of the summer, and just to try to put that into a little perspective, from January until August, manufacturing had been progressing on schedule even including these two new strains that were recommended for use in vaccines, and it was anticipated there were going to be about 100 million doses of vaccine from all of the manufacturers combined for this year. In August of 2004, Chiron notified regulatory authorities about a sterility issue and indicated that investigation to identify the cause and the implementation of corrections was underway, and at that time Chiron made a public announcement indicating that there would be a possible delay in distribution and possibly a reduction in the amount of vaccine that would be available. You also probably all know that in early October of 2004, the MHRA, the UK regulatory authority, announced that they were suspending Chiron's license to manufacture inactivated influenza vaccine for three months, and that was based on the issues that have previously been identified and were in investigation and correction by Chiron. Subsequently, over the next few weeks and certainly by November of 2004, it became clear after consultation between FDA and MHRA that the vaccine that Chiron had planned to make was not going to be available for us in the United States."

Response to unexpected difficulties

"In response to that, there were a number of things that happened within the Public Health Service, and I'll just very briefly indicate some of those. At FDA there was a lot of work done to evaluate manufacturers who were not licensed in the United States to identify whether their vaccines could be used under IND. There was consultation with manufacturers to discuss regulatory mechanisms going forward from this time for getting approval of new products in the United States. That includes accelerated approval, fast track and priority

reviews to facilitate those new licenses, and all of these things actually have been continuing."[27]

Flu vaccine manufacturing

Flu vaccines are available both as an injection of killed virus and as nasal spray of live attenuated influenza virus (LAIV) (sold as FluMist). Clinical trials suggest that the live virus may be more effective at preventing infection, but FluMist has not been approved in the United States for use in children younger than 5.[28]

Flu vaccine is usually grown in fertilized chicken eggs. Both types of flu vaccines are contraindicated for those with severe allergies to egg proteins and people with a history of Guillain-Barré syndrome.[29]

On October 5, 2004, Chiron Corporation, a corporation contracted to deliver half of the expected flu vaccine for the United States and a significant portion to the UK, issued a press release[30] that stated it was unable to dispense its stock for the 2004-2005 season, due to suspension of the corporation's license to produce the vaccine by the Medicines and Healthcare Products Regulatory Agency. However, the Centers for Disease Control and Prevention took action to enlist the help of other companies such as MedImmune and Aventis Pasteur to supply vaccine in high-risk populations in the United States.

H5N1

WHO pandemic phases

1. Low risk
2. New virus
3. Self limiting
4. Person to person
5. Epidemic exists
6. Pandemic exists

There are several H5N1 vaccines for several of the avian H5N1 varieties, some for use in humans and some for use in poultry. H5N1 continually mutates, meaning vaccines based on current samples of avian H5N1 cannot be depended upon to work in the case of a future pandemic of H5N1. While there can be some cross-protection against related flu strains, the best protection would be from a vaccine specifically produced for any future pandemic flu virus strain. Dr. Daniel Lucey, co-director of the Biohazardous Threats and Emerging Diseases graduate program at Georgetown University has made this point, "There is no H5N1 pandemic so there can be no pandemic vaccine." However, "pre-pandemic vaccines" have been created; are being refined and tested; and do have some promise both in furthering research and preparedness for the next pandemic. Vaccine manufacturing companies are being encouraged to increase capacity so that if a pandemic vaccine is needed, facilities will be available for rapid production of large amounts of a vaccine specific to a new pandemic strain.

Problems with H5N1 vaccine production include:

- lack of overall production capacity

- lack of surge production capacity (it is impractical to develop a system that depends on hundreds of millions of 11-day old specialized eggs on a standby basis)
- the pandemic H5N1 might be lethal to chickens

Cell culture (cell-based) manufacturing technology can be applied to influenza vaccines as they are with most viral vaccines and thereby solve the problems associated with creating flu vaccines using chicken eggs as is currently done.[31][32] The US government has purchased from Sanofi Pasteur and Chiron Corporation several million doses of vaccine meant to be used in case of an influenza pandemic of H5N1 avian influenza and is conducting clinical trials with these vaccines.[33] Researchers at the University of Pittsburgh have had success with a genetically engineered vaccine that took only a month to make and completely protected chickens from the highly pathogenic H5N1 virus.[34]

According to the United States Department of Health & Human Services:

In addition to supporting basic research on cell-based influenza vaccine development, HHS is currently supporting a number of vaccine manufacturers in the advanced development of cell-based influenza vaccines with the goal of developing U.S.-licensed cell-based influenza vaccines produced in the United States. Dose-sparing technologies. Current U.S.-licensed vaccines stimulate an immune response based on the quantity of HA (hemagglutinin) antigen included in the dose. Methods to stimulate a strong immune response using less HA antigen are being studied in H5N1 and H9N2 vaccine trials. These include changing the mode of delivery from intramuscular to intradermal and the addition of immune-enhancing adjuvant to the vaccine formulation. Additionally, HHS is soliciting contract proposals from manufacturers of vaccines, adjuvants, and medical devices for the development and licensure of influenza vaccines that will provide dose-sparing alternative strategies.[35]

Chiron Corporation is now recertified and under contract with the National Institutes of Health to produce 8,000-10,000 investigational doses of Avian Flu (H5N1) vaccine. MedImmune and Aventis Pasteur are under similar contracts.[36] The United States government hopes to obtain enough vaccine in 2006 to treat 4 million people. However, it is unclear whether this vaccine would be effective against a hypothetical mutated strain that would be easily transmitted through human populations, and the shelflife of stockpiled doses has yet to be determined.[37]

The New England Journal of Medicine reported on March 30, 2006 on one of dozens of vaccine studies currently being conducted. The Treanor et al. study was on vaccine produced from the human isolate (A/Vietnam/1203/2004 H5N1) of a virulent clade 1 influenza A (H5N1) virus with the use of a plasmid rescue system, with only the hemagglutinin and neuraminidase genes expressed and administered without adjuvant. "The rest of the genes were derived from an avirulent egg-adapted influenza A/PR/8/34 strain. The hemagglutinin gene was further modified to replace six basic amino acids associated with high pathogenicity in birds at the cleavage site between hemagglutinin 1 and hemagglutinin 2. Immunogenicity was assessed by microneutralization and hemagglutination-inhibition assays with the use of the vaccine virus, although a subgroup of samples were tested with the use of the wild-type influenza A/Vietnam/1203/2004 (H5N1) virus." The results of this study combined with others scheduled to be completed by Spring 2007 is hoped will provide

a highly immunogenic vaccine that is cross-protective against heterologous influenza strains.[38]

On August 18, 2006. the World Health Organization changed the H5N1 strains recommended for candidate vaccines for the first time since 2004. "The WHO's new prototype strains, prepared by reverse genetics, include three new H5N1 subclades. The hemagglutinin sequences of most of the H5N1 avian influenza viruses circulating in the past few years fall into two genetic groups, or clades. Clade 1 includes human and bird isolates from Vietnam, Thailand, and Cambodia and bird isolates from Laos and Malaysia. Clade 2 viruses were first identified in bird isolates from China, Indonesia, Japan, and South Korea before spreading westward to the Middle East, Europe, and Africa. The clade 2 viruses have been primarily responsible for human H5N1 infections that have occurred during late 2005 and 2006, according to WHO. Genetic analysis has identified six subclades of clade 2, three of which have a distinct geographic distribution and have been implicated in human infections:

- Subclade 1, Indonesia
- Subclade 2, Middle East, Europe, and Africa
- Subclade 3, China

On the basis of the three subclades, the WHO is offering companies and other groups that are interested in pandemic vaccine development these three new prototype strains:

- An A/Indonesia/2/2005-like virus
- An A/Bar headed goose/Quinghai/1A/2005-like virus
- An A/Anhui/1/2005-like virus

[...] Until now, researchers have been working on prepandemic vaccines for H5N1 viruses in clade 1. In March, the first clinical trial of a US vaccine for H5N1 showed modest results. In May, French researchers showed somewhat better results in a clinical trial of an H5N1 vaccine that included an adjuvant. Vaccine experts aren't sure if a vaccine effective against known H5N1 viral strains would be effective against future strains. Although the new viruses will now be available for vaccine research, WHO said clinical trials using the clade 1 viruses should continue as an essential step in pandemic preparedness, because the trials yield useful information on priming, cross-reactivity, and cross-protection by vaccine viruses from different clades and subclades."[39][40]

Flu seasons

2003-2004 season

The production of flu vaccine requires a lead time of about six months before the season. It is possible that by flu season a strain becomes common for which the vaccine does not provide protection. In the 2003-2004 season the vaccine was produced to protect against A/Panama, A/New Caledonia, and B/Hong Kong. A new strain, A/Fujian, was discovered after production of the vaccine started and vaccination gave only partial protection against this strain.

Nature magazine reported that the Influenza Genome Sequencing Project, using phylogenetic analysis of 156 H3N2 genomes, "explains the appearance, during the 2003–

2004 season, of the 'Fujian/411/2002'-like strain, for which the existing vaccine had limited effectiveness" as due to an epidemiologically significant reassortment. "Through a reassortment event, a minor clade provided the haemagglutinin gene that later became part of the dominant strain after the 2002–2003 season. Two of our samples, A/New York/269/2003 (H3N2) and A/New York/32/2003 (H3N2), show that this minor clade continued to circulate in the 2003–2004 season, when most other isolates were reassortants."[41]

According to the CDC:

During the 2003-2004 influenza season, influenza A (H1), A (H3N2), and B viruses co-circulated worldwide, and influenza A (H3N2) viruses predominated. Several Asian countries reported widespread outbreaks of avian influenza A (H5N1) among poultry. In Vietnam and Thailand, these outbreaks were associated with severe illnesses and deaths among humans. In the United States, the 2003-2004 influenza season began earlier than most seasons, peaked in December, was moderately severe in terms of its impact on mortality, and was associated predominantly with influenza A (H3N2) viruses.[42]

During September 28, 2003 - May 22, 2004, WHO and NREVSS collaborating laboratories in the United States tested 130,577 respiratory specimens for influenza viruses; 24,649 (18.9%) were positive. Of these, 24,393 (99.0%) were influenza A viruses, and 249 (1.0%) were influenza B viruses. Among the influenza A viruses, 7,191 (29.5%) were subtyped; 7,189 (99.9%) were influenza A (H3N2) viruses, and two (0.1%) were influenza A (H1) viruses. The proportion of specimens testing positive for influenza first increased to >10% during the week ending October 25, 2003 (week 43), peaked at 35.2% during the week ending November 29 (week 48), and declined to <10% during the week ending January 17, 2004 (week 2). The peak percentage of specimens testing positive for influenza during the previous four seasons had ranged from 23% to 31% and peaked during late December to late February.[42]

As of June 15, 2004, CDC had antigenically characterized 1,024 influenza viruses collected by U.S. laboratories since October 1, 2003: 949 influenza A (H3N2) viruses, three influenza A (H1) viruses, one influenza A (H7N2) virus, and 71 influenza B viruses. Of the 949 influenza A (H3N2) isolates characterized, 106 (11.2%) were similar antigenically to the vaccine strain A/Panama/2007/99 (H3N2), and 843 (88.8%) were similar to the drift variant, A/Fujian/411/2002 (H3N2). Of the three A (H1) isolates that were characterized, two were H1N1 viruses, and one was an H1N2 virus. The hemagglutinin proteins of the influenza A (H1) viruses were similar antigenically to the hemagglutinin of the vaccine strain A/New Caledonia/20/99. Of the 71 influenza B isolates that were characterized, 66 (93%) belonged to the B/Yamagata/16/88 lineage and were similar antigenically to B/Sichuan/379/99, and five (7%) belonged to the B/Victoria/2/87 lineage and were similar antigenically to the corresponding vaccine strain B/Hong Kong/330/2001.[42]

H9N2

In December 2003, one confirmed case of avian influenza A (H9N2) virus infection was reported in a child aged 5 years in Hong Kong. The child had fever, cough, and nasal discharge in late November, was hospitalized for 2 days, and fully recovered. The source of this child's H9N2 infection is unknown.[42]

H5N1

During January—March 2004, a total of 34 confirmed human cases of avian influenza A (H5N1) virus infection were reported in Vietnam and Thailand. The cases were associated with severe respiratory illness requiring hospitalization and a case-fatality proportion of 68% (Vietnam: 22 cases, 15 deaths; Thailand: 12 cases, eight deaths). A substantial proportion of the cases were among children and young adults (i.e., persons aged 5—24 years). These cases were associated with widespread outbreaks of highly pathogenic H5N1 influenza among domestic poultry.[42]

H7N3

During March 2004, health authorities in Canada reported two confirmed cases of avian influenza A (H7N3) virus infection in poultry workers who were involved in culling of poultry during outbreaks of highly pathogenic H7N3 on farms in the Fraser River Valley, British Columbia. One patient had unilateral conjunctivitis and nasal discharge, and the other had unilateral conjunctivitis and headache. Both illnesses resolved without hospitalization.[42]

H7N2

During the 2003-2004 influenza season, a case of avian influenza A (H7N2) virus infection was detected in an adult male from New York, who was hospitalized for upper and lower respiratory tract illness in November 2003. Influenza A (H7N2) virus was isolated from a respiratory specimen from the patient, whose acute symptoms resolved. The source of this person's infection is unknown.[42]

2004-2005 season

According to the CDC:

On the basis of antigenic analyses of recently isolated influenza viruses, epidemiologic data, and postvaccination serologic studies in humans, the Food and Drug Administration's Vaccines and Related Biological Products Advisory Committee (VRBPAC) recommended that the 2004—05 trivalent influenza vaccine for the United States contain A/New Caledonia/20/99-like (H1N1), A/Fujian/411/2002-like (H3N2), and B/Shanghai/361/2002-like viruses. Because of the growth properties of the A/Wyoming/3/2003 and B/Jiangsu/10/2003 viruses, U.S. vaccine manufacturers are using these antigenically equivalent strains in the vaccine as the H3N2 and B components, respectively. The A/New Caledonia/20/99 virus will be retained as the H1N1 component of the vaccine.[42]

2005-2006 season

The vaccines produced for the 2005-2006 season use:

- an A/New Caledonia/20/1999-like(H1N1);
- an A/California/7/2004-like(H3N2) (or the antigenically equivalent strain A/New York/55/2004);
- a B/Jiangsu/10/2003-like viruses.

In people in the US, overall flu and pneumonia deaths were below those of a typical flu season with 84% Influenzavirus A and the rest Influenzavirus B. Of the patients who had Type A viruses, 80% had viruses identical or similar to the A bugs in the vaccine. 70% of the people testing positive for a B virus had Type B Victoria, a version not found in the vaccine.[43]

"During the 2005-06 season, influenza A (H3N2) viruses predominated overall, but late in the season influenza B viruses were more frequently isolated than influenza A viruses. Influenza A (H1N1) viruses circulated at low levels throughout the season. Nationally, activity was low from October through early January, increased during February, and peaked in early March. Peak activity was less intense, but activity remained elevated for a longer period of time this season compared to the previous three seasons. The longer period of elevated activity may be due in part to regional differences in the timing of peak activity and intensity of influenza B activity later in the season."[44]

2006-2007 season

The 2006-07 influenza vaccine composition recommended by the World Health Organization on February 15, 2006 and the US FDA's Vaccines and Related Biological Products Advisory Committee (VRBPAC) on February 17, 2006 use:

- an A/New Caledonia/20/99 (H1N1)-like virus;
- an A/Wisconsin/67/2005 (H3N2)-like virus (A/Wisconsin/67/2005 and A/Hiroshima/52/2005 strains);
- a B/Malaysia/2506/2004-like virus from B/Malaysia/2506/2004 and B/Ohio/1/2005 strains which are of B/Victoria/2/87 lineage.[45]

Flu vaccine for nonhumans

Horses with horse flu can run a fever, have a dry hacking cough, have a runny nose, and become depressed and reluctant to eat or drink for several days but usually recover in 2 to 3 weeks. "Vaccination schedules generally require a primary course of 2 doses, 3-6 weeks apart, followed by boosters at 6-12 month intervals. It is generally recognised that in many cases such schedules may not maintain protective levels of antibody and more frequent administration is advised in high-risk situations."[46]

"[P]oultry vaccines, made on the cheap, are not filtered and purified [like human vaccines] to remove bits of bacteria or other viruses. They usually contain whole virus, not just the hemagglutin spike that attaches to cells. Purification is far more expensive than the work in eggs, Dr. Stöhr said; a modest factory for human vaccine costs $100 million, and no veterinary manufacturer is ready to build one. Also, poultry vaccines are "adjuvated" — boosted — with mineral oil, which induces a strong immune reaction but can cause inflammation and abscesses. Chicken vaccinators who have accidentally jabbed themselves have developed painful swollen fingers or even lost thumbs, doctors said. Effectiveness may also be limited. Chicken vaccines are often only vaguely similar to circulating flu strains — some contain an H5N2 strain isolated in Mexico years ago. 'With a chicken, if you use a vaccine that's only 85 percent related, you'll get protection,' Dr. Cardona said. 'In humans,

you can get a single point mutation, and a vaccine that's 99.99 percent related won't protect you.' And they are weaker [than human vaccines]. 'Chickens are smaller and you only need to protect them for six weeks, because that's how long they live till you eat them,' said Dr. John J. Treanor, a vaccine expert at the University of Rochester. Human seasonal flu vaccines contain about 45 micrograms of antigen, while an experimental A(H5N1) vaccine contains 180. Chicken vaccines may contain less than 1 microgram. 'You have to be careful about extrapolating data from poultry to humans,' warned Dr. David E. Swayne, director of the agriculture department's Southeast Poultry Research Laboratory. 'Birds are more closely related to dinosaurs.'"[47]

Researchers, led by Nicholas Savill of the University of Edinburgh in Scotland, used mathematical models to simulate the spread of H5N1 and concluded that "at least 95 per cent of birds need to be protected to prevent the virus spreading silently. In practice, it is difficult to protect more than 90 per cent of a flock; protection levels achieved by a vaccine are usually much lower than this."[48]

31. ^ According to the US HHS (United States Department of Health & Human Services) Pandemic Influenza Plan Appendix F: Current HHS Activities last revised on November 8, 2005 at http://www.hhs.gov/pandemicflu/plan/appendixf.html : Currently, influenza vaccine for the annual, seasonal influenza program comes from four manufacturers. However, only a single manufacturer produces the annual vaccine entirely within the U.S. Thus, if a pandemic occurred and existing U.S.-based influenza vaccine manufacturing capacity was completely diverted to producing a pandemic vaccine, supply would be severely limited. Moreover, because the annual influenza manufacturing process takes place during most of the year, the time and capacity to produce vaccine against potential pandemic viruses for a stockpile, while continuing annual influenza vaccine production, is limited. Since supply will be limited, it is critical for HHS to be able to direct vaccine distribution in accordance with predefined groups (see Appendix D); HHS will ensure the building of capacity and will engage states in a discussion about the purchase and distribution of pandemic influenza vaccine. Vaccine production capacity: The protective immune response generated by current influenza vaccines is largely based on viral hemagglutinin (HA) and neuraminidase (NA) antigens in the vaccine. As a consequence, the basis of influenza vaccine manufacturing is growing massive quantities of virus in order to have sufficient amounts of these protein antigens to stimulate immune responses. Influenza vaccines used in the United States and around world are manufactured by growing virus in fertilized hens' eggs, a commercial process that has been in place for decades. To achieve current vaccine production targets millions of 11-day old fertilized eggs must be available every day of production. In the near term, further expansion of these systems will provide additional capacity for the U.S.-based production of both seasonal and pandemic vaccines, however, the surge capacity that will be needed for a pandemic response cannot

be met by egg-based vaccine production alone, as it is impractical to develop a system that depends on hundreds of millions of 11-day old specialized eggs on a standby basis. In addition, because a pandemic could result from an avian influenza strain that is lethal to chickens, it is impossible to ensure that eggs will be available to produce vaccine when needed. In contrast, cell culture manufacturing technology can be applied to influenza vaccines as they are with most viral vaccines (e.g., polio vaccine, measles-mumps-rubella vaccine, chickenpox vaccine). In this system, viruses are grown in closed systems such as bioreactors containing large numbers of cells in growth media rather than eggs. The surge capacity afforded by cell-based technology is insensitive to seasons and can be adjusted to vaccine demand, as capacity can be increased or decreased by the number of bioreactors or the volume used within a bioreactor. In addition to supporting basic research on cell-based influenza vaccine development, HHS is currently supporting a number of vaccine manufacturers in the advanced development of cell-based influenza vaccines with the goal of developing U.S.-licensed cell-based influenza vaccines produced in the United States.

HIV vaccine

An *HIV vaccine* is a hypothetical vaccine against HIV, the etiological agent of AIDS. As there is no known cure for AIDS, the search for a vaccine has become part of the struggle against the disease.

The urgency of the search for a vaccine against HIV stems from the AIDS-related death toll of over 25 million people since 1981.[1] Indeed, in 2002, AIDS became the primary cause of mortality due to an infectious agent in Africa (UNAIDS, 2004).

Alternative medical treatments to a vaccine do exist. Highly active antiretroviral therapy (HAART) has been highly beneficial to many HIV-infected individuals since its introduction in 1996 when the protease inhibitor-based HAART initially became available. HAART allows the stabilisation of the patient's symptoms and viremia, but they do not cure the patient of HIV, nor of the symptoms of AIDS (Martinez-Picardo et al., 2000). And, importantly, HAART does nothing to prevent the spread of HIV through people with undiagnosed HIV infections. Safer sex measures have also proven insufficient to halt the spread of AIDS in the worst affected countries, despite some success in reducing infection rates.

Therefore, a HIV vaccine is generally considered as the most likely, perhaps the only way by which the AIDS pandemic can be halted. However, after over 20 years of research, HIV-1 remains a difficult target for a vaccine.

Difficulties in developing an HIV vaccine

In 1984, after the confirmation of the etiological agent of AIDS by Prof. Robert Gallo, the United States Health and Human Services Secretary Margaret Heckler declared that a vaccine would be available within two years (Associated Press, 1984). However, the classical vaccination approaches that have been successful in the control of various viral diseases by priming the adaptive immunity to recognise the viral envelope proteins have failed in the case of HIV-1, as the epitopes of the viral envelope are too variable. Furthermore, the functionally important epitopes of the gp120 protein are masked by glycosylation,

trimerisation and receptor-induced conformational changes making it difficult to block with neutralising antibodies. In February 2003, Vaxgen announced that their AIDSVAX vaccine was a failure in North America as there was not a statistically significant reduction of HIV infection within the study population (Francis et al., 2003). In November 2003, it also failed clinical trials in Thailand for the same reason. These vaccines both targeted gp120 and were specific for the geographical regions (Billich et al., 2001).

The ineffectiveness of previously developed vaccines primarily stems from two related factors. First, HIV is highly mutable. Because of the virus' ability to rapidly respond to selective pressures imposed by the immune system, the population of virus in an infected individuals typically evolves so that it can evade the two major arms of the adaptive immune system; humoral (antibody-mediated) and systemic (mediated by T cells) immunity. Second, HIV isolates are themselves highly variable. HIV can be categorized into multiple clades and subtypes with a high degree of genetic divergence. Therefore, the immune responses raised by any vaccine need to be broad enough to account for this variability. Any vaccine that lacks this breadth is unlikely to be effective.

The typical animal model for vaccine research is the monkey, often the macaque. The monkeys can be infected with SIV or the chimeric SHIV for research purposes. However, the well-proven route of trying to induce neutralizing antibodies by vaccination has stalled because of the great difficulty in stimulating antibodies that neutralise heterologous primary HIV isolates (Poignard et al., 1999). Some vaccines based on the virus envelope have protected chimpanzees or macaques from homologous virus challenge (Berman et al., 1990), but in clinical trials, individuals who were immunised with similar constructs became infected after later exposure to HIV-1 (Connor et al., 1998).

The human body can defend itself against HIV, as work with monoclonal antibodies (MAb) has proven. That certain individuals can be asymptomatic for decades after infection is encouraging.

Research achievements

Research supports the contention that a safe and effective vaccine is possible. Vaccines against other diseases where correlates were not known and where there were no ideal animal model have been developed.

Most HIV is transmitted heterosexually, which is known to be less efficient than parenteral exposure. Finally, individuals who become infected with HIV do not succumb to the disease for years even in the absence of anti-retroviral therapy, suggesting that the human immune system is capable of controlling HIV infection partially or temporarily.

Enormous effort has been put into understanding how HIV works; it has produced a number of approaches to vaccination, none of which have been effective. Methods attempted include recombinant proteins, synthetic peptides, recombinant viral vectors, recombinant bacterial vectors, recombinant particles, DNA vaccines to induce production of a specific antigen, and whole-killed and live-attenuated HIV, though these latter two have not progressed into clinical trials in uninfected individuals due to an unfavorable benefit/risk ratio. The role of broadly neutralising antibodies (NAb) is under investigation, although earlier results were discouraging. vaccines are used to investigate the HIV glycoproteins. Attacks on particular parts of the RNA code of the virus have shown some promise, such as those against the nef gene which regulates viral replication.

On November 16, 2004, researchers at the French Institut Pasteur announced that they had been able to induce antibodies to significantly block HIV from infecting human cells, an achievement hailed as an important step towards an HIV vaccine. (365gay.com)

On November 29, 2004, Wei Lu, Jean-Marie Andrieu, and colleagues at the University of Paris in France and Pernambuco Federal University in Recife, Brazil, tested a vaccine on 18 Brazilian patients whose T-cell counts stopped dropping after getting three under-the-skin injections of the tailor-made vaccine. Novel Vaccine Stops HIV

On December 1, 2004, Swedish media announced that a new vaccine will be tested on 40 volunteers. If the new method is successful, vaccinations will be performed in Tanzania next year.

On March 13, 2005, China announced it began human trials for an AIDS vaccine. 49 volunteers between the ages of 18 and 50 would receive the vaccine.

On April 14, 2006, Atlanta 12 uninfected volunteers are to start getting the newly developed HIV vaccine.

The burden of HIV-related disease and transmission in Africa demands that enhanced efforts be made to treat large numbers of infected people with antiretroviral drugs, despite the cost and the emergence of resistant strains, while effective preventative vaccines are developed. Also, access to care and the development of simplified monitoring schemes for positive and negative treatment effects, as well as effective planning on how to obtain and distribute HIV vaccines needs to be addressed. This will be an important step if a large scale phase III HIV-vaccine trial is to be effective (WHO-UNAIDS, 2001), as this may bypass what we saw with antiretroviral therapy, that drugs were initially widely used in only developed countries.

Clinical trials to date

17 vaccine candidates are in phase I trials and four in phase I/II. There is only one in phase III (the NIH/Department of Defense's ALVAC vCP 1521 canary pox vector/AIDSVAX prime-boost vaccine trial now under way in Thailand).

Up to May 2000 over 60 phase I/II trials of candidate vaccines had been conducted worldwide. Most initial approaches focused on the HIV envelope protein. At least thirteen different gp120 and gp160 envelope candidates have been evaluated, in the US predominantly through the AIDS Vaccine Evaluation Group. Most research focused on gp120 rather than gp41/gp160, as the latter are generally more difficult to produce and did not initially offer any clear advantage over gp120 forms. Overall, they have been safe and immunogenic in diverse populations, have induced neutralizing antibody in nearly 100% recipients, but rarely induced CD8+ cytotoxic T lymphocytes (CTL). Mammalian derived envelope preparations have been better inducers of neutralizing antibody than candidates produced in yeast and bacteria. Although the vaccination process involved many repeated "booster" injections, it was very difficult to induce and maintain the high anti-gp120 antibody titers necessary to have any hope of neutralizing an HIV exposure.

The availability of several recombinant canarypox vectors has provided interesting results that may prove to be generalizable to other viral vectors. Increasing the complexity of the canarypox vectors by inclusion of more genes/epitopes has increased the percent of volunteers that have detectable CTL to a greater extent than did increasing the dose of the viral vector. Importantly, CTLs from volunteers were able to kill peripheral blood mononuclear cells infected with primary isolates of HIV, suggesting that induced CTLs could have biological significance. In addition, cells from at least some volunteers were able to kill cells infected with HIV from other clades, though the pattern of recognition was not uniform among volunteers. As canarypox is the first candidate HIV vaccine that has induced cross-clade functional CTL responses,

Other strategies that have progressed to phase I trials in uninfected persons include peptides, lipopeptides, DNA, an attenuated Salmonella vector, lipopeptides, p24, etc. Specifically, candidate vaccines that induce one or more of the following are being sought:

- broadly neutralizing antibody against HIV primary isolates;
- cytotoxic T cell responses in a vast majority of recipients;
- strong mucosal immune responses.

On December 13, 2004, a large phase II clinical trial of a novel HIV vaccine began enrolling volunteers at sites in North America, South America, the Caribbean and Australia. The organizers were seeking 3,000 participants. The trial was co-funded by the National Institute of Allergy and Infectious Diseases (NIAID), part of the National Institutes of Health (NIH), and the pharmaceutical company Merck & Co. Inc. Merck developed the experimental vaccine to stimulate HIV-specific cellular immunity, which prompts the body to produce T cells that kill HIV-infected cells. In previous smaller trials, this vaccine was found to be safe and to induce cellular immune responses against HIV in more than half of volunteers.[1]

The Merck vaccine contains a weakened adenovirus that serves as a carrier for three subtype B HIV genes. Subtype B is the most prevalent HIV subtype in the regions of the study sites. Adenoviruses are among the main causes of upper respiratory tract ailments such as

the common cold. Because the vaccine contains only three HIV genes housed in a weakened adenovirus, study participants cannot become infected with HIV or get a respiratory infection from the vaccine.

Organizers expect that it will take approximately one and a half years to fully enroll volunteers into the study. NIAID and Merck expect the trial be completed in four-and-a-half years, with results anticipated in 2009. More information on enrollment can be found at HVTN's Web site.

Novel approaches, including modified vaccinia Ankara (MVA), adeno-associated virus, Venezuelan Equine Encephalitis (VEE) replicons, and codon-optimized DNA have proven to be strong inducers of CTL in macaque models, and have provided at least partial protection in some models. Most of these approaches are, or will soon, enter clinical studies.

Economics of vaccine development

A June 2005 study estimates that $682 million is spent on AIDS vaccine research annually (CITE).

Economic issues with developing an AIDS vaccine include the need for advance purchase commitment (or advance market commitments) because after an AIDS vaccine has been developed, governments and NGOs may be able to bid the price down to marginal cost (CITE).

Conducting trials of HIV vaccines in the countries most affected by the epidemic is a challenge,[76] albeit one that has been successfully met in Thailand. When one or more HIV-1 vaccines is identified, the task will be just beginning. The next step will be ensuring access for populations where the need is the greatest. Currently, over 60 million people have become infected with HIV-1 and hundreds of millions are at risk. Many of these individuals have little access to medical care, no access to adult vaccinations and live in countries where the per capita expenditure on health care is a few dollars.

Often, HIV-1 is ill understood and stigmatized. Diagnostic tests or algorithms may need to be altered. Education will be needed to convey not only the value but the anticipated limitations of the vaccines, so that other preventive strategies will be maintained. The role of community organizations in maintaining this balance will be critical. Regulatory approvals in numerous countries will be required. The issues in the USA are complex.[77] Internationally, there are greater challenges. If a vaccine has not been demonstrated to be universally effective against every HIV-1 subtype, the standard paradigm of approval in one or more industrialized countries followed years or even decades later by acceptance in and distribution to developing countries will not apply. Both the governments of countries affected by HIV-1 and the international regulatory and health authorities must plan ahead for the advent of an HIV-1 vaccine to avoid unnecessary delays.

HIV-1 vaccines might induce antibody responses that would completely prevent HIV-1 infection by strains of virus that are sufficiently well matched to the vaccine. Unfortunately, HIV-1 evolves continuously both within an individual (the source of infection) and within human populations. Therefore, a vaccinated person might be protected initially, but later encounter a virus against which he or she is not immune. Multivalent vaccines or repeated immunization with an updated vaccine may be required for continued protection. Thus, eventually, one might imagine licensure not of a specific HIV-1 vaccine but of a method for

producing the vaccine and its updated versions, somewhat analogous to the annual updates of influenza vaccine.

The scientific challenges involved in discovery of a safe and effective vaccine against HIV-1, although daunting, are only the prelude. The task of developing and deploying a vaccine against HIV-1 will be enormous (i.e. gaining licensure and scaling up to produce vaccine for worldwide distribution, developing distribution methods and establishing purchase mechanisms will require an unprecedented co-operative effort by governments, international agencies, philanthropic organizations and the private sector).[78] Recent recognition of the importance of controlling HIV-1 for public health, economic and political stability has been encouraging and there has been substantial growth in academic, government, nonprofit and pharmaceutical industry vaccine research, but the fight is not over. Stopping the march of the pandemic will conserve economic and human resources needed to care for those already infected. Ending the HIV-1 epidemic is critical to allow economic development and promote political stability in the developing world and to reduce loss of life and suffering worldwide.

Controversy

Reginald Finger, M.D., M.P.H., a member of the Advisory Committee on Immunization Practices (ACIP) in the U.S., has stated that the Committee would have to carefully consider an HIV vaccine's effects on sexual activity.

In an interview with Michael Specter of The New Yorker[2], he said:

"'We would have to look at that closely ... With any vaccine for H.I.V., disinhibition ... would certainly be a factor, and it is something we will have to pay attention to with a great deal of care.'"

Disinhibition is a "medical term for the absence of fear," in this case, fear of sexual activity.

Similar controversy has arisen in response to the recent introduction of the HPV vaccine, which prevents infection with certain strains of human papillomavirus, another sexually transmitted disease.

ACIP is an influential government committee linked to the Centers for Disease Control. ACIP is charged with advising the President on prevention of vaccine-related diseases. Dr. Finger's term expired in June, 2006.

MMR vaccine

The *MMR vaccine* is a mixture of live attenuated viruses, administered via injection for immunization against measles, mumps and rubella. It is generally administered to children around the age of one year, with a booster dose before starting school (i.e. age 4/5).

It is widely used around the world; since introduction of its earliest versions in the 1970s, over 500 million doses have been used in over 60 countries. As with all vaccinations, long-term effects and efficacy are subject to continuing study. The vaccine is sold by e.g. Merck as M-M-R II[1] and GlaxoSmithKline as Priorix.

Before the widespread use of a vaccine against *measles*, its incidence was so high that patients born before 1949 are assumed to have had measles. Today the incidence of measles has fallen to less than one percent of people under the age of 30 in countries with routine childhood vaccination. Measles has a significant complication rate, which includes pneumonitis and encephalitis.

Studies, such as a Centers for Disease Control (CDC) report on the effect of vaccination against measles in Africa between 1996-2002, have shown that vaccination markedly reduces the mortality rate due to measles.

Mumps is another viral disease of childhood that was once very common. A known but relatively rare complication of mumps is sterility in males.

Rubella, otherwise known as *German measles*, was also very common before the advent of widespread vaccination. The major risk of rubella is if a pregnant woman is infected, her baby may contract congenital rubella from her, which can cause significant congenital defects.

All three diseases are highly contagious.

The MMR vaccine was introduced to induce immunity less painfully than three separate injections at the same time, sooner than at three separate encounters, and more efficiently than either. The incidence and therefore the complications of the three diseases above have declined significantly and this is generally attributed to widespread population vaccination.

Adverse Effects

There are a number of adverse effects listed in the product documentation for the MMR vaccine.[1] Additional side effects and variants are reported including: a rash or slight fever for a few days, one to two weeks after receiving the vaccine, occasionally accompanied by a mild swelling of the salivary glands and some aching or swelling of the joints, respectively from the measles, mumps and rubella components, which have differing incubation periods. They are usually mild and temporary, vanishing within a few days. There are rare reports of more serious adverse effects — only about one in every 100,000 vaccinations is reported to have resulted in a severe adverse effect such as encephalitis or meningitis. Acute disseminated encephalomyelitis is a rare severe adverse effect of the vaccine.

In the UK, the vaccine was the subject of controversy after a 1998 paper by Dr. Andrew Wakefield, which claimed to have found a possible link between MMR and the onset of behavioral abnormalities in children. Numerous peer-reviewed studies have since failed to show any correlation. Since its publication, this conclusion of the study has been retracted by ten of Wakefield's co-authors, and his call for parents to boycott the vaccine in favor of single injections one year apart, has been heavily criticized, both on scientific grounds and for triggering a decline in vaccination rates.[2]

Parents may choose to have each of the three components given separately, but the overwhelming medical opinion is that such spacing of injections does not reduce the chance of adverse effects, but increases the opportunity for infection by the two diseases not immunized against first.

Weighing adverse effects and benefits

While there are recognized effects, rarely serious, from each component of the MMR vaccine, from a public health perspective, the benefit to the population outweighs these concerns. The consensus of medical opinion is that the vaccine is very safe.

Development, Formulation and Administration

The component viral strains of MMR vaccine were developed by propagation in animal cells. The live viruses require animal cells as a host for production of more virus.

For example, in the case of mumps and measles viruses, the virus strains were grown in embryonated hens' eggs and chick embryo cell cultures. This produced strains of virus which

were adapted for the hens egg and less well-suited for human cells. These strains are therefore called attenuated strains. They are sometimes referred to as neuroattenuated because these strains are less virulent to human neurons than the wild strains.[3] [4]

Disease Immunized - Component Vaccine - Virus Strain - Propagation Medium - Growth Medium

Measles - Attenuvax - Enders' attenuated Edmonston strain [5] - chick embryo cell culture - Medium 199

Mumps - Mumpsvax[6] - Jeryl Lynn (B level) strain[7] - chick embryo cell culture - Medium 199

Rubella - Meruvax II - Wistar RA 27/3 strain of live attenuated rubella virus - WI-38 human diploid lung fibroblasts - MEM (solution containing buffered salts, fetal bovine serum, human serum albumin and neomycin, etc.)

The virus is extracted from the human albumin growth medium via the Cohn cold ethanol fractionation method. [1]

MMR II is supplied freeze-dried (lyophilized) and contains live viruses. Before injection it is reconstituted with the solvent provided. It is administered by a subcutaneous injection.

Polio vaccine

Two *polio vaccines* are used throughout the world to combat polio. The first was developed by Jonas Salk, first tested in 1952, and announced to the world by Salk on April 12, 1955. It consists of an injected dose of killed polio virus. Thereafter, Albert Sabin produced an oral polio vaccine using live but weakened (attenuated) virus. Human trials of Sabin's vaccine began in 1957 and it was licensed in 1962.

When the live-virus Sabin oral vaccine was developed, it gained in popularity for several reasons. First, it can 'infect' other, non-vaccinated individuals with whom the vaccinated person has close contact and confer some immunity to them. Second, because the oral vaccine acts in the gut, it confers immunity there and reduces the spread of the wild virus. The injected vaccine, acting through the bloodstream, immunizes the individual but does not reduce the potential for spreading the wild virus. Third, the live-virus oral vaccine is cheaper than the killed-virus vaccine. Finally, the oral vaccine is easier to administer than the injected vaccine, so patients are more likely to complete the immunization series and attain full immunity. Though Salk's vaccine had reduced the incidence of polio to a tiny fraction of what it was in the early 1950s, Sabin's vaccine was considered superior for these reasons and became the standard treatment. The killed-virus vaccine immunized people against the effects of the virus, but the virus could still spread from person to person. It was the live-virus vaccine that enabled the complete eradication of the wild polio virus in the United States.

The major disadvantage of the live-virus vaccine is that it can result in sporadic cases of polio either from the vaccine itself or from the circulation of the vaccine. There is neither risk from the killed-virus vaccine.

In each country, as the incidence of wild polio reaches a very low level, the time comes to change from live vaccine to killed. In the United States the Centers for Disease Control decided this point was reached in 2000 and use of the live-virus vaccine was discontinued. In the UK the change occurred in 2005 and for convenience polio vaccine was combined with Tetanus toxoid and Diphtheria. In states with higher incidence and thus a different relative risk between efficacy and reversion, live vaccine is still used. The live virus also has stringent requirements for transport and storage, which are a problem in some areas.

The two vaccines have eliminated polio from most of the countries in the world and reduced early cases from hundreds of thousands per year to only 1000 worldwide in 2001.

Initial attempts to develop a vaccine were hampered by the difficulty of obtaining enough virus. Growing it in the brains of monkeys produced only small quantities. Rats were used later, but a breakthrough came in 1948, when John Franklin Enders, Thomas Huckle Weller, and Frederick Chapman Robbins developed a method for growing the virus in the laboratory. This breakthrough greatly facilitated vaccine research. Enders and his colleagues were awarded the Nobel Prize in Physiology or Medicine in 1954.

Simian virus contamination

Some medical researchers have expressed fear that rare human cancers may be linked to contamination by the monkey virus SV40 of a proportion of polio vaccines administered in the 1950s and 1960s. Contamination of the vaccines administered to tens of millions of Americans, in both the injected and oral forms, was first discovered in 1961.

Since then, government officials have insisted there is no evidence the simian virus is harmful to humans. But in recent years, dozens of scientific studies have found the virus in a steadily increasing number of rare brain, bone and lung-related tumors. The simian virus has been detected in tumors removed from people never inoculated with the contaminated vaccine, which has raised further concerns.

Vaccine critics assert that the few studies on the cancer-causing effects of SV40 are scientifically flawed, and that health officials have downplayed the potential risks since finding, in 1961, that the contaminant caused tumors in rodents.

Anti-vaccinationists

After the introduction of vaccination in 1796, the first anti-vaccination society was formed in 1798. In the 19th and early 20th centuries, various organizations declared their opposition to vaccination. Until Pasteur and Lister demonstrated the basis of infection and how to prevent it, vaccinations were as dangerous as other surgical treatments of the time. The view of the British government throughout was that vaccination was safer than variolation, and this is not generally disputed; variolation was safer than random infection with smallpox, but potentially spread smallpox infection itself.

The medical community overwhelmingly supports vaccination as an effective and safe way to prevent the spread and reduce the impact of infectious illnesses. Public health advocates overwhelmingly consider that the benefit to the public justifies mandatory programs.

Timeline

After the work of Edward Jenner, vaccination became widespread in the United Kingdom in the early 1800s.[1] Variolation, which had preceded vaccination, was banned in 1840 because of its greater risks. Public policy and successive Vaccination Acts first encouraged vaccination and then made it mandatory, with the highest penalty for refusal being a prison sentence. This was a significant change in the relationship between the British state and its citizens, and there was a public backlash. Initially this was focused against compulsory vaccination, and later included arguments that vaccination was dangerous and ineffective.

In the USA, President Thomas Jefferson took a close interest in vaccination, alongside Dr Waterhouse, chief physician at Boston. Jefferson encouraged the development of ways to transport vaccine material through the Southern states, which included measures to avoid damage by heat, a leading cause of ineffective batches. Smallpox outbreaks were contained by the latter half of the 19th century, a development widely attributed to vaccination of a large portion of the population[2]. Vaccination rates fell after this decline in smallpox cases, and the disease again became epidemic in the 1870s.

Anti-vaccination activity increased again in the USA in the late 19th century. After a visit to New York in 1879 by William Tebb, a prominent British anti-vaccinationist, the Anti-Vaccination Society of America was founded. The New England Anti-Compulsory Vaccination League was formed in 1882, and the Anti-Vaccination League of New York City in 1885.

Arguments against vaccination

The first arguments against vaccination were theological.[3] Some anti-vaccinationists still base their stance against vaccination with reference to the Bible.[4]

In a 2002 paper in the British Medical Journal, two medical historians suggest that the arguments made against the safety and effectiveness of vaccines in the 21st century are similar to those of the early anti-vaccinationists.[5] Another author in the JRSM(2005) describes the differences between contemporary anti-vaccination campaigns and those before 1907.[6]

Anti-vaccinationists argue that:

- Large smallpox epidemics have occurred in highly vaccinated populations, presenting figures from 1905 in the Philippines. Historians note that the Philippine-American War between 1899 and 1913 caused major disruptions to medical facilities, which were noted to damage the effectiveness of vaccines.
- 90% of the decline in infectious disease incidence occurred before the application of specific vaccines.

Even before Pasteur's work on the nature of infection, there was evidence that contagions spread from person to person, even though microscopes were not yet available and the nature of the contagion (microorganisms) could not be elucidated. Subsequently, as demonstrated by Ignaz Semmelweis, Joseph Lister and others, the knowledge that there were specific modes of cross-infection and that these could be avoided diffused through the population. One argument presented by some modern anti-vaccinationists (e.g. Whale.to) is that Pasteur's theory was incorrect and Antoine Bechamp's germ theory[7] better represented the transmission of disease. This view is not widespread, but is not criticised on anti-vaccinationist websites. This view of the genesis of disease provided no rationale for sterilising instruments, and an overlap in those decades between anti-vaccinationist thinking and Bechampist potentially contributed to deaths from infection and cross-infection.

Infection as a complication of vaccination is almost absent in the 20th century in developed countries, but in developing countries re-use of needles has contributed to the spread of HIV. There is an overlap in anti-vaccinationist thought, with the denial both of HIV as the unique causative organism of AIDS and with denial that viruses cause disease. (Viral and bacterial DNA is listed as a dangerous constituent of vaccines by some authors without disagreement visible, from other anti-vaccinationists). These arguments oppose conventional medical arguments that favour expensive public health precautions against HIV infection.

Consequences of success

Success in opposing vaccination, or a particular vaccination, will be reflected in a reduction in use of all or specific vaccinations. If a vaccine is beneficial, then such success will lead to harm; if a vaccine is harmful, then such success will lead to benefit.

The arguments over which of these occurred were considerable even in the 19th century with only a single vaccination to consider - smallpox. After the Royal Commission, which reported in considerable detail, the Royal Statistical Society devoted a meeting to considering the statistical aspects of the argument. The Royal Commission concluded that smallpox vaccination was effective.

From 1796 to 1905, large changes in English society added to the difficulties of analysis. In later periods, changes in hygiene and sanitation have been much less dramatic, and thus the confounding factors are less around the introduction of measles, rubella and Haemophilus B vaccinations.

Events following reductions in vaccination

In several countries since 1960, reductions in the use of some vaccines were followed by increases in the diseases' morbidity and mortality.

It has been suggested that, because the death and illness rate is so low in most first world countries, there is no need for vaccination. This could be interpreted to mean that when a public health measure is effective, it should be discontinued.

In the absence of assertions that contracting infectious diseases is either a necessary part of development, or confers specific benefits apart from specific (to that disease) immunity, it is commonly accepted that surveillance for infectious disease and isolation of individuals contracting an infectious disease are cornerstones of public health policy. In the 19th century, the city of Leicester in the UK achieved a high level of isolation of smallpox cases and great reduction in spread compared to other areas. The mainstay of Leicester's approach to conquering smallpox was to decline vaccination and put their public funds into sanitary improvements. Bigg's account of the public health procedures in Leicester, presented as evidence to the Royal Commission, refers to erysipelas, an infection of the superficial tissues which was a complication of any surgical procedure.

A component of current-day anti-vaccinationist argument is against the medical establishment . This renders those convinced more likely to avoid reporting illness, and weakens the tracing and control of infection . An imported measles case in Iowa is one illustration of the problem this might cause.

UK: DPT 1970s-80s

In the 1970's and 1980's there was a campaign (in which the newspaper The Sunday Times was particularly involved) against the use of the Diphtheria, Pertussis and Tetanus (DPT) "triple jab" vaccine. This lead to a decline in public confidence and an increase in cases of pertussis (whooping cough) and the subsequent death of some children. The scare ended in the UK after a March 1988 ruling in the High Court in London that, on the balance of

probabilities, the vaccine did not cause permanent neurological damage [3]. A similar pattern was thought to occur in the 1990's with the MMR vaccine causing autism; the single study this was based on has now been discredited.

The Netherlands: measles (1999-2000)

An outbreak at a religious community and school in The Netherlands illustrates the effect of measles in an unvaccinated population.[8] The population in the several provinces affected had a high level of immunisation with the exception of one of the religious denominations who traditionally do not accept vaccination. The three measles-related deaths and 68 hospitalizations that occurred among 2961 cases in the Netherlands demonstrate that measles can be severe and may result in death even in industrialized countries.

Ireland: measles (2000)

From late 1999 until the summer of 2000, there was a measles outbreak in North Dublin, Ireland. At the time, the national immunisation level had fallen below 80%, and in part of north Dublin the level was around 60%. There were more than 100 hospital admissions from over 300 cases. Three children died and several more were gravely ill, some requiring mechanical ventilation to recover.[9],[10]

Anti-vaccinationist material

Anti-vaccination writings on the Internet are characterised by a number of differences from medical and scientific literature.[5] These include:

- Promiscuous copying and reduplication.[11]
- Tendency to be without corrections, even when an initial report is shown to be false (e.g. Donnegan and Schreiber references below). See also absent correction
- Deficiency of references to allow readers, should they wish, to check sources.[12]
- Personal attacks on individual doctors.
- Dishonest or fallacious arguments.[13]
- The sites show a high degree of interlinkage.[11]

There is a considerable overlap with homeopathy and various conspiracy theories, and a subset of the material shades into the appearance of psychosis.[14] An example, which vaccinationists say is dishonest, is the dismissal of immunisation by some critics because it has not eliminated any disease. In 1979 the World Health Organisation (WHO) announced that smallpox had been eradicated; WHO described a huge effort involving many people and various public health strategies, of which immunisation was an important one. Anti-vaccinationists present this as an assertion that the result came solely by vaccination, and then assert that instead it came about solely by historical force.

Over each time period, infectious disease mortality has been falling for all common diseases (UK Office for National Statistics); anti-vaccinationists argue that this is because of improvements in nutrition and living conditions, not because of immunisation.

Anti-vaccination organisations

Historical

Aims and results of the early movements

In Massachusetts, the argument continued from that about variolation, with a minority religious view strongly put that others should eschew immunisation and accept the smallpox that God sent. Cotton Mather and other leaders favoured efforts to prevent disease.

In the USA, the Commonwealth of Massachusetts was the first to make vaccination mandatory, in 1908. In the UK, vaccination was provided free from 1840 under the Vaccination Act. In 1873, a further Vaccination Act made vaccination compulsory. Resistance to compulsion grew, and in 1885, after riots in Leicester, a Royal Commission sat and reported 7 years later, recommending the abolition of cumulative penalties. This was accomplished in the 1898 Act, which also introduced a conscience clause, allowing parents who did not believe that vaccination was efficacious or safe to obtain exemption. This extended the concept of the "conscientious objector" in English law. The aims of the protesters and organisations had thus been achieved in *1898*.

Since the reversion from compulsory immunisation in the UK, opposition has continued at a lower level. After 1993, several national organisations appeared on the Web. Continuity with the older organisations is not apparent.

Opposition could no longer focus on the right to determine what is done to one's children, and therefore the primary arguments against vaccination changed. Focus transferred to arguments that immunisation did not have an effect; that it had a negative, rather than beneficial effect; or that although immunisation had a beneficial effect in the short term, any benefit may be negated by long term negative consequences.

These changes have resulted in arguments based upon hypotheses that are susceptible to disproof rather than philosophical questions of the relationship of individuals to state or deity.

General

The historian Nadja Durbach [6] notes that in the early 19th century, the anti-vaccination movement drew members from across a wide range of society. Fitzpatrick reviewing it adds that in recent years, it has been reduced to a predominantly middle-class phenomenon.

The state

"Vaccination is unique among de facto mandatory requirements in the modern era, requiring individuals to accept the injection of a medicine or medicinal agent into their bodies, and it has provoked a spirited opposition. This opposition began with the first vaccinations, has not ceased, and probably never will. From this realisation arises a difficult issue: how should the mainstream medical authorities approach the anti-vaccination movement? A passive reaction could be construed as endangering the health of society, whereas a heavy handed approach can threaten the values of individual liberty and freedom of expression that we cherish." BMJ

Most states in the USA require immunization, or obtaining exemption, before enrolment in public school. Exemptions are typically for people who have compromised immune systems, allergies to the components used in vaccinations or strongly-held objections. The American Academy of Pediatrics considers parental waivers of immunization a form of child abuse and neglect.

Anti-vaccinationist organisations publicise the procedure for obtaining exemption. Immunizations are often compulsory for military enlistment.

Anti-vaccinationist assertions

Many assertions are replicated in several websites and repeated by individuals who have been categorised as anti-vaccinationist. Peter Morrell, a part time academic in England, describes one set. They are generally presented as individual propositions, rather than a nesting set of propositions ; this contrasts with scientific argument where classification and consolidation are fundamental

No benefit

Some anti-vaccinationists offering alternative medical practices assert that there has never been any benefit to public health from vaccination[16]. Similarly they assert that all the reduction of communicable diseases which were rampant in conditions where overcrowding, poor sanitation, almost non-existent hygiene and a yearly period of very restricted diet existed, are reduced because of changes in conditions excepting vaccination .

50 percent

As in:

- "50% of deaths occur in vaccinated children" with the implication that there is an even chance regardless of immunisation, and that the immunised population is identical to the unimmunised .
- "50% of deaths occur in children below the age of vaccination" with the implication that they would not be protected by personal immunisation, and therefore not protected at all . Herd immunity is not mentioned.

90 percent

A recurring argument is that a 90% (eg 99.4% for measles in England and Wales from 1901/2 averaged) reduction in a specific disease occurred between two dates, the latter just before introduction of vaccination or immunisation against that disease, and that therefore any subsequent reduction is due to the same forces of history, and none of it is because of vaccination.

(See also **vaccine controversy**)

In on-line responses

Responses to papers or reports of scientific or political enquiry in the BMJ attract responses repeatedly deploying characteristic arguments in characteristic fashion from a small population of frequent responders [10]. Mainstream doctors regard these arguments as having been refuted.

Attacks on a broad front

Science

Assertions that immunisation cannot work because the theory on which it works is incorrect have been made .

Doctors' behaviour

In 2006 immunisation of medical, nursing and paramedical staff in the UK national health service is believed to be complete .

Cell-lines

A reluctance to use (viral) vaccines derived from human cell-lines is a definite principled objection. Secular ethical, humanist and mainstream religious views generally do not reject them. The element of presentation of the argument, in terms of absolutes and the evil of those preparing the vaccines distinguishes arguments from an anti-vaccinationist stance from the discussion of proportionate benefit and harm in a continuum of ethics.

Thiomersal

Thiomersal is being phased out (already in some European countries) and the USA is following. Recently, largely in the USA, it has been suggested that the organic mercury content of thiomersal in child vaccines might contribute to autism.[17][18] The 2004 Institute of Medicine panel favoured rejecting any causal relationship between thiomersal-containing vaccines and autism. The interests in this are vested, for example, governments wishing public health policies to proceed, pharmaceutical companies preferring not to pay huge damages, and (in the absence of no-fault compensation) large monetary gains for successful litigants and their counsel. Anti-vaccination sites publicise the assertions of danger more prominently than these findings , or the fact that thiomersal has recently (eg Oct 2004 in the UK) been removed from many vaccines for use in the Western world (but not the third world).

Effect on public morality

In the USA, some conservative Christian groups, for instance the Family Research Council, have opposed mandatory vaccination for diseases that are typically spread via sexual contact (e.g. Hepatitis and HPV). They believe that the possibility of disease serves as a deterrent against risky sexual contact, and that removing the possibility of disease would have the unintended side effect of encouraging risky sexual contact, particularly among teenagers.[19]

Vaccine controversy

The *vaccine controversy* encompasses many issues over the benefits and risks of vaccines.

Vaccines are widely credited with reducing the prevalence and consequences of many diseases. National and international public health organizations have made vaccination a central part of their strategies. The consensus of health organizations and medical doctors is that mass vaccination campaigns have been an essential and effective component of eradication or control of several deadly diseases via individual and herd immunity.

Critics question the claimed efficacy and safety of such programs, often citing lack of research on the adverse effects as the cause. The medical community, however, overwhelmingly supports vaccination as an effective and safe means of preventing the spread and reducing the impact of infectious illnesses. The majority of public health advocates holds the opinion that the benefit to the public justifies mandatory programs.

Research continues into both the development of new vaccines for a broadening array of diseases and the efficacy and safety of vaccines already in common use.

The case for widespread vaccines

Public health officials, the medical community and public opinion overwhelmingly agree that children should routinely be vaccinated against a range of diseases, such as measles, polio, diphtheria, rubella, tetanus, pertussis, hepatitis B, and others. Some vulnerable groups are also advised to be vaccinated against influenza. Supporters of widespread vaccination policies contend that:

- Vaccines have saved more lives than any other form of medical intervention. Among the most striking successes are the worldwide destruction of smallpox and the near eradication of polio.
- Vaccines are a cost-effective way of ensuring health, compared to treatment of a manifest disease. Routine childhood immunization saves about $40 billion in overall healthcare and social costs per birth year cohort vaccinated.
- Vaccines prevent epidemics in vulnerable areas. When vaccination against polio was recently halted in Nigeria, for instance, the number of cases significantly rose. A recent measles outbreak in 2005 in Indiana was attributed to lack of vaccination among children whose parents refused vaccination
- Critics of vaccination often lack relevant qualifications.
- Other critics of vaccination, such as Robert F. Kennedy, Jr. and Andrew Wakefield, are part of a plaintiffs' lawyers' campaign to generate contingent fees from litigation against vaccine manufacturers using junk science.
- Physicians almost uniformly support polyvalent (more than one antigen) vaccines, such as DPT and MMR, as being in the best interests of the child. The reasons given are that it reduces the unprotected exposure to all but one of the components over that of spaced immunization with single components, one injection is less uncomfortable than several, and it is more cost-effective for parents.
- If individual or multiple vaccinations were to "weaken the immune system", then they would be expected to increase hospitalization for other infections following immunization. Epidemiological surveys give a probability below one in a thousand that this happens. The statistical power of the study — given the Cohort size— is too small to reduce uncertainty further.

Criticism of widespread vaccine policy

The practice of vaccination has been opposed by some since its inception in the late 18th century, but criticism has become more visible in the US and some other developed countries in recent years, roughly paralleling the widespread availability of online information. While positions vary from outright rejection of the practice to calls for more selective and cautious use of vaccination, one or several of the following arguments are typically invoked:

- Critics claim that the public health benefits of vaccinations are exaggerated. They further claim that the mortality rates of some illnesses were already dramatically reduced before vaccines were introduced, and claim that further reductions cannot immediately be attributed to vaccines.
- Secondary and long-term effects on the immune system from introducing immunogens and adjuvants directly into the body are not fully

understood. Some autoimmune diseases like Acute disseminated encephalomyelitis, Guillain-Barré syndrome, Transverse myelitis and multiple sclerosis are known to be connected to vaccines, which suggests other autoimmune disorders might also be vaccine-related [1][2]

- The recommended vaccination schedule does not consider the cumulative effect of being exposed to multiple immunogens at the same time and at a young age.
- At least some vaccine studies did not include such young children (e.g., 5 week old infants, 2 month old infants), yet vaccination schedules start with newborns. There can be a vast difference between the weight and all around development of a newborn baby versus a toddler, yet this is not accounted for.
- Opponents of current vaccination policy question whether vaccinations actually create immunity against the targeted diseases, since some people who have been vaccinated still contracted the illness.
- By not exposing children to common childhood illnesses, they may be more susceptible to diseases at a point when their immune system is weakened, e.g., at an old age or when sick for other reasons.
- As is true with any medication, adverse events to the vaccine (even when rare) may be worse than the disease itself, and there are isolated reports of serious health damage and even death, within hours or a few days of vaccination. Although there are now various national databases where reported reactions can be recorded, anti-vacinationists claim that serious adverse events are grossly under-reported.
- There are a number of possible conflicts of interest that may affect the research design, findings, and opinions about vaccines, including financial interests of companies, the self-regulatory mechanism of medical doctors, and fear of the consequences should vaccines be found to be dangerous (see 2000 Simpsonwood CDC conference for example of such fears). But there are also concerns that opponents of vaccines may be seeking to enrich themselves through litigation or the sale of alternatives, by spreading fear and misjudgment among the public.
- Religious objections, by certain churches and by Christian Scientists to all forms of medical intervention.
- In many studies, adverse effects of vaccines are actively monitored only for a short time, e.g. 14 days.
- In many studies, the vaccine efficacy and safety research is not done by comparing to a group not receiving the vaccine, but to a group receiving a different vaccine for a different disease or a coctail of vaccine additives (e.g. aluminum adjuvants) - thus the research is not designed to show and can not show real vaccine efficacy or safety

The MMR controversy

Controversy has arisen regarding the safety of the MMR vaccine, because a handful of scientists and parents argue that the vaccine is the cause of the increased incidence of autism noted in western countries and Japan, and bowel disorders such as Crohn's disease. A theory advanced by proponents of the link is that the MMR vaccine overwhelms an immune system they assert is already struggling from the effect of thimerosal contained in previous vaccines. They assert that live measles virus in the formulation of the MMR is detrimental to susceptible individuals in a fashion in which wild measles never was.

During the 1980s and 1990s, a number of lawsuits were brought in the United States against manufacturers of vaccines, alleging the vaccines had caused a variety of physical and mental disorders in children. While these were inconclusive, they did lead to a massive jump in the costs of the MMR vaccine, as pharmaceutical companies sought to cover potential liabilities by lobbying for legislative protection. By 1993, Merck KGaA had become the only company willing to sell MMR vaccines in the United States and the United Kingdom. Two other MMR vaccines were withdrawn in the UK in 1992 on safety grounds arising from the strain of mumps component.

In September 1995, the Legal Aid Board in the UK granted a number of families financial assistance to pursue legal claims against the state health authorities and the vaccine's manufacturers, claiming that their children were killed or seriously injured by the MMR vaccine. A pressure group called JABS (Justice, Awareness, Basic Support) was established to represent families with children who, their parents said, were "vaccine-damaged."

In 1996, in New Zealand claims by an academic from Melbourne University that MMR contained a human blood product, serum albumin, and could therefore spread Creutzfeldt-Jakob disease caused anxiety. This did not last, since serum albumin was not an ingredient of the MMR vaccine.

Dr. Andrew Wakefield's report

1998 Lancet paper

In February 1998, a group led by Dr. Andrew Wakefield wrote a paper (on which almost all the other authors later issued a retraction of an interepretation; see below), Ileal-lymphoid-nodular hyperplasia, non-specific colitis, and pervasive developmental disorder in children published in the respected medical journal The Lancet. The report analysed the cases of twelve children with developmental disorders admitted to the Royal Free Hospital in north London in 1996-1997, described a collection of bowel symptoms, which Wakefield asserted was evidence of a possible novel syndrome, which he would later call autistic enterocolitis, and recommended further study into the possible link between the condition and environmental triggers, i.e., the MMR vaccine. The paper proposed links between gastrointestinal symptoms and developmental disorders in twelve children that were alleged to be associated in time with MMR vaccination. No conclusions about causal links, such as that MMR could lead to autism, were reached. However, at a press conference before the paper's publication, Dr Wakefield said that he thought it prudent to use single vaccines instead of the MMR triple vaccine until this could be ruled out as an environmental trigger, given that parents of eight of the twelve children studied were said to have blamed the MMR

vaccine, saying that symptoms of autism had set in within days of vaccination at approximately 14 months. He declared, "I can't support the continued use of these three vaccines given in combination until this issue has been resolved." In a video news release, issued by the hospital to broadcasters in advance of the press conference, he called for MMR to be "suspended in favour of the single vaccines."

Controversy following publication of report

The paper, press conference and video sparked a major health scare in the United Kingdom. The subsequent debate became polarised. Wakefield's research was misused by parties from both sides of the argument. The controversy was seized upon by some UK newspapers, which argued that separate vaccines ought to be available on the National Health Service (NHS) (It can be argued that these newspapers may have been serving their own interest by promoting this "health scare story" up the news agenda). Wakefield became subject to attacks, his critics questioning the validity and the ethics of the research. The UK government and medical authorities, such as the NHS, stressed extensive epidemiological evidence that failed to show any connection between MMR and developmental disorders. These denials were disbelieved by some parents, not least because previous government pronouncements on safety had been faulty, such as in the 'Mad Cow' (BSE) affair. The government was also alleged to be unwilling to support the use of separate vaccines because the NHS could not afford them. As a result, the takeup of MMR dropped sharply, from 92% in 1996 to 84% in 2002. In some parts of London, it was said to be as low as 60% - far below the rate thought to be needed to avoid an epidemic of measles. Although an epidemic has not yet occurred, measles rates have risen and doctors have warned of the likelihood of a future epidemic, because of the failure of the protection offered by herd immunity.

A factor in the controversy is that only the combined vaccine is available through the UK National Health Service; those who do not wish to have it given to their children must either have the separate vaccines given privately, or not vaccinate their children at all. The Prime Minister, Tony Blair, has refused to state whether his son Leo has received the MMR vaccine, but has strongly supported the vaccine in public. The Chancellor, Gordon Brown, has confirmed his son has been immunised[3].

The great majority of doctors prefer to administer the combined vaccine rather than the separate ones, as it is less distressing to the child, and parents are more likely to attend for one vaccination than for three.

Epidemiologic research on hundreds of thousands of children in numerous studies continues to show no link between MMR and autism. Critics of these epidemiology studies, such as retired British clinician John Walker-Smith, although a supporter of the triple vaccine, have pointed out that epidemiology is a 'blunt tool' and may miss causal relationships. For example, it can be difficult to find two populations of sufficient size which differ only in whether they were vaccinated.

Dr. Wakefield left his job at the Royal Free Hospital in 2001. His continued research includes involvement in scientific collaborations in the U.S and Europe, and a report on possible immunologic, metabolic, and pathologic changes occurring in what Wakefield has called "autistic enterocolitis", links between intestinal disease and neurologic disorders in

children, and the potential relationship of these disorders to environmental causes, such as vaccines.

Conflict of interest allegations

In February 2004, it emerged that when Wakefield had published The Lancet report, £55,000 funding was received by the Royal Free Hospital from lawyers seeking evidence of any link between autism and the MMR vaccine. According to a Sunday Times investigation, several of the parents quoted as saying that MMR had damaged their children were also litigants. Although Wakefield maintains the funding was properly disclosed from the outset, allegations have been made that the funding was not revealed to either The Lancet or Wakefield's co-researchers. On February 20, 2005, The Lancet said it should have never published Wakefield's study, which was "flawed" because Dr Wakefield had "a fatal conflict of interest." Several of Dr. Wakefield's co-researchers also strongly criticised the lack of disclosure.

Retraction of an interpretation of the Lancet paper

The investigation which led to 10 of the 13 authors of the 1998 Lancet paper formally retracting the interpretation that the article claimed a link between MMR and autism was carried out by Brian Deer for The Sunday Times of London. Deer continued his investigation in a British television documentary, "MMR: What They Didn't Tell You", broadcast on November 18, 2004. This documentary alleged that Wakefield had applied for patents on a vaccine that was a rival of the MMR vaccine, and that he knew of test results from his own laboratory at the Royal Free hospital that contradicted his claims.

General Medical Council Investigation

The General Medical Council, which is responsible for licensing doctors and Supervising Medical Ethics in the UK were reported to be investigating the affair and in June 2006 was reported to be prepared to accuse Wakefield of four charges: "that he published inadequately founded research, failed to obtain ethical committee approval for the work, obtained funding for it improperly, and subjected children to "unnecessary and invasive investigations." This could result in him being struck off the Medical Register in the UK.

Recent studies

Epidemiological research continues to show a dramatic increase in the incidence of autism, but whether the increase is real, rather than an artifact of changes in diagnosis and reporting, is unknown, and no causal connection has been demonstrated to the MMR vaccine. Since Wakefield's paper, there has been substantial clinical research investigating his claim to have found measles virus located in the gut of proportion of children, much of which has been financed by litigation, with the results not reported on legal grounds.

- In October 2004, the Journal of American Physicians and Surgeons, formerly the Medical Sentinel, magazine of the conservative Association of

American Physicians and Surgeons, published a paper by Wakefield supporters and concluded that "Developing safer vaccination strategies and supporting further investigation of the hypothesized link between the MMR vaccine and autism should have a high priority." It also noted that in Denmark Thimerosal is eliminated as a factor in any relationship between MMR and autism.

- Also in October 2004, a review, financed by the European Union, was published in the October 2004 edition of Vaccine[4] that assessed the evidence given in 120 other studies and considered unintended effects of the MMR vaccine. The authors concluded that
    - the vaccine is associated with some positive and negative side effects,
    - it was "unlikely" that there was a connection between MMR and autism, and
    - "The design and reporting of safety outcomes in MMR vaccine studies ... are largely inadequate".
- In January 2005, intensive research in a single county in Minnesota reported an eightfold increase in the incidence of autism over a period beginning in the early eighties and ending in the late nineties but found no evidence of a link with MMR. The authors of the research suggested that the increase in autism was due to an increased awareness of the disorder, a growth in services, and changing definitions.
- Japan provided a natural experiment on the subject: combined MMR vaccine was introduced in 1989, but the programme was terminated in 1993 and only single vaccines used thereafter.[21] In March 2005 a study of over 30,000 children (278 cases) born in one district of Yokohama concluded "The incidence of all autistic spectrum disorders (ASD), and of autism, continued to rise after MMR vaccine was discontinued. The incidence of autism was higher in children born after 1992 who were not vaccinated with MMR than in children born before 1992 who were vaccinated. The incidence of autism associated with regression was the same during the use of MMR and after it was discontinued." Autism rose (from 46-86 cases per 10,000 children, to 97-161/10,000). The authors concluded: "The significance of this finding is that MMR vaccination is most unlikely to be a main cause of ASD, that it cannot explain the rise over time in the incidence of ASD, and that withdrawal of MMR in countries where it is still being used cannot be expected to lead to a reduction in the incidence of ASD."[5] This study did not question whether or not both MMR and separate vaccines were capable of contributing to ASD, Crohns and other disorders; with separate vaccines, rather than MMR, being responsible for a more severe effect.
- Dr. Wakefield contends the pattern of autism rates revealed by the data support his hypothesis . His views, however, have found little support.[6]
- In October 2005, the Cochrane Library published a review of 31 scientific studies, and concluded that "there was no credible evidence behind claims of harm from the MMR vaccination" and "MMR is an important vaccine that has prevented diseases that still carry a heavy burden of death ....."[23] However the authors of the report also stated that "the design and reporting of

safety outcomes in MMR vaccine studies, both pre- and post-marketing, are largely inadequate."[7] Cochrane, based in Oxford, England, is widely regarded by scientists as the most authoritative independent reviewer of medical literature, and the custodian of evidence-based medicine.

- A Journalist for UPI, Dan Olmsted, has conducted a journalistic investigation reported in his "Age of Autism" column and did not find many never-vaccinated children with autism. Olmsted looked for autistic children among unvaccinated Amish; in a subset of homeschooled children who are not vaccinated for religious reasons; and in a pediatric practice in Chicago with several thousand never-vaccinated children. Partly as a result of this, a U.S. Congresswoman has produced a draft Autism Bill
- In 2006 a study is underway, led by Arthur Krigsman of New York University School of Medicine, involving 275 children. Serious intestinal inflammations have been found in some of the autistic children and biopsies of gut tissue have been performed on 82 of them. Of these, 70 are said to have shown evidence of the measles virus. The study is yet to be completed or peer reviewed.[8]

Antisense therapy

Antisense therapy is a form of treatment for genetic disorders or infections. When the genetic sequence of a particular gene is known to be causative of a particular disease, it is possible to synthesize a strand of nucleic acid (DNA, RNA or a chemical analogue) that will bind to the messenger RNA (mRNA) produced by that gene and inactivate it, effectively turning that gene "off".

This synthesized nucleic acid is termed an "anti-sense" oligonucleotide because its base sequence is complementary to the gene's messenger RNA (mRNA), which is called the "sense" sequence (so that a sense segment of mRNA " 5'-AAGGUC-3' " would be blocked by the anti-sense mRNA segment " 3'-UUCCAG-5' ").

Antisense drugs are being researched to treat lung cancer, diabetes and diseases such as asthma and arthritis with an inflammatory component. Most potential therapies have not yet produced significant clinical results, though one antisense drug, fomivirsen (marketed as Vitravene), has been approved by the US Food and Drug Administration (FDA) as a treatment for cytomegalovirus retinitis.

Biochemical engineering

Biochemical engineering is a branch of chemical engineering that mainly deals with the design and construction of unit processes that involve biological organisms or molecules. Biochemical engineering is often taught as a supplementary option to chemical engineering due to the similarities in both the background subject curriculum and problem-solving techniques used by both professions. Its applications are used in the pharmaceutical, biotechnology, and water treatment industries.

The Bioreactor

A *bioreactor* may refer to any device or system that supports a biologically active environment. In one case, a bioreactor is a vessel in which is carried out a chemical process which involves organisms or biochemically active substances derived from such organisms. This process can either be aerobic or anaerobic. These bioreactors are commonly cylindrical, ranging in size from some liter to cube meters, and are often made of stainless steel.

A bioreactor may also refer to a device or system meant to grow cells or tissues in the context of cell culture. These devices are being developed for use in tissue engineering.

On the basis of *mode of operation*, a bioreactor may be classified as batch, fed batch or continuous (e.g. Continuous stirred-tank reactor model). An example of a bioreactor is the chemostat.

Organism growing in bioreactor may be suspended or immobilized . The simplest, where cells are immobilized, is a Petri dish with agar gel. Large scale immobilized cell bioreactors are:

- packed bed
- fibrous bed
- membrane

Bioreactor design

Bioreactor design is quite a complex engineering task. Under optimum conditions the microorganisms or cells are able to perform their desired function with great efficiency. The bioreactor's environmental conditions like gas (i.e., air, oxygen, nitrogen, carbon dioxide) flowrates, temperature, pH and dissolved oxygen levels, and agitation speed/circulation rate need to be closely monitored and controlled.

Most industrial bioreactor manufacturers use vessels, sensors, controllers, and a control system, networked together for their bioreactor system, see programmable logic controller (PLC).

Fouling can harm the overall sterility and efficiency of the bioreactor, especially the heat exchangers. To avoid it the bioreactor must be easily cleanable and must be as smooth as possible (therefore the round shape).

A heat exchanger is needed to maintain the bioprocess at a constant temperature. Biological fermentation is a major source of heat, therefore in most cases bioreactors need water refrigeration. They can be refrigerated with an external jacket or, for very large vessels, with internal coils.

In an aerobic process, optimal oxygen transfer is perhaps the most difficult task to accomplish. Oxygen is poorly soluble in water -and even less in fermentation broths- and is relatively scarce in air (20.8%). Oxygen transfer is usually helped by agitation, that is also needed to mix nutrients and to keep the fermentation homogeneous. There are however limits to the speed of agitation, due both to high power consumption (which is proportional to the cube of the speed of the electric motor) and the damage to organisms due to excessive tip speed.

Industrial bioreactors usually employ bacteria or other simple organisms that can withstand the forces of agitation. They are also simple to sustain, requiring only simple nutrient solutions and can grow at astounding rates.

In bioreactors where the goal is grow cells or tissues for experimental or therapeutic purposes, the design is significantly different from industrial bioreactors. Many cells and tissues, especially mammalian, must have a surface or other structural support in order to grow, and agitated environments are often destructive to these cell types and tissues. Higher organisms also need more complex growth medium.

NASA Tissue Cloning Bioreactor

NASA has developed a new type of bioreactor that artificially grows tissue in cell cultures. NASA's tissue bioreactor can grow heart tissue, skeletal tissue, ligaments, cancer tissue for study, and other types of tissue.

For more information on artificial tissue culture.

Biopharmaceuticals

Biopharmaceuticals are medical drugs (see pharmacology) produced using biotechnology. They are proteins (including antibodies), nucleic acids (DNA, RNA or antisense oligonucleotides) used for therapeutic or in vivo diagnostic purposes, and are produced by means other than direct extraction from a native (non-engineered) biological source. [1]

The first such substance approved for therapeutic use was recombinant human insulin (rHI, trade name Humulin), which was developed by Genentech and marketed by Eli Lilly and Company in 1982.

The large majority of biopharmaceutical products are pharmaceuticals that are derived from life forms. Small molecule drugs are not typically regarded as biopharmaceutical in nature by the industry. However members of the press and the business and financial community often extend the definition to include pharmaceuticals not created through biotechnology. That is, the term has become an oft-used buzzword for a variety of different companies producing new, apparently high-tech pharmaceutical products.

When a biopharmaceutical is developed, the company will typically apply for a patent, which is a grant for exclusive manufacturing rights. This is the primary means by which the developer of the drug can recover the investment cost for development of the biopharmaceutical. The patent laws in the United States and Europe differ somewhat on the requirements for a patent, with the European requirements are perceived as more difficult to satisfy. The total number of patents granted for biopharmaceuticals has risen significantly since the 1970s. In 1978 the total patents granted was 30. This had climbed to 15,600 in 1995, and by 2001 there were 34,527 patent applications.[2]

Within the United States, the Food and Drug Administration (FDA) exerts strict control over the commercial distribution of a pharmaceutical product, including biopharmaceuticals. Approval can require several years of clinical trials, including trials with

human volunteers. Even after the drug is released, it will still be monitored for performance and safety risks.

The manufacture of the drug must satisfy the "current Good Manufacturing Practices" regulations of the FDA. They are typically manufactured in a clean room environment with set standards for the amount of airborne particles.

Classification of biopharmaceuticals

- Blood factors (Factor VIII and Factor IX)
- Thrombolytic agents (tissue plasminogen activator)
- Hormones (Insulin, growth hormone, gonadotrophins)
- Haematopoietic growth factors (Erythropoietin, colony stimulating factors)
- Interferons (Interferons-±, -^{2}, -^{3})
- Interleukin-based products (Interleukin-2)
- Vaccines (Hepatitis B surface antigen)

- Monoclonal antibodies **(Various)**

- Additional products (tumour necrosis factor, therapeutic enzymes)

Uses

- Erythropoietin - Treatment of anaemia
- Interferon-± - Treatment of leukaemia

Interferon-^{2} - Treatment of multiple sclerosis
Monoclonal antibody - Treatment of rheumatoid arthritis
Colony stimulating factors - Treatment of neutropenia
Glucocerebrosidase - Treatment of Gaucher's disease

Large scale production

Biopharmaceuticals may be produced from microbial cells (e.g. recombinant E. coli), mammalian cell lines (see cell culture) and plant cell cultures (see plant tissue culture) in bioreactors of various configurations.

Important issues of concern are cost of production (a low volume, high purity product is desirable) and microbial contamination (by bacteria, viruses, mycoplasma, etc). Alternative platforms of production which are being tested include whole plants (plant-made pharmaceuticals).

Transgenics

A potentially controversial method of producing biopharmaceuticals involves transgenic organisms, particularly plants and animals that have been genetically modified to produce

drugs. The production of these organisms represents a significant risk on the part of the investor, both in terms of the risk of failure to produce the required organism, and in the risk of non-acceptance by government bodies due to the perceived risks and from ethical issues. Biopharmaceutical crops also represent a risk of cross-contamination with non-engineered crops, or crops engineered for non-medical purposes.

One potential approach to this technology is the creation of a transgenic mammal that can produce the biopharmaceutical in its milk (or blood or urine). Once an animal is produced, typically using the pronuclear microinjection method, it becomes efficacious to use cloning technology to create additional offspring that carry the favorable modified genome. [3] The first such drug manufactured from the milk of a genetically-modified goat was ATryn®, but marketing permission was blocked by the European Medicines Agency in February 2006.[4] This decision was reversed in June 2006 and approval was given August 2006. [5]

Gene therapy

Gene therapy is the insertion of genes into an individual's cells and tissues to treat a disease, and hereditary diseases in particular. Gene therapy typically aims to supplement a defective mutant allele with a functional one. Although the technology is still in its infancy, it has been used with some success. Antisense therapy is not strictly a form of gene therapy, but is often lumped together with them.

Background

In the 1980s, advances in molecular biology had already enabled human genes to be sequenced and cloned. Scientists looking for a method of easily producing proteins — such as insulin, the protein deficient in diabetes mellitus type 1 — investigated introducing human genes to bacterial DNA. The modified bacteria then produce the corresponding protein, which can be harvested and injected in people who cannot produce it naturally.

On September 14, 1990 researchers at the U.S. National Institutes of Health performed the first approved gene therapy procedure on four-year old Ashanti DeSilva. Born with a rare genetic disease called severe combined immunodeficiency (SCID), she lacked a healthy immune system, and was vulnerable to every passing germ. Children with this illness usually develop overwhelming infections and rarely survive to adulthood; a common childhood illness like chickenpox is life-threatening. Ashanti led a cloistered existence--avoiding contact with people outside her family, remaining in the sterile environment of her home, and battling frequent illnesses with massive amounts of antibiotics.

In Ashanti's gene therapy procedure, doctors removed white blood cells from the child's body, let the cells grow in the lab, inserted the missing gene into the cells, and then infused the genetically modified blood cells back into the patient's bloodstream. Laboratory tests have shown that the therapy strengthened Ashanti's immune system; she no longer has recurrent colds, she has been allowed to attend school, and she was immunized against whooping cough. This procedure was not a cure; the white blood cells treated genetically only work for a few months, and the process must be repeated every few months. (VII, Thompson [First] 1993).

Although this simplified explanation of a gene therapy procedure sounds like a happy ending, it is little more than an optimistic first chapter in a long story; the road to the first approved gene therapy procedure was rocky and fraught with controversy. The biology of human gene therapy is very complex, and there are many techniques that still need to be developed and diseases that need to be understood more fully before gene therapy can be used appropriately. The public policy debate surrounding the possible use of genetically engineered material in human subjects has been equally complex. Major participants in the debate have come from the fields of biology, government, law, medicine, philosophy, politics, and religion, each bringing different views to the discussion.

Scientists took the logical step of trying to introduce genes straight into human cells, focusing on diseases caused by single-gene defects, such as cystic fibrosis, hemophilia, muscular dystrophy and sickle cell anemia. However, this has been much harder than modifying simple bacteria, primarily because of the problems involved in carrying large sections of DNA and delivering it to the right site on the genome.

Basic process

In most gene therapy studies, a "normal" gene is inserted into the genome to replace an "abnormal," disease-causing gene. A carrier molecule called a vector must be used to deliver the therapeutic gene to the patient's target cells. Currently, the most common vector is a virus that has been genetically altered to carry normal human DNA. Viruses have evolved a

way of encapsulating and delivering their genes to human cells in a pathogenic manner. Scientists have tried to take advantage of this capability and manipulate the virus genome to remove disease-causing genes and insert therapeutic genes.

Target cells such as the patient's liver or lung cells are infected with the vector. The vector then unloads its genetic material containing the therapeutic human gene into the target cell. The generation of a functional protein product from the therapeutic gene restores the target cell to a normal state.

Types of gene therapy

In theory it is possible to transform either somatic cells (most cells of the body) or cells of the germline (such as sperm cells, ova, and their stem cell precursors). All gene therapy so far in people has been directed at somatic cells, whereas germline engineering in humans remains only a highly controversial prospect. For the introduced gene to be transmitted normally to offspring, it needs not only to be inserted into the cell, but also to be incorporated into the chromosomes by genetic recombination.

Somatic gene therapy can be broadly split in to two categories: ex vivo (where cells are modified outside the body and then transplanted back in again) and in vivo (where genes are changed in cells still in the body.) Recombination-based approaches in vivo are especially uncommon, because for most DNA constructs recombination has a very low probability.

Broad methods

There are a variety of different methods to replace or repair the genes targeted in gene therapy.

- A normal gene may be inserted into a nonspecific location within the genome to replace a nonfunctional gene. This approach is most common.
- An abnormal gene could be swapped for a normal gene through homologous recombination.
- The abnormal gene could be repaired through selective reverse mutation, which returns the gene to its normal function.
- The regulation (the degree to which a gene is turned on or off) of a particular gene could be altered.

Vectors in gene therapy

Viruses

All viruses attack their hosts and introduce their genetic material into the host cell as part of their replication cycle. This genetic material contains basic 'instructions' of how to produce more copies of these viruses, hijacking the body's normal production machinery to serve the needs of the virus. The host cell will carry out these instructions and produce additional copies of the virus, leading to more and more cells becoming infected. Some types of viruses actually physically insert their genes into the host's genome (it is the defining

feature of retroviruses, the family of viruses that includes HIV, the virus that causes AIDS). This incorporates the genes of that virus among the genes of the host cell for the life span of that cell.

Doctors and molecular biologists realized that viruses like this could be used as vehicles to carry 'good' genes into a human cell. First, a scientist would remove the genes in the virus that cause disease. Then they would replace those genes with genes encoding the desired effect (for instance, insulin production in the case of diabetics). This procedure must be done in such a way that the genes which allow the virus to insert its genome into its host's genome are left intact. This can be confusing, and requires significant research and understanding of the virus' genes in order to know the function of each. An example:

> A virus is found which replicates by inserting its genes into the host cell's genome. This virus has two genes- A and B. Gene A encodes a protein which allows this virus to insert itself into the host's genome. Gene B actually causes the disease this virus is associated with. Gene C is the "normal" or "desirable" gene we want in the place of gene B. Thus, by re-engineering the virus so that gene B is replaced by gene C, while allowing gene A to properly function, this virus could introduce your 'good gene'- gene C into the host cell's genome without causing any disease.

All this is clearly an oversimplification, and numerous problems exist that prevent gene therapy using viral vectors, such as: trouble preventing undesired effects, ensuring the virus will infect the correct target cell in the body, and ensuring that the inserted gene doesn't disrupt any vital genes already in the genome. However, this basic mode of gene introduction currently shows much promise and doctors and scientists are working hard to fix any potential problems that could exist.

Retroviruses

The genetic material in retroviruses is in the form of RNA molecules, while the genetic material of their hosts is in the form of DNA. When a retrovirus infects a host cell, it will introduce its RNA together with some enzymes into the cell. This RNA molecule from the retrovirus must produce a DNA copy from its RNA molecule before it can be considered for part of the genetic material of the host cell. The process of producing a DNA copy from an RNA molecule is termed reverse transcription. It is carried out by one of the enzymes carried in the virus, called reverse transcriptase. After this DNA copy is produced and is free in the nucleus of the host cell, it must be incorporated into the genome of the host cell. That is, it must be inserted into the large DNA molecules in the cell (the chromosomes). This process is done by another enzyme carried in the virus called integrase.

Now that the genetic material of the virus is incorporated and has become part of the genetic material of the host cell, we can say that the host cell is now modified to contain a new gene. If this host cell divides later, its descendants will all contain the new genes.

One of the problems of gene therapy using retroviruses is that the integrase enzyme can insert the genetic material of the virus in any arbitrary position in the genome of the host. If genetic material happens to be inserted in the middle of one of the original genes of the host cell, this gene will be disrupted (insertional mutagenesis). If the gene happens to be one regulating cell division, uncontrolled cell division (i.e., cancer) can occur. This problem has recently begun to be addressed by utilizing zinc finger nucleases[1] or by including certain

sequences such as the beta-globin locus control region[6] to direct the site of integration to specific chromosomal sites.

Gene therapy trials to treat severe combined immunodeficiency (SCID) were halted or restricted in the USA when leukemia was reported in three of eleven patients treated in the French Therapy X-linked SCID (XSCID) gene therapy trial. Ten XSCID patients treated in England have not presented leukemia to date and have had similar success in immune reconstitution. Gene therapy trials to treat SCID due to deficiency of the Adenosine Deaminase (ADA) enzyme continue with relative success in the USA, Italy and Japan.

Adenoviruses

Adenoviruses are viruses that carry their genetic material in the form of double-stranded DNA. They cause respiratory (especially the common cold), intestinal, and eye infections in humans. When these viruses infect a host cell, they introduce their DNA molecule into the host. The genetic material of the adenoviruses is not incorporated into the host cell's genetic material. The DNA molecule is left free in the nucleus of the host cell, and the instructions in this extra DNA molecule are transcribed just like any other gene. The only difference is that these extra genes are not replicated when the cell is about to undergo cell division so the descendants of that cell will not have the extra gene. As a result, treatment with the adenovirus will require readministration in a growing cell population although the absence of integration into the host cell's genome should prevent the type of cancer seen in the SCID trials. This vector system has shown real promise in treating cancer and indeed the first gene therapy product to be licenced is an adenovirus to treat cancer.

Adeno-associated viruses

Adeno-associated viruses, from the parvovirus family, are small viruses with a genome of single stranded DNA. These viruses can insert genetic material at a specific site on chromosome 19. There are a few disadvantages to using AAV, including the small amount of DNA it can carry (low capacity) and the difficulty in producing it. This type of virus is being used, however, because it is non-pathogenic (most people carry this harmless virus). In contrast to adenoviruses, most people treated with AAV will not build an immune response to remove the virus and the cells that have been successfully treated with it. Several trials with AAV are on-going or in preparation, mainly trying to treat muscle and eye diseases; the two tissues where the virus seems particularly useful. However, clinical trials have also been initiated where AAV vectors are used to deliver genes to the brain. This is possible because AAV viruses can infect non-dividing (quiescent) cells, such as neurons in which their genomes be expressed for a long time. In recent human trials, CD8+ immune cells have recognised the AAV infected cells as compromised and killed these cells accordingly. This action appears to be triggered by part of the capsid or outer coat of the type 2 virus. Recent studies have shown that humans will likely react in the same way against the new serotype 8 AAV as well.

Envelope protein pseudotyping of viral vectors

The viral vectors described above have natural host cell populations that they infect most efficiently. Retroviruses have limited natural host cell ranges, and although adenovirus and adeno-associated virus are able to infect a relatively broader range of cells efficiently, some cell types are refractory to infection by these viruses as well. Attachment to and entry into a susceptible cell is mediated by the protein envelope on the surface of a virus. Retroviruses and adeno-associated viruses have a single protein coating their membrane, while adenoviruses are coated with both an envelope protein and fibers that extend away from the surface of the virus. The envelope proteins on each of these viruses bind to cell-surface molecules such as heparin sulfate, which localizes them upon the surface of the potential host, as well as with the specific protein receptor that either induces entry-promoting structural changes in the viral protein, or localizes the virus in endosomes wherein acidification of the lumen induces this refolding of the viral coat. In either case, entry into potential host cells requires a favorable interaction between a protein on the surface of the virus and a protein on the surface of the cell. For the purposes of gene therapy, one might either want to limit or expand the range of cells susceptible to transduction by a gene therapy vector. To this end, many vectors have been developed in which the endogenous viral envelope proteins have been replaced by either envelope proteins from other viruses, or by chimeric proteins. Such chimera would consist of those parts of the viral protein necessary for incorporation into the virion as well as sequences meant to interact with specific host cell proteins. Viruses in which the envelope proteins have been replaced as described are referred to as pseudotyped viruses. For example, the most popular retroviral vector for use in gene therapy trials has been the lentivirus Simian Immunodeficiency virus coated with the envelope proteins, G-protein, from Vesicular Stomatitus virus. This vector is referred to as VSV G-pseudotyped lentivirus, and infects an almost universal set of cells. This tropism is characteristic of the VSV G-protein with which this vector is coated. Many attempts have been made to limit the tropism of viral vectors to one or a few host cell populations. This advance would allow for the systemic administration of a relatively small amount of vector. The potential for off-target cell modification would be limited, as well as many concerns from the medical community. Most attempts to limit tropism have used chimeric envelope proteins bearing antibody fragments. These vectors show great promise for the development of "magic bullet" gene therapies.

Non-viral methods

Non-viral methods present certain advantages over viral methods; simple large scale production and low host immunogenicity being just two. Previously, low levels of transfection and expression of the gene held non-viral methods at a disadvantage, however recent advances in vector technology has yielded molecules and techniques with transfection efficiencies similar to that of viruses.

Naked DNA

This is the simplest method of non-viral transfection. Clinical trials have been carried out of intramuscular injection of a naked DNA plasmid have occurred with some success, however the expression has been very low in comparison to other methods of transfection. In addition to trials with plasmids, there have been trials with naked PCR product, which have had similar or greater success, however this success does not compare to that of the other methods, leading to research into more efficient methods for delivery of the naked DNA such as electroporation and the use of a "gene gun", which shoots DNA coated gold particles into the cell using high pressure gas.

Oligodeoxynucleotides

The use of synthetic oligodeoxynucleotides in gene therapy is to inactivate the genes involved in the disease process. There are several methods by which this is achieved. One strategy uses antisense specific to the target gene to disrupt the transcription of the faulty gene. Another uses small catalytic molecules of RNA called siRNA to cleave specific unique sequences in the mRNA transcript of the faulty gene, disrupting translation of the faulty mRNA, and therefore expression of the gene. A further strategy uses double stranded oligodeoxynucleotides as a decoy for the transcription factors that are required to activate the transcription of the target gene. The transcription factors bind to the decoys instead of the promoter of the faulty gene which reduces the transcription of the target gene, lowering expression.

Lipoplexes and polyplexes

To improve the delivery of the new DNA into the cell, the DNA must be protected from damage and its entry into the cell must be facilitated. To this end new molecules, lipoplexes and polyplexes, have been created that have the ability to protect the DNA from undesirable degradation during the transfection process.

Plasmid DNA can be covered with lipids in an organized structure like a micelle or a liposome. When the organized structure is complexed with DNA it is called a lipoplex. There are three types of lipoplexes, anionic (negatively charged), neutral or cationic (positively charged). Initially, anionic and neutral lipids were used for the construction of lipoplexes for synthetic vectors. However, although there is little toxicity associated with them, they are compatible with body fluids and there was a possibility of adapting them to be tissue specific, they are complicated and time consuming to produce so attention was turned to the cationic versions.

Cationic lipids, due to their positive charge, naturally complex with the negatively charged DNA. Also as a result of their charge they interact with the cell membrane, endocytosis of the lipoplex occurs and the DNA is released into the cytoplasm. The cationic lipids also protect against degradation of the DNA by the cell.

The most common use of lipoplexes has been in gene transfer into cancer cells, where the supplied genes have activated tumor suppressor control genes in the cell and decrease the activity of oncogenes. Recent studies have shown lipoplexes to be useful in transfecting

respiratory epithelial cells, so they may be used for treatment of genetic respiratory diseases such as cystic fibrosis.

Complexes of polymers with DNA are called polyplexes. Most polyplexes consist of cationic polymers and their production is regulated by ionic interactions. One large difference between the methods of action of polyplexes and lipoplxes is that polyplexes cannot release their DNA load into the cytoplasm, so to this end, co-transfection with endosome-lytic agents (to lyse the endosome that is made during endocytosis, the process by which the polyplex enters the cell) such as inactivated adenovirus must occur. However this isn't always the case, polymers such as polyethylenimine have their own method of endosome disruption.

Hybrid methods

Due to every method of gene transfer having shortcomings, there has been some hybrid methods developed that combine two or more techniques. Virosomes are one example; they combine liposomes with an inactivated HIV or influenza virus. This has been shown to have more efficient gene transfer in respiratory epithelial cells than either viral or liposomal methods alone. Other methods involve mixing other viral vectors with cationic lipids or hybridising viruses.

Recent developments in gene therapy

Scientist at the National Institutes of Health (Bethesda, MD) have successfully treated metastatic melanoma in two patients using killer T cells genetically retargeted to attack the cancer cells. This study constitutes the first demonstration that gene therapy can be effective in treating cancer. The study results have been published in Science (October 2006).

In May 2006 a team of scientists led by Drs. Luigi Naldini and Brian Brown from the San Raffaele Telethon Institute for Gene Therapy (HSR-TIGET) in Milan, Italy reported a breakthrough for gene therapy in which they developed a way to prevent the immune system from rejecting a newly delivered gene. Similar to organ transplanation, gene therapy has been plagued by the problem of immune rejection. So far, delivery of the 'good' gene has been difficult because the immune sytem does not recognize the new gene and rejects the cells carrying it. To overcome this problem, the HSR-TIGET group utilized a newly uncovered network of genes regulated by molecules known as microRNAs. Dr. Naldini's group reasoned that they could use this natural function of microRNA to selectively turn off the identity of their therapeutic gene in cells of the immune system and prevent the gene from being found and destroyed. The researchers injected mice with the gene containing an immune-cell microRNA target sequence, and spectacularly, the mice did not reject the gene, as previously occurred when vectors without the microRNA target sequence were used. This work will have important implications for the treatment of hemophilia and other genetic diseases by gene therapy [1].

In March 2006 an international group of scientists announced the successful use of gene therapy to treat two adult patients for a disease affecting myeloid cells. The study, published

in Nature Medicine, is believed to be the first to show that gene therapy can cure diseases of the myeloid system

University of California, Los Angeles, research team gets genes into the brain using liposomes coated in a polymer called polyethylene glycol (PEG). The transfer of genes into the brain is a significant achievement because viral vectors are too big to get across the "blood-brain barrier." This method has potential for treating Parkinson's disease. See *Undercover genes slip into the brain* at NewScientist.com (March 20, 2003).

RNA interference or gene silencing may be a new way to treat Huntington's. Short pieces of double-stranded RNA (short, interfering RNAs or siRNAs) are used by cells to degrade RNA of a particular sequence. If a siRNA is designed to match the RNA copied from a faulty gene, then the abnormal protein product of that gene will not be produced. See *Gene therapy may switch off Huntington's* at NewScientist.com (March 13, 2003).

New gene therapy approach repairs errors in messenger RNA derived from defective genes. Technique has potential to treat the blood disorder thalassaemia, cystic fibrosis, and some cancers. See *Subtle gene therapy tackles blood disorder* at NewScientist.com (October 11, 2002).

Researchers at Case Western Reserve University and Copernicus Therapeutics are able to create tiny liposomes 25 nanometers across that can carry therapeutic DNA through pores in the nuclear membrane. See *DNA nanoballs boost gene therapy* at NewScientist.com (May 12, 2002).

Sickle cell is successfully treated in mice. See *Murine Gene Therapy Corrects Symptoms of Sickle Cell Disease* from March 18, 2002, issue of The Scientist.

The success of a multi-center trial for treating children with SCID (severe combined immune deficiency or "bubble boy" disease) held from 2000 and 2002 was questioned when two of the ten children treated at the trial's Paris center developed a leukemia-like condition. Clinical trials were halted temporarily in 2002, but resumed after regulatory review of the protocol in the United States, the United Kingdom, France, Italy, and Germany. (V. Cavazzana-Calvo, Thrasher and Mavilio 2004; see also '*Miracle' gene therapy trial halted* at NewScientist.com, October 3, 2002).

Problems and ethics

For the safety of gene therapy, the Weismann barrier is fundamental in the current thinking. Soma-to-germline feedback should therefore be impossible. However, there are indications that the Weissman barrier can be breached. One way it might possibly be breached is if the treatment were somehow misapplied and spread to the testes and therefore would infect the germline against the intentions of the therapy.

Some of the problems of gene therapy include:

- Short-lived nature of gene therapy - Before gene therapy can become a permanent cure for any condition, the therapeutic DNA introduced into target cells must remain functional and the cells containing the therapeutic DNA must be long-lived and stable. Problems with integrating therapeutic DNA into the genome and the rapidly dividing nature of many cells prevent gene therapy from achieving any long-term benefits. Patients will have to undergo multiple rounds of gene therapy.

- Immune response - Anytime a foreign object is introduced into human tissues, the immune system is designed to attack the invader. The risk of stimulating the immune system in a way that reduces gene therapy effectiveness is always a potential risk. Furthermore, the immune system's enhanced response to invaders it has seen before makes it difficult for gene therapy to be repeated in patients.
- Problems with viral vectors - Viruses, while the carrier of choice in most gene therapy studies, present a variety of potential problems to the patient -- toxicity, immune and inflammatory responses, and gene control and targeting issues. In addition, there is always the fear that the viral vector, once inside the patient, may recover its ability to cause disease.
- Multigene disorders - Conditions or disorders that arise from mutations in a single gene are the best candidates for gene therapy. Unfortunately, some of the most commonly occurring disorders, such as heart disease, high blood pressure, Alzheimer's disease, arthritis, and diabetes, are caused by the combined effects of variations in many genes. Multigene or multifactorial disorders such as these would be especially difficult to treat effectively using gene therapy.
- Chance of inducing a tumor - If the DNA is integrated in the wrong place in the genome, for example in a tumor suppressor gene, it could induce a tumor.

In popular culture

Gene therapy plays a major role in the sci-fi series Stargate Atlantis, as a certain type of alien technology can only be used if one has a certain gene which is given to the members of the team through gene therapy. Gene therapy also plays a major role in the plot of the James Bond movie Die Another Day. The Yellow Bastard from Frank Miller's Sin City was also apparently the recipient of gene therapy.

Gene therapy is a crucial plot element in the video game Metal Gear Solid, where it has been used to enhance the battle capabilities of enemy soldiers.

Publications

Molecular Therapy is the official journal of the American Society of Gene Therapy, and is a rapid-publication, peer-reviewed journal covering all aspects of human gene, cell, protein and nucleic acid therapy.

Chemopreventive agents

Chemoprophylaxis refers to the administration of a medication for the purpose of preventing disease. Antibiotics, for example, may be administered to patients with disorders of immune system function to prevent infection (particularly opportunistic infection). Antibiotics may also be administered to healthy individuals to limit the spread of an epidemic, or to patients who have repeated infections (such as urinary tract infections) to prevent recurrence.

In some cases, chemoprophylaxis is initiated to prevent the spread of an existing disease in an individual to a new organ system, as when intrathecal chemotherapy is administered in patients with malignancy to prevent brain metastasis.

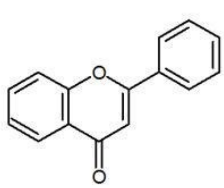
A related term is primary prevention, in which measures are undertaken to prevent the onset of disease in individuals who are susceptible (as when patients receive aspirin or statins to delay the development of coronary artery disease).

The use of chemoprophylaxis is limited primarily by two factors:

- All medications have the potential to cause side effects. In general, chemoprophylaxis should be initiated only when the benefits of treatment outweigh the risks.
- The cost associated with chemoprophylaxis may be prohibitive, particularly when the cost of treatment is high or the incidence of the target disease is low. Many forms of chemoprophylaxis are therefore not cost-effective.

Chemoprophylaxis is also used to treat several different varieties of meningococcal infections for close contact exposure to Neisseria menigitidis.

Flavonoids



Molecular structure of flavone

The term *flavonoid* refers to a class of plant secondary metabolites based around a phenylbenzopyrone structure. Flavonoids are most commonly known for their antioxidant activity. Flavonoids are also commonly referred to as *bioflavonoids* in the media – these terms are equivalent and interchangeable, since all flavonoids are biological in origin.

Biosynthesis

Flavonoids are synthesized by the phenylpropanoid pathway in which the amino acid phenylalanine is used to produce 4-coumaryl-CoA. This can be combined with malonyl-CoA to yield the true backbone of flavonoids, a group of compounds called chalcones. Ring-closure of these compounds results in the familiar form of flavonoids, a three-ringed structure (polyphenols). The metabolic pathway continues through a series of enzymatic modifications to yield flavanones ’ dihydroflavonols ’ anthocyanins. Along this pathway many products can be formed, including the flavonols, flavan-3-ols, proanthocyanidins (tannins) and a host of other polyphenolics.

Biological effects

Flavonoids are widely distributed in plants fulfilling many functions including producing yellow or red/blue pigmentation in flowers and protection from attack by microbes and insects. The widespread distribution of flavonoids, their variety and their relatively low toxicity compared to other active plant compounds (for instance alkaloids) mean that many animals, including humans, ingest significant quantities in their diet. Flavonoids have been found in high concentrations in butterflies and moths sequestered from dietary intake at the larval stage and then stored in adult tissues.

Flavonoids have been referred to as "nature's biological response modifiers" because of strong experimental evidence of their inherent ability to modify the body's reaction to allergens, viruses, and carcinogens. They show anti-allergic, anti-inflammatory[1] , anti-microbial and anti-cancer activity. In addition, flavonoids act as powerful antioxidants, protecting against oxidative and free radical damage.

Consumers and food manufacturers have become interested in flavonoids for their medicinal properties, especially their potential role in the prevention of cancers and cardiovascular disease. The beneficial effects of fruit, vegetables, and tea or even red wine have been attributed to flavonoid compounds rather than to known nutrients and vitamins.

Important flavonoids

Quercetin

Quercetin is a flavonoid that forms the "backbone" for many other flavonoids, like rutin. In studies, quercetin is found to be the most active of the flavonoids, and many medicinal plants owe much of their activity to their high quercetin content. Quercetin has demonstrated significant anti-inflammatory activity because of direct inhibition of several initial processes of inflammation. For example, it inhibits both the manufacture and release of histamine and other allergic/inflammatory mediators. In addition, it exerts potent antioxidant activity and vitamin C-sparing action.

Oligomeric proanthocyanidins

Proanthocyanidins extracts demonstrate a wide range of pharmacological activity. Their effects include increasing intracellular vitamin C levels, decreasing capillary permeability and fragility, scavenging oxidants and free radicals, and inhibiting destruction of collagen, the most abundant protein in the body.

Epicatechin

Epicatechin improves blood flow and thus seems good for cardiac health. Cocoa, the major ingredient of dark chocolate, is loaded with epicatechin and has been found to have nearly twice the antioxidant content of red wine and up to three times that of green tea.

Important dietary sources

Good sources of flavonoids include all citrus fruits, berries, onions, parsley, legumes, green tea, red wine, seabuckthorn, and dark chocolate (that with a cocoa content of seventy percent or greater).

Citrus

The citrus bioflavonoids include hesperidin, quercetin, rutin (a sugar of quercetin), and tangeritin. In addition to possessing antioxidant activity and an ability to increase intracellular levels of vitamin C, rutin and hesperidin exert beneficial effects on capillary permeability and blood flow. They also exhibit some of the anti-allergy and anti-inflammatory benefits of quercetin. Quercetin can also inhibit reverse transcriptase, part of the replication process of retroviruses (Spedding et al. 1989). The therapeutical relevance of this inhibition has not been established. Hydroxyethylrutosides (HER) have been used in the treatment of capillary permeability, easy bruising, hemorrhoids, and varicose veins.

Green Tea

Green tea polyphenols are potent antioxidant compounds that have demonstrated greater antioxidant protection than vitamins C and E. Green tea may also increase the activity of antioxidant enzymes. Green tea polyphenols may inhibit cancer by blocking the formation of cancer-causing compounds and suppressing the activation of carcinogens. The major polyphenols in green tea are *flavonoids* (catechin, epicatechin, epicatechin gallate, epigallocatechin gallate(EGCG), and proanthocyanidins).

Though both green tea and black tea are derived from the same plant (Camellia sinensis), they possess different antioxidants. In producing black tea the leaves are allowed to oxidize, during which enzymes present in the tea convert many polyphenols to larger molecules with different biological effects. However, green tea is produced by lightly steaming the fresh-cut leaf, which inactivates these enzymes, and oxidation does not occur.

Availability through microorganisms

A number of recent research articles have demonstrated the efficient production of flavonoid molecules from recombinant microorganisms. Such an approach opens the possibility of readily producing these compounds using renewable feedstocks and thus increasing the availability of rare flavonoid molecules for human and animal feed through dietary supplements.

Subgroups

Over 5000 naturally occurring flavonoids have been characterized from various plants. They have been classified according to their chemical structure, and are usually subdivided into 6 subgroups[2]:

- *Flavones* use the 2-phenylbenzopyrone skeleton shown *without a hydroxyl group at the 3 position*.

Examples: Luteolin, Apigenin

- *Flavonols* use the 2-phenylbenzopyrone skeleton shown *with a hydroxyl group at the 3 position*.

Examples: Quercetin, Kaempferol, Myricetin, Isorhamnetin, Pachypodol, Rhamnazin

- **Flavanones** use the 2-phenylbenzopyrone skeleton with the saturated 2,3 bond and without a hydroxyl group at the 3 position.

Examples: Hesperetin, Naringenin, Eriodictyol

- *Flavan-3-ols* use the 2-phenylbenzopyran skeleton

Examples: (+)-Catechin, (+)-Gallocatechin, (-)-Epicatechin, (-)-*Epigallocatechin, (-)-Epicatechin 3-gallate, (-)-Epigallocatechin 3-gallate, Theaflavin, Theaflavin 3-gallate, Theaflavin 3'-gallate, Theaflavin 3,3' digallate, Thearubigins

- *Isoflavones* use the 3-phenylbenzopyrone skeleton

Examples: Genistein, Daidzein, Glycitein

- Anthocyanidins.

Examples: Cyanidin, Delphinidin, Malvidin, Pelargonidin, Peonidin, Petunidin

Anthocyanins

Anthocyanins (from Greek: ½¸ÌÂ (anthos) = flower + ºÅ±½ÌÂ (kyanos) = blue) are water-soluble vacuolar flavonoid pigments that appear red to blue, according to pH. They are synthesized exclusively by organisms of the plant kingdom, and have been observed to occur in all tissues of higher plants, providing color in leaves, stems, roots, flowers, and fruits.

Function

In flowers, anthocyanin pigments function as pollinator attractants, and in fruits, the colorful skins attract animals which will eat the fruits and disperse the seeds. In photosynthetic tissues (such as leaves), anthocyanins have been shown to act as a "sunscreen", protecting cells from photo-damage by absorbing UV and blue-green light, thereby protecting the tissues from photoinhibition, or high light stress. This has been shown to occur in red juvenile leaves, autumn leaves, and broad-leaved evergreen leaves that turn red during the winter. It is also thought that red coloration of leaves may camouflage leaves from herbivores blind to red wavelengths, or signal unpalatability to herbivores, since anthocyanin synthesis often coincides with synthesis of unpalatable phenolic compounds.

In addition to their role as light-attenuators, anthocyanins also act as powerful antioxidants, helping to protect the plant from radicals formed by UV light and during metabolic processes. This antioxidant property is conserved even after consumption by another organism, which is another reason why fruits and vegetables with red skins and tissues are a nutritious food source.

Occurrence

foodstuff - Anthocyanin in mg per 100 g foodstuff

blackcurrant 190-270

chokeberry 200-1000

aubergine 750

orange ~200

blackberry ~115

vaccinium 80-420

raspberry 10-60

cherry 350-400

redcurrant 80-420

red grape 30-750

red wine 24-35

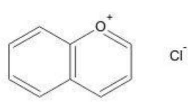
Not all land plants contain anthocyanin and in the Caryophyllales, Cactus and Galium mollugo they are replaced by betacyanins.

Anatomically, anthocyanins are found mostly in flowers and fruits but also in leaves, stems, and roots. In these parts they are found predominantly in outer cell layers such as the epidermis and peripheral mesophyll cells. The amounts are relatively large: one kilogram of blackberry for example contains approximately 1.15 gram, and red and black legumes can contain 20 gram per 1 kg. Other plants rich in anthocyanins are blackcurrant, chokeberry, cherry, eggplant, blue grape, Vaccinium and red cabbage and also the Usambara-violet. Anthocyanins are less abundant in banana, asparagus, pea, fennel, pear and potato. Most frequent in nature are the glycosides of cyanidin, delphinidin, malvidin, pelargonidin, peonidin and petunidin. Roughly 2% of all hydrocarbons fixated in photosynthesis are converted into flavonoids and their derivatives such as the anthocyanins. This is no less than 10[9] tons per year.

In plants anthocyanins are present together with other natural pigments like the closely chemically related flavonoids, carotenoids, anthoxanthins and betacyanins.

In still relatively young plants or new growth, where chlorophyll and wax production has not yet begun and which would be unprotected from UV light, anthocyanin production increases. Parts or even the whole plant are colored by these "juvenile anthocyanins," and thereby protected from damage. As soon as chlorophyll production begins, the production of the anthocyanin dye is reduced. The build-up of anthocyanin in plants is specific to the plant type, since it depends on the soil conditions, light, warmth and plant type and/or sort. Plants that have only a single anthocyanin as pigment is extremely rare, but occurs nevertheless. The absence or particularly strong prevalence for a certain anthocyanin in a plant is due to genetic circumstances.

Structure



Benzopyrylium salts, Chloride as counterion

The pigment components of the anthocyanidins, the sugar-free anthocyanins, can be identified based on the structure of a large group of polymethine dye, as salt derivative of benzopyrylium (a cationic form of benzopyran, i.e an oxygen-containing heterocycle pyran fused to a benzene ring). The pyran ring in anthocyanin is connected to a phenyl group at the 2-position, which can carry different substituents. The counterion for the cationic oxygen in the pyran ring is mostly chloride. With this positive charge the anthocyanins differ from other flavonoids. The anthocyanins, anthocyanidins with sugar group, are mostly 3-glucosides of the anthocyanidins. In red wine, especially after maturation, many derivatives of the anthocyanins can be found.

The anthocyanins are subdivided into the sugar-free anthocyanidine aglycons and the anthocyanin glycosides. They are considered secondary metabolites and allowed as a food additive with E number 163. As of 2003 more than 400 anthocyanins had been reported[1] while more recent literature (early 2006), puts the number at more than 550 different anthocyanins. The difference in chemical structure that occurs in response to changes in pH is the reason why anthocyanins are often used as pH indicator, as they change from red in acids to blue in bases.

Biosynthesis

Anthocyanin pigments are assembled from two different streams of chemical raw materials in the cell: both starting from the C2 unit acetate (or acetic acid) derived from photosynthesis, one stream involves the shikimic acid pathway to produce the amino acid phenylalanine. The other stream (the acetic acid pathway) produces 3 molecules of malonyl-Coenzyme A, a C3 unit. These streams meet and are coupled together by the enzyme chalcone synthase (CHS), which forms an intermediate chalcone via a polyketide folding mechanism that is commonly found in plants. The chalcone is subsequently isomerized by the enzyme chalcone isomerase (CHI) to the prototype pigment naringenin, which is subsequently oxidized by enzymes such as flavanone hydroxylase (FHT or F3H), flavonoid 3' hydroxylase and flavonoid 3' 5'-hydroxylase. These oxidation products are further reduced by the enzyme dihydroflavonol 4-reductase (DFR) to the corresponding leucoanthocyanidins. It was believed that leucoanthocyanidins are the immediate precursors of the next enzyme, a

dioxygenase referred to as anthocyanidin synthase (ANS) or leucoanthocyanidin dioxygenase (LDOX). It was recently shown however that flavan-3-ols, the products of leucoanthocyanidin reductase (LAR), are the true substrates of ANS/LDOX. The resulting, unstable anthocyanidins are further coupled to sugar molecules by enzymes like UDP-3-O-glucosyl transferase to yield the final relatively stable anthocyanins. More than five enzymes are thus required to synthesize these pigments, each working in concert. Any even minor disruption in any of the mechanism of these enzymes by either genetic or environmental factors would halt anthocyanin production.

Autumn Leaf Color

Many science text books incorrectly state that all autumn coloration (including red) is simply the result of breakdown of green chlorophyll, which unmasks the already-present orange, yellow, and red pigments (carotenoids, xanthophylls, and anthocyanins, respectively). While this is indeed the case for the carotenoids and xanthophylls (orange and yellow pigments), anthocyanins are not present until the leaf begins breaking down the chlorophyll, during which time the plant begins to synthesize the anthocyanin, presumably for photoprotection during nitrogen translocation.

Recent research

In December 2004 a peer-reviewed study at Michigan State University published by the American Chemical Society noted that anthocyanin could boost insulin production by up to 50%. However the study leader noted that despite the initial excitement, more study would be needed. Also in 2005, an article published in Applied and Environmental Microbiology demonstrated for the first time the biosynthesis of anthocyanins in bacteria.

Polyphenol antioxidant

A *polyphenol antioxidant* is a type of antioxidant characterized by the presence of several phenol functions. In human health these compounds, numbering over 4000 distinct species, are thought to be instrumental in combating oxidative stress, a syndrome causative of some neurodegenerative diseases and some cardiovascular diseases.

The main source of polyphenol antioxidants is nutritional, since they are found in a wide array of phytonutrient-bearing foods. For example, most legumes; fruits such as apples,

blackberries, cantaloupe, cherries, cranberries, grapes, pears, plums, raspberries, and strawberries; and vegetables such as broccoli, cabbage, celery, onion and parsley are rich in polyphenol antioxidants. Red wine, chocolate, green tea, olive oil, bee pollen and many grains are alternative sources. The principal benefit of ingestion of antioxidants seems to stem from the consumption of a wide array of phytonutrients; correspondingly, the role of dietary supplements as a method of realizing these health benefits is the subject of considerable discussion.

Biochemical regulation

The regulation chemistry consists of a polyphenol antioxidant's ability to scavenge free radicals and up-regulate certain metal chelation reactions. That is to say various reactive oxygen species must be continually removed from cells to maintain healthy metabolic function. Some specific free radicals affected are the reactive oxygen species singlet oxygen, peroxynitrite and hydrogen peroxide. Diminishing the concentrations of reactive oxygen species can have several benefits. Since reactive oxygen species are linked to mobilization of ion transport systems, they are known to have roles in oxidative signalling. In particular, platelets involved in wound repair and blood homeostasis can release reactive oxygen species to recruit platelets to sites of injury. These also provide a link to the adaptive immune system via the recruitment of leukocytes. When polyphenol down-regulate reactive oxygen species formation, they also contribute to improved endothelial health through anti-inflammatory action.

Biological consequences

Occurrence of an abundance of polyphenol antioxidants is associated with several salutary effects in higher animal species:

- Reduction in inflammatory effects such as coronary artery disease[1][2] including specific medical research into the pathways of improved endothelial health via downregulation of oxidative LDL.[3]
- More generally the tea polyphenol (medically known as TP) antioxidant epigallocatechin gallate, has been shown to reduce reactive oxygen species levels in vivo.[4] Reactive oxygen species are important markers for inflammatory diseases.
- Some polyphenol antioxidants, such as resveratrol, inhibit occurrence and/or growth of mammalian tumors.[5]
- A variety of other beneficial health effects have been attributed to consumption of foods rich in polyphenolic antioxidants. Among these salutary effects discussed are anti-aging consequences such as slowing the process of skin wrinkling.[6] For some of the side-benefits (such as prevention of peripheral artery disease), further research is continuing to clarify the role polyphenol antioxidants may have.[7][8]

Difficulty in analyzing effects of specific chemicals

It is inherently difficult to evaluate the medical effects of specific polyphenolic antioxidants, since such a large number of individual compounds may occur even in a single food. For example, over sixty different chemically distinct flavonoids are known to occur in a given red wine. Numerous scientific studies have been conducted to attempt to arrive at one consistent index for food antioxidant power. Since it has been proved that the dietary intake of compounds having antioxidant activity is medically important, various chemical, biological, and electrochemical methods have been proposed to evaluate the antioxidant power of compounds such as polyphenols. Wine, although nonessential, has a high polyphenol content up to two to three grams per liter in red wines obtained by traditional maceration. The polyphenol content of wines is usually evaluated by the Folin-Ciocalteu reagent, which provides an appropriate response to the requirements of wine manufacturers. Statistical least squares analysis has been conducted to demonstrate the Folin method correlates well with alternative chemical and biological procedures for determining antioxidant potential.[9] Therefore, there is some reason to believe more universally accepted protocols may be forthcoming to permit quantitative evaluation of antioxidant strength of polyphenol antioxidant compounds.

Other more detailed chemical reseach has been conducted elucidating the difficulty of isolating individual polyphnolic antioxidants. Fajardo-Lirai et al. have demonstrated that significant variation in polyphenol content among various brands of tea can explain[10] the inconsistency in previous epidemiological studies that have tried to correlate beneficial health effects of polyphenol antioxidants using specific green tea blends. The Oxygen Radical Absorbance Capacity (ORAC) test is a possible emerging standard by which science measures antioxidant power in foods and dietary supplements

Practical aspects of dietary polyphenol antioxidants

There is debate regarding the total body absorption of dietary intake of polyphenolic compounds. While individual studies seem to demonstrate the favourable health effects of certain specific polyphenols, more research is needed to understand the interactions between a variety of these chemicals acting in concert within the human body. In particular there is evidence that some combinations of foods may inhibit efficient intestinal transfer of certain polyphenol antioxidants; refined sugars, for example, have been shown to impede this uptake under certain circumstances.[11] Furthermore caution should be exercised in attempting diets depending largely on dietary supplements as opposed to a broad array of food sources, since the quality and concentrations of beneficial chemicals in some commercial products is subject to question, given lack of Food and Drug Administration (FDA) regulation.

Topical application of polyphenol antioxidants

There is some data that reactive oxygen species play a role in the process of aging. The skin is exposed to various exogenous sources of oxidative stress, including ultraviolet radiation. These spectral components are generally viewed as responsible for the extrinsic type of skin aging, sometimes termed photo-aging. It has been shown not only that increased levels of protective low molecular weight antioxidants through a diet rich in phytochemicals,

but also by direct topical dermal application[12] have proved that a few low molecular weight antioxidants, notably vitamins C and E, ascorbate and tocopherol, as well as lipoic acid, exert protective effects against oxidative stress. However, controlled long-term studies on the efficacy of low molecular weight antioxidants in the prevention or treatment of skin aging in humans is lacking.

Tannins

Tannins are astringent, bitter-tasting plant polyphenols that bind and precipitate proteins. The term tannin refers to the source of tannins used in tanning animal hides into leather; however, the term is applied to any large polyphenolic compound containing sufficient hydroxyls and other suitable groups (such as carboxyls) to form strong complexes with proteins and other macromolecules. Tannins have molecular weights ranging from 500 to over 20,000.

Tannins are usually divided into hydrolyzable tannins and condensed tannins (proanthocyanidins). At the center of a hydrolyzable tannin molecule, there is a polyol carbohydrate (usually D-glucose). The hydroxyl groups of the carbohydrate are partially or totally esterified with phenolic groups such as gallic acid (in gallotannins) or ellagic acid (in ellagitannins). Hydrolyzable tannins are hydrolyzed by weak acids or weak bases to produce carbohydrate and phenolic acids. Condensed tannins, also known as proanthocyanidins, are polymers of 2 to 50 (or more) flavonoid units that are joined by carbon-carbon bonds, which are not susceptible to being cleaved by hydrolysis. While hydrolyzable tannins and most condensed tannins are water soluble, some very large condensed tannins are insoluble.

Tannins may be employed medicinally in antidiarrheal, hemostatic, and antihemorrhoidal compounds. Also, they produce different colors with ferric chloride (either blue, blue black, or green to greenish black) according to the type of tannin.

Examples of gallotannins are the esters of tannic acid (C76H52O46) with glucose, found in the leaves and bark of many plant species.

Tea

The tea plant (Camellia sinensis) is an example of a plant with a naturally high tannin content. Green tea leaves are unquestionably a major plant source of tannins, as they not only contain the tannic and gallic acid groups, but also a proanthocyanidin (a type of flavanol) named prodelphinidin. When any type of tea leaf is steeped in hot water for an excessively long time period it brews a "tart" (astringent) flavor that is characteristic of tannins (and other components). New varieties of Camellia sinensis have been specifically bred for a lower tannin content. If ingested in excessive quantities, tannins inhibit the absorption of minerals such as iron into the body. This is because tannins are metal ion chelators, and tannin-chelated metal ions are not bioavailable.

Wine

Tannins (mainly condensed tannins) are also found in wine, particularly red wine. Tannins in wine can come from many sources and the tactile properties differ depending on the source. Tannins in grape skins and seeds (the latter being especially harsh) tend to be more noticeable in red wines, which are fermented while in contact with the skins and seeds. Tannins extracted from grapes are condensed tannins, which are polymers of procyanidin monomers. Hydrolysable tannins are extracted from the oak wood the wine is aged in. Hydrolysable tannins are more easily oxidised than condensed tannins.

Modern winemakers take great care to minimize undesirable tannins from seeds by crushing grapes gently to extract their juice. Pressing the grapes results in press wine which is more tannic and might be kept separately. Wines can also take on tannins if matured in oak or wood casks with a high tannin content. Tannins play an important role in preventing oxidation in aging wine and appear to polymerize and make up a major portion of the sediment in wine.

Pomegranates

Pomegranates contain a diverse array of tannins, particularly hydrolysable tannins. The most abundant of pomegranate tannins are called punicalagins. Punicalagins have a molecular weight of 1038 and are the largest molecule found intact in rat plasma after oral ingestion (Biomed. Pharmacother. 2002, 56, 276-82) and were found to show no toxic effects in rats who were given a 6% diet of punicalagins for 37 days. (J. Agric. Food Chem. 2003, 51, 3493-3501). Punicalagins are also found to be the major component responsible for pomegranate juice's antioxidant and health benefits (J Agric Food Chem 2000 48 (10) 4581-89).

Several dietary supplements and nutritional ingredients are available that contain extracts of whole pomegranate and/or are standardized to punicalagins, the marker compound of pomegranate. Extracts of pomegranate are also 'Generally Recognized As Safe' (GRAS) by the United States. It has been recommended to look for pomegranate ingredients that mimic the polyphenol ratio of the fruit, as potent synergistic effects have been observed in 'natural spectrum' extracts, especially pomegranate concentrate normalized to punicalagins (J Nutr Biochemistry 2005 (16) 360-367).

Leather

Tannins are an important ingredient in the process of tanning leather. Oak bark has traditionally been the primary source of tannery tannin, though synthetic tanning agents are also in use today.

Turmeric

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Liliopsida
Subclass: Zingiberidae
Order: Zingiberales
Family: Zingiberaceae
Genus: Curcuma
Species: *C. longa*

Binomial name *Curcuma longa*

Turmeric (Curcuma longa, also called *tumeric* or *kunyit* in some Asian countries[1]) is a spice commonly used in curries and other South Asian cuisine. Its active ingredient is curcumin. It is a significant ingredient in most commercial curry powders. Turmeric is also used to give a yellow color to some prepared mustards, canned chicken broth, and other foods (often as a much cheaper replacement for saffron). It makes a poor fabric dye as it is not very lightfast (the degree to which a dye resists fading due to light exposure).

Turmeric, a representative of plant genus Curcuma, is a member of the ginger family, Zingiberaceae.

In Ayurvedic medicine, turmeric is thought to have many healthful properties. It is taken in some Asian countries as a dietary supplement, which allegedly helps with stomach problems and other ailments. It is popular as a tea in Okinawa, Japan. It is currently being investigated for possible benefits in Alzheimer's disease, cancer and liver disorders.

Sangli, a town in the southern part of the Indian state of Maharashtra, is the largest and most important trading centre for turmeric in Asia or perhaps in the entire world.

Food additive

Turmeric (coded as E100 when used as a food additive) is used in product systems that are packaged to protect them from sunlight. The oleoresin is used for oil-containing products. The curcumin/polysorbate solution or curcumin powder dissolved in alcohol is used for water containing products. Over-colouring, such as in pickles, relishes and mustard, is sometimes used to compensate for fading.

Turmeric has found application in canned beverages, baked products, dairy products, ice cream, yogurts, yellow cakes, biscuits, popcorn-color, sweets, cake icings, cereals, sauces, gelatines, direct compression tablets, etc. In combination with Annatto (E160b) it has been used to colour cheeses, dry mixes, salad dressings, winter butter and margarine.

Medicine

The medicinal properties of the turmeric have for millennia been known to the ancient Indians and have been expounded in the Ayurvedic texts. It is only in recent years that Western scientists have increasingly recognised the medicinal properties of turmeric. According to a 2005 article in the Wall Street Journal titled, "Common Indian Spice Stirs Hope," research activity into curcumin, the active ingredient in turmeric, is exploding. Two hundred and fifty-six curcumin papers were published in the past year according to a search of the U.S. National Library of Medicine. Supplement sales have increased 35% from 2004, and the U.S. National Institutes of Health has four clinical trials underway to study curcumin treatment for pancreatic cancer, multiple myeloma, Alzheimer's, and colorectal cancer.

A 2004 UCLA-Veterans Affairs study involving genetically altered mice suggests that curcumin, the active ingredient in turmeric, might inhibit the accumulation of destructive beta amyloids in the brains of Alzheimer's disease patients and also break up existing plaques. "Curcumin has been used for thousands of years as a safe anti-inflammatory in a variety of ailments as part of Indian traditional medicine," Gregory Cole, Professor of medicine and neurology at the David Geffen School of Medicine at UCLA said.

Another 2004 study conducted at Yale University involved oral administration of circumin to mice homozygous for the most common allele implicated in cystic fibrosis. Treatment with circumin restored physiologically-relevant levels of protein function.

Recent studies have shown that turmeric can be effective in fighting a number of STDs including chlamydia and gonorrhea.

Investigations into the low incidence of colorectal cancer amongst ethnic groups with a large intake of curries compared with the indigenous population have suggested that some active ingredients of turmeric may have anti-cancer properties.

Anti-tumoral effects against melanoma cells have been demonstrated.

Second-stage trials of a turmeric-based drug as a possible treatment for cancer are currently underway. However, according to recent research results, the component curcumin causes degradation of the human protein p53. p53 is responsible for removing damaged cells that are likely to become tumors, suggesting curcumin could accelerate tumor development.

Consuming large doses is not recommended in cases of gallstones, obstructive jaundice, acute bilious colic and toxic liver disorders.

Curry Pharmaceuticals, based in North Carolina, is studying the use of a curcumin cream for psoriasis treatment. Another company is already selling a cream based on curcumin called "Psoria-Gold," which shows anecdotal promise of treating the disease.

A recent study involving mice has shown that turmeric slows the spread of breast cancer into lungs and other body parts. Turmeric also enhances the effect of taxol in reducing metastasis of breast cancer.

It is also said that turmeric can strengthen the blood-brain barrier against attacks that result from auto-immune diseases (such as Multiple sclerosis).

In the November 2006 issue of Arthritis & Rheumatism, a study was published that showed the effectiveness of turmeric in the reduction of joint inflammation, and recommended clinical trials as a possible treatment for the alleviation of arthritis symptoms.

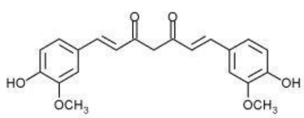
Cosmetics

Turmeric is currently used in the formulation of some sun screens. Turmeric paste is used by Indian women to keep them free of superfluous hair.

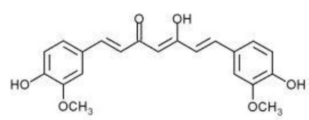
The Government of Thailand is funding a project to extract and isolate tetrahydrocurcuminoids (THC) from turmeric. THCs are colorless compounds that might have antioxidant and skin lightening properties and might be used to treat skin inflammations, making these compounds useful in cosmetics formulations.

Chemistry

The active substance of turmeric is the polyphenol *curcumin*, also known as C.I. 75300, or Natural Yellow 3. Systematic chemical name is (1E,6E)-1,7-bis(4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione. It can exist at least in two tautomeric forms, keto and enol. The keto form is preferred in solid phase and the enol form in solution.



Curcumin Keto form



Curcumin Enol form

Notes

1. ^ Turmeric is known by different names in different languages. Some examples include:
    - "Arishina" in Kannada
    - "Halad" in Marathi
    - "Haldi" in Hindi and Gujarati.
    - "Holood" in Bengali.
    - "®žÍš^{3}Í" (manjal) in Tamil.
    - "Pasupu" in Telugu.
    - "ÜÄ" (jiang huang) in Chinese.

Medicinal chemistry

Medicinal or *pharmaceutical chemistry* is a scientific discipline at the intersection of chemistry and pharmacy involved with designing, synthesizing and developing pharmaceutical drugs. Medicinal chemistry involves the identification, synthesis and development of new chemical entities suitable for therapeutic use. It also includes the study of existing drugs, their biological properties, and their quantitative structure-activity relationships (QSAR). Pharmaceutical chemistry is focused on quality aspects of medicines and aims to assure fitness for the purpose of medicinal products.

Medicinal chemistry is a highly interdisciplinary science combining organic chemistry with biochemistry, computational chemistry, pharmacology, molecular biology, statistics, and physical chemistry.

Process of drug discovery

Discovery

The first step of drug discovery involves the identification of new active compounds, often called "hits", which are typically found by screening many compounds for the desired biological properties. These hits can come from natural sources, such as plants, animals, or fungi. More often, the hits can come from synthetic sources, such as historical compound collections and combinatorial chemistry.

Recent developments in robotics and miniaturization have greatly accelerated and automated the screening process. Typically, a company will assay over 100,000 individual compounds before moving to the optimization step.

Optimization

The second step of drug discovery involves the synthetic modification of the hits in order to improve the biological properties of the compound pharmacophore. The quantitative structure-activity relationship of the pharmacophore play an important part in finding "lead compounds", which exhibit the most potency, most selectivity, best pharmacokinetics and least toxicity.

Development

The final step involves the rendering the "lead compounds" suitable for use in clinical trials. This involves the optimization of the synthetic route for bulk production, and the preparation of a suitable drug formulation.

Bioavailability

In pharmacology, *bioavailability* is used to describe the fraction of an administered dose of medication that reaches the systemic circulation, one of the principal pharmacokinetic properties of drugs. By definition, when a medication is administered intravenously, its bioavailability is 100%. However, when a medication is administered via other routes (such as by mouth), its bioavailability decreases (due to incomplete absorption and first-pass metabolism). Bioavailability is one of the essential tools in pharmacokinetics, as bioavailability must be considered when calculating dosages for non-intravenous routes of administration.

Definition

Bioavailability is a measurement of the rate and extent of a therapeutically active drug that reaches the systemic circulation and is available at the site of action.[1]

It is expressed as the letter F.

Absolute bioavailability

Absolute bioavailability measures the availability of the active drug in systemic circulation after non-intravenous administration (i.e., after oral, rectal, transdermal, subcutaneous administration).

In order to determine absolute bioavailability of a drug, a pharmacokinetic study must be done to obtain a plasma drug concentration vs time plot for the drug after both intravenous (IV) and non-intravenous administration. The absolute bioavailability is the dose-corrected area under curve (AUC) non-intravenous divided by AUC intravenous. For example, the formula for calculating F for a drug administered by the oral route (po) is given below.

$$F = \frac{[AUC]_{po} * dose_{IV}}{[AUC]_{IV} * dose_{po}}$$

Therefore, a drug given by the intravenous route will have an absolute bioavailability of 1 (F=1) while drugs given by other routes usually have an absolute bioavailability of less than one.

Relative bioavailability

This measures the bioavailability of a certain drug when compared with another formulation of the same drug, usually an established standard, or through administration via a different route. When the standard consists of intravenously administered drug, this is known as absolute bioavailability.

$$relative\ bioavailability = \frac{[AUC]_A * dose_B}{[AUC]_B * dose_A}$$

Factors influencing bioavailability

The absolute bioavailability of a drug, when administered by an extravascular route, is usually less than one (i.e. F<1). Various physiological factors reduce the availability of drugs prior to their entry into the systemic circulation,

Such factors may include, but are not limited to:

- poor absorption from the gastrointestinal tract
- degradation or metabolism of the drug prior to absorption
- hepatic first pass effect

Each of these factors may vary from patient to patient, and indeed in the same patient over time. Whether a drug is taken with or without food will affect absorption, other drugs taken concurrently may alter absorption and first-pass metabolism, intestinal motility alters the dissolution of the drug and may affect the degree of chemical degradation of the drug by intestinal microflora. Disease states affecting liver metabolism or gastrointestinal function will also have an effect.

Drug design

Drug design is the approach of finding drugs by design, based on their biological targets. Typically a drug target is a key molecule involved in a particular metabolic or signalling pathway that is specific to a disease condition or pathology, or to the infectivity or survival of a microbial pathogen.

Some approaches attempt to stop the functioning of the pathway in the diseased state by causing a key molecule to stop functioning. Drugs may be designed that bind to the active region and inhibit this key molecule. However these drugs would also have to be designed in such a way as not to affect any other important molecules that may be similar in appearance to the key molecules. Sequence homologies are often used to identify such risks.

Other approaches may be to enhance the normal pathway by promoting specific molecules in the normal pathways that may have been affected in the diseased state.

The structure of the drug molecule that can specifically interact with the biomolecules can be modeled using computational tools. These tools can allow a drug molecule to be constructed within the biomolecule using knowledge of its structure and the nature of its active site. Construction of the drug molecule can be made inside out or outside in depending on whether the core or the R-groups are chosen first. However many of these approaches are plagued by the practical problems of chemical synthesis.

Newer approaches have also suggested the use of drug molecules that are large and proteinaceous in nature rather than as small molecules. There have also been suggestions to make these using mRNA. Gene silencing may also have therapeutical applications.

Rational drug design

Unlike the historical method of drug discovery, by trial-and-error testing of chemical substances on animals, and matching the apparent effects to treatments, rational drug design begins with a knowledge of specific chemical responses in the body or target organism, and tailoring combinations of these to fit a treatment profile. Due to the complexity of the drug design process two terms of interest are still Serendipity and bounded rationality.

An important case study in rational drug design is imatinib, a tyrosine kinase inhibitor designed specifically for the bcr-abl fusion protein that is characteristic for Philadelphia chromosome-positive leukemias (chronic myelogenous leukemia and occasionally acute lymphocytic leukemia). Imatinib is substantially different from previous drugs for cancer, as most agents of chemotherapy simply target rapidly dividing cells, not differentiating between cancer cells and other tissues.

Examples of designed drugs

- Cimetidine, the prototypical H^2-receptor antagonist from which the later members of the class were developed
- Selective COX-2 inhibitor NSAIDs
- SSRIs (selective serotonin reuptake inhibitors), a class of antidepressants
- Zanamivir**, an** antiviral drug
- Enfuvirtide, a peptide HIV entry inhibitor

Drug discovery

In medicine, biotechnology and pharmacology, *drug discovery* is the process by which drugs are discovered and/or designed.

In the past most drugs have been discovered either by identifying the active ingredient from traditional remedies or by serendipitous discovery. A new approach has been to understand how disease and infection are controlled at the molecular and physiological level and to target specific entities based on this knowledge.

The process of drug discovery involves the identification of candidates, synthesis, characterization, screening, and assays for therapeutic efficacy. Once a compound has shown its value in these tests, it will begin the process of drug development prior to clinical trials.

Despite advances in technology and understanding of biological systems, drug discovery is still a long process with low rate of new therapeutic discovery. Information on the human genome, its sequence and what it encodes has been hailed as a potential windfall for drug discovery, promising to virtually eliminate the bottleneck in therapeutic targets that has been one limiting factor on the rate of therapeutic discovery.[1] However, data indicates that "new targets" as opposed to "established targets" are more prone to drug discovery project failure in general.[2] This data corroborates some thinking underlying a pharmaceutical industry trend beginning at the turn of the twenty-first century and continuing today which finds more risk aversion in target selection among multi-national pharmaceutical companies.[3]

Targets: New and Established

The definition of "target" itself is something debated within the pharmaceutical industry. However, the distinction between a "new" and "established" target can be made without a full understanding of just what a "target" is. This distinction is typically made by pharmaceutical companies engaged in discovery and development of small molecule therapeutics.

"Established targets" are those for which there is a good scientific understanding, supported by a lengthy publication history, of both how the target functions in normal physiology and how it is involved in human pathology. This does not imply that the mechanism of action of drugs that are thought to act through a particular established targets is fully understood. Rather, "established" relates directly to the amount of background information available on a target, in particular functional information. The more such information is available, the less investment is (generally) required to develop a therapeutic directed against the target. The process of gathering such functional information is called "target validation" in pharmaceutical industry parlance. Established targets also include those that the pharmaceutical industry has had experience mounting drug discovery campaigns against in the past; such a history provides information on the chemical feasibility of developing a small molecular therapeutic against the target and can provide licensing opportunities and freedom-to-operate indicators with respect to small molecule therapeutic candidates.

In general, "new targets" are all those targets that are not "established targets" but which have been or are the subject of drug discovery campaigns. These typically include newly discovered proteins, or proteins whose function has now become clear as a result of basic scientific research.

The majority of targets currently selected for drug discovery efforts are proteins. Two classes predominate: G-protein-coupled receptors (or GPCRs) and protein kinases.

Screening and Design

The process of finding a new drug against a chosen target for a particular disease usually involves high-throughput screening (HTS), wherein large libraries of chemicals are tested for their ability to modify the target. For example, if the target is a novel GPCR, compounds will be screened for their ability to inhibit or stimulate that receptor (see antagonist and agonist): if the target is a protein kinase, the chemicals will be tested for their ability to inhibit that kinase.

Another important function of HTS is to show how selective the compounds are for the chosen target. The ideal is to find a molecule which will interfere with only the chosen target, but not other, related targets. To this end, other screening runs will be made to see whether the "hits" against the chosen target will interfere with other related targets - this is the process of *cross-screening*. Cross-screening is important, because the more unrelated targets a compound hits, the more likely that off-target toxicity will occur with that compound once it reaches the clinic.

It is very unlikely that a perfect drug candidate will emerge from these early screening runs. It is more often observed that several compounds are found to have some degree of activity, and if these compounds share common chemical features, one or more pharmacophores can then be developed. At this point, medicinal chemists will attempt to use structure-activity relationships (SAR) to improve certain features of the lead molecules:

- increase activity against the chosen target
- reduce activity against unrelated targets
- improve the "drug-like" or ADME properties of the molecule.

This process will require several iterative screening runs, during which, it is hoped, the properties of the new molecular entities will improve, and allow the favoured compounds to go forward to in vitro and in vivo testing for activity in the disease model of choice.

While HTS is a commonly used method for novel drug discovery, it is not the only method. It is often possible to start from a molecule which already has some of the desired properties. Such a molecule might be extracted from a natural product or even be a drug on the market which could be improved upon (so-called "me too" drugs). Other methods, such as virtual high throughput screening, where screening is done using computer-generated models and attempting to "dock" virtual libraries to a target, are also often used.

Another important method for drug discovery is drug design, whereby the biological and physical properties of the target are studied, and a prediction is made of the sorts of chemicals that might (eg.) fit into an active site. Novel pharmacophores can emerge very rapidly from these exercises.

Once a lead molecule series has been established with sufficient target potency and selectivity and favourable drug-like properties, one or two compounds will then be proposed for drug development. The best of these is generally called the "lead" compound, while the other will be designated as the "backup".

Pharmacokinetics

Pharmacokinetics is a branch of pharmacology dedicated to the study of the time course of substances and their relationship with an organism or system. In practice, this discipline is applied mainly to drug substances, though in principle it concerns itself with all manner of compounds residing within an organism or system, such as nutrients, metabolites, endogenous hormones, toxins, etc. So, in basic terms, while pharmacodynamics explores what a drug does to the body, pharmacokinetics explores what the body does to the drug.

Absorption and disposition

Pharmacokinetics has been broadly divided into two categories of study: absorption and disposition. Once a drug is administered as a dose, these processes begin simultaneously.

Absorption

The process of absorption can be seen as increasing the amount of a compound or dose x introduced into a system. Absorption studies seek to define the rate of input, dx/dt, of the dose x. For example, a constant rate infusion, R, of a drug might be 1 mg/hr, while the integral over time of dx/dt is referred to as the extent of drug input, x(t), ie. the total amount of drug x administered up to that particular time t. Sometimes the drug is assumed to be absorbed

from the gastrointestinal tract in the form of a 1st order process with a 1st-order rate of absorption designated as Ka. Complex absorption profiles can be created by the use of controlled, extended, delayed or timed release of drugs from a dosage form.

Pharmacokinetics has many applications in drug therapy. By studying absorption -- the amount of a drug which gets into the system (bloodstream) following administration -- pharmacokinetics may guide the formulation of drug products. The amount of drug released from different formulations may vary; for example, two different tablets containing the same amount of drug chemical may not release the same amount into the bloodstream; a pharmacokinetic absorption study can determine whether or not the two tablets are equivalent and can be used interchangeably.

Disposition

Disposition is further subdivided into the study of the distribution, metabolism and elimination or excretion of a drug. Thus, pharmacokinetics is sometimes referred to as ADME.

The processes of disposition can be seen as clearing the system of a dose, or disposing of the dose. The disposition process distributes the compound or substance within the system, converts or metabolizes it, and eliminates the parent compound or products of the parent compound by passing them from the system into the urine, feces, sweat, exhalation or other routes of elimination. Sometimes compounds or their products may remain essentially indefinitely in the system by incorporation into the system.

The one-compartmental case

The functional form of the systemic clearance, Cls, of a drug x is equal to -(dx/dt)/c(t), where x(t) is the amount of drug present and c(t) is the observed drug concentration (for example in blood plasma). The units of clearance are given in terms of volume/time so that a generalized, well stirred volume is cleared of an amount of a substance x per unit of time following introduction into such volume. This well stirred volume V is the volume of distribution of a substance x (drug), and is essentially a proportionality constant between x(t) and c(t), such that x(t)=c(t)×V.

The total apparent systemic clearance Cls/(F×F*) is related to Cls, where F signifies bioavailability and F* signifies the first pass effect of an administered substance. If F and F* are known, the true systemic clearance, Cls, can be obtained by multiplying the observed apparent systemic clearance Cls/(F×F*) by F and F*. Cls is composed of many clearance components, two of the most common are the renal and non-renal components of clearance, Clr and Clnr, respectively, such that Cls = Clr + Clnr.

Modeling pharmacokinetic systems

Pharmacokinetics systems can be determined to be linear or nonlinear, and time-invariant or time-varying with respect to the mathematical modeling involved for any one of these processes.

Linear pharmacokinetic processes are generally the least complex to study and linear systems theory has been applied to modeling many pharmacokinetic systems when linearity can be assumed. One test of a drug's linearity is obtained by observing the AUC for several different administered doses. If the AUC varies directly with administered dose then the apparent systemic clearance of the drug, Cl, remains constant.

Nonlinear time-varying systems can be very difficult to solve and may have no closed-form solutions (meaning they have to be solved numerically on a case-by-case basis).

There is an extensive body of mathematical knowledge with many practitioners working in the area. This knowledge has roots in engineering, statistics, and medicine.

Pharmacodynamics

Pharmacodynamics is the study of the biochemical and physiological effects of drugs and the mechanisms of drug action and the relationship between drug concentration and effect. It is often summarily stated that pharmacodynamics is the study of what a drug does to the body, whereas pharmacokinetics is the study of what the body does to a drug.

Drug action

Desired activity

The desired activity of a drug is mainly due to one of the following:

- Cellular membrane disruption

Chemical reaction
Interaction with enzyme proteins
Interaction with structural proteins
Interaction with carrier proteins
Interaction with ion channels

- Ligand binding to receptors:
    - Hormone receptors
    - Neuromodulator receptors

Neurotransmitter receptors

General anesthetics are believed to work by disordering the neural membranes, thereby altering the Na+ influx. Antacids and chelating agents combine chemically in the body. Enzyme-substrate binding is a way to alter the production or metabolism of key endogenous chemicals, for example aspirin irreversibly inhibits the enzyme prostaglandin synthetase (cyclooxygenase) thereby preventing inflammatory response. Colchicine, a drug for gout, interferes with the function of the structural protein tubulin, while Digitalis, a drug still used in heart failure, inhibits the activity of the carrier molecule, Na-K-ATPase pump. The widest

class of drugs act as ligands which bind to receptors which determine cellular effects. Upon drug binding, receptors can elicit their normal action (agonist), blocked action (antagonist), or even action opposite to normal (anti-agonist).

In principle, a pharmacologist would aim for a certain plasma concentration of the drug for a desired level of response. In reality, there are many factors affecting this goal. Pharmacokinetic factors determine peak concentrations, and levels cannot be maintained with absolute consistency because of metabolic breakdown and excretory clearance. Genetic factors may exist which would alter metabolism or drug action itself, and a patient's immediate status may also affect indicated dosage.

Undesirable effects

Undesirable effects of a drug include:

- Increased probability of cell mutation (carcinogenic activity)
- A multitude of simultaneous assorted actions which may be deleterious
- Interaction (additive, multiplicative, or metabolic)
- Induced physiological damage, or abnormal chronic conditions

Receptor binding

The binding of ligands (drug) to receptors is governed by the law of mass action which relates the large-scale status to the rate of numerous molecular processes. The rates of formation and un-formation can be used to determine the equilibrium concentration of bound receptors. Although the receptors are fixed to a 2-dimensional membrane, an arbitrary control volume can be used to calculate the dissociation constant,

$$L + R \leftrightarrow L{\cdot}R \quad K_d = \frac{[L][R]}{[L{\cdot}R]}$$

where L=ligand, R=receptor, square brackets [] denote concentration. The fraction of bound receptors is found as $(1+[R]/[L{\cdot}R])^{-1}$, which can then be expressed using K_d as,

This expression is one way to consider the efficacy of a drug, in which the response may be directly proportional to the fraction of bound receptors. Often the response is determined as a function of log[L] to consider many orders of dosage range. It is useful to note that 50% of the receptors are bound when $[L]=K_d$.

A plot of the function for the bound fraction of receptors forms a typical model for the dose response of a drug. The graph shown represents the dose-response for two hypothetical receptor agonists, plotted in a semi-log fashion. The curve toward the left represents a higher potency (potency arrow does not indicate direction of increase) since lower concentrations are needed for a given response. The efficacy increases as a function of concentration.

Multicellular pharmacodynamics

The concept of pharmacodynamics has been expanded to include *Multicellular Pharmacodynamics* (MCPD). MCPD is the study of the static and dynamic properties and relationships between a set of drugs and a dynamic and diverse multicellular 4 dimensional organization. It is the study of the workings of a drug on a minimal multicellular system (mMCS), both in vivo and in silico. *Networked Multicellular Pharmacodynamics* (Net-MCPD) further extends the concept of MCPD to model regulatory genomic networks together with signal transduction pathways, as part of a complex of interacting components in the cell. For a fuller explanation of these concepts see the articles:

- Jackson, R.C. (2003) Predictive software for drug design and development. Pharmaceutical Development and Regulation 1 ((3)), 159-168.
- Werner, E., In silico multicellular systems biology and minimal genomes, DDT vol 8, no 24, pp 1121-1127, Dec 2003. (Introduces the concepts MCPD and Net-MCPD)

Pharmaceutical industry

A *pharmaceutical company*, or *drug company*, is a company licensed to discover, develop, market and distribute drugs.

History

Most major pharmaceutical companies were founded in the late 19th and early 20th centuries, although it is only since the 1950's the industry got underway in earnest. The discovery of penicillin is widely regarded as the birth of modern pharmaceuticals - this was the moment where systematic scientific approaches, understanding of human biology and sophisticated manufacturing techniques all made the development of medicines possible. The industry remained relatively small scale until a long period of scientific advancements through the 1970s to present day elevated some companies to become among the most profitable and productive in the world.

The industry has delivered significantly improved treatment for patients and morbidity/ mortality rates across developing countries continue to fall due in no small part to the innovation of research-based pharmaceutical companies.

There are currently more than 200 major pharmaceutical companies. As in some other industries, economic pressures are forcing pharmaceutical companies toward greater efficiency. [1] The costs of research and manufacture of ever more sophisticated medicines

grows every year and the tension between the affordability of new medicines and their benefits look certain to be a continuing major debating point.

Biotechnology has offered new possibilities for the future. The first generation of 'biologic' therapies are already in use, especially in cancer. Vaccines, after many years in the research doldrums, are a renewed focus of interest as better understanding of genetics offers new ideas on how disease might be prevented. Looking to the far future it may even be possible, through the emerging science of pharmacogenomics, to tailor medicines to each individual.

Biotechnology company

A biotechnology company is any company that uses biological systems, living organisms, or derivatives thereof, to make or modify products or processes for specific use. Often biotechnology companies produce pharmaceuticals. Typically a biopharmaceutical made in this manner is composed of very large molecules that are unstable and must be administered by injection in a physician's office.

It remains a very exploratory area. Biotech companies very often start life as very small spin-offs from university research departments and are high-tech 'start-up' companies. They often need to get bought out or enter into a licensing agreement with a big mainstream pharmaceutical company to see their idea actually available for patients.

Drug discovery

Drug discovery is the process by which drugs are discovered and/or designed. In the past most drugs have been discovered either by identifying the active ingredient from traditional remedies or by serendipitous discovery. The new approach has been to understand how disease and infection are controlled at the molecular and physiology level and to target specific entities based on this knowledge. New technologies and Data Management/Informatics systems are now employed to speed up this process.

New drugs begin in the laboratory with chemists, scientists and pharmacologists who identify cellular and genetic factors that play a role in specific diseases. "They search for chemical and biological substances that target these biological markers and are likely to have drug-like effects. Out of every 5,000 new compounds identified during the discovery process, only five are considered safe for testing in human volunteers after preclinical evaluations. After three to six years of further clinical testing in patients, only one of these compounds is ultimately approved as a marketed drug for treatment. The following sequence of research activities begins the process that results in development of new medicines:"

Target identification

"Drugs usually act on either cellular or genetic chemicals in the body, known as targets, which are believed to be associated with disease. Scientists use a variety of techniques to identify and isolate a target and learn more about its functions and how these influence

disease. Compounds are then identified that have various interactions with drug targets helpful in treatment of a specific disease."

Target prioritization/validation

"To select targets most likely to be useful in the development of new treatments for disease, researchers analyze and compare each drug target to others based on their association with a specific disease and their ability to regulate biological and chemical compounds in the body. Tests are conducted to confirm that interactions with the drug target are associated with a desired change in the behavior of diseased cells. Research scientists can then identify compounds that have an effect on the target selected."

Lead identification

"A lead compound or substance is one that is believed to have potential to treat disease. Laboratory scientists can compare known substances with new compounds to determine their likelihood of success. Leads are sometimes developed as collections, or libraries, of individual molecules that possess properties needed in a new drug. Testing is then done on each of these molecules to confirm its effect on the drug target."

Lead optimization

"Lead optimization compares the properties of various lead compounds and provides information to help pharmaceutical and biotechnology companies select the compound or compounds with the greatest potential to be developed into safe and effective medicines. Often during this same stage of development, lead prioritization studies are conducted in living organisms (in vivo) and in cells in the test tube (in vitro) to compare various lead compounds and how they are metabolized and affect the body."

Drug development

Drug development is considered a costly and intensive process. Of all compounds investigated for use in humans only a small fraction is eventually approved, and only after heavy investment in pre-clinical development, clinical trials, and safety monitoring to determine the safety and efficacy of a compound. Most clinical trials are randomized and controlled. The cost for a new drug (new chemical entity) is estimated to be about 1 billion USD. This figure is however disputed:[3] Half of this amount are opportunity costs, others are costs for the development of all unsuccessful drugs. Apart from that: the author (di Masi) has never published details about his calculations or estimates. Depending on a number of considerations, a company may apply for and be granted a patent for the drug or the process of producing the drug for about 20 years. Only after rigorous study and testing, which can take as long as 12 years, will governmental authorities grant permission for the company to market and sell the drug. In special circumstances, such as the search for effective drugs to

treat AIDS, the Food and Drug Administration (FDA) has encouraged an abbreviated process for drug testing and approval called fast-tracking

Clinical testing is usually described as consisting of Phase I, Phase II and Phase III clinical studies In each successive phase, increasing numbers of patients are tested. There are a large number of firms worldwide that support clinical trials and perform clinical trials services for pharmaceutical firms.

Phase I Clinical Studies

"Phase I studies are designed to verify safety and tolerability of the candidate drug in humans and typically take six to nine months. These are the first studies conducted in humans. A small number of subjects, usually from 20 to 100 healthy volunteers, take the investigational drug for short periods of time. Testing includes observation and careful documentation of the pharmacodynamics and the pharmacokinetics of the drug - how the drug acts in the body, how it is absorbed, distributed, metabolized, excreted, its half-life etc."

Phase II Clinical Studies

"Phase II studies are designed to determine effectiveness and further study the safety of the candidate drug in humans. Depending upon the type of investigational drug and the condition it treats, this phase of development generally takes from six months up to three years. Testing is conducted with up to several hundred patients suffering from the condition the investigational drug is designed to treat. This testing determines safety and effectiveness of the drug in treating the condition and establishes the minimum and maximum effective dose. Most Phase II clinical trials are randomized, or randomly divided into groups, one of which receives the investigational drug, one of which gets a placebo containing no medication and sometimes a third that receives a current standard treatment to which the new investigational drug will be compared. In addition, most Phase II studies are double-blinded, meaning that neither patients nor researchers evaluating the compound know who is receiving the investigational drug or placebo."

Phase III Clinical Studies

"Phase III studies provide expanded testing of effectiveness and safety of an investigational drug, usually in randomized, and blinded clinical trials. Depending upon the type of drug candidate and the condition it treats, this phase usually requires one to four years of testing. In Phase III, safety and efficacy testing is conducted with several hundred to thousands of volunteer patients suffering from the condition the investigational drug treats."

New Drug Application

"(NDA)/Marketing Authorization Application (MAA) NDAs (in the U.S.) and MAAs (in the UK) are examples of applications to market a new drug. Such applications document safety and efficacy of the investigational drug and contain all the information collected during the

drug development process. At the conclusion of successful preclinical and clinical testing, this series of documents is submitted to the FDA in the U.S. or to the applicable regulatory authorities in other countries. The application must present substantial evidence that the drug will have the effect it is represented to have when people use it or under the conditions for which it is prescribed, recommended or suggested in the labeling. Obtaining approval to market a new drug frequently takes between six months and two years."

Orphan drug

There are special rules for certain rare diseases ("orphan diseases") involving fewer than 200,000 people in the United States. Because medical research and development of drugs to treat such diseases is financially disadvantageous, companies that do so are rewarded with tax reductions and a monopoly on that orphan drug for a limited time (seven years).

Post-approval surveillance

Some medications only show to have safety issues after they are marketed, as clinical trials are of a limited size, such as the 3,000 test subjects required by the FDA. Post-marketing surveillance ensures that after marketing the safety of a drug is monitored closely. In certain instances, its indication may need to be limited to particular patient groups, and in others the substance is withdrawn from the market completely.

After the FDA (or other regulatory agency for drugs marketed outside the U.S.) approves a new drug, pharmaceutical companies may conduct additional studies, including Phase IIIb and Phase IV studies.[6] "Late-stage drug development studies of approved, marketed drugs may continue for several months to several years."

Phase IIIb/IV Studies

"Phase IIIb trials, which often begin before approval, may supplement or complete earlier trials by providing additional safety data or they may test the approved drug for additional conditions for which it may prove useful. Phase IV studies expand testing of a proven drug to broader patient populations and compare the long-term effectiveness and/or cost of the drug to other marketed drugs available to treat the same condition."

Post-Market Studies

"Post-market studies test a marketed drug in new age groups or patient types. Some studies focus on previously unknown side effects or related risk factors. As with all stages of drug development testing, the purpose is to ensure the safety and effectiveness of marketed drugs."-side effects that are dangerous.

This activity is also often referred to as phase V and often entails the use of a large focus group.

Products

Drug information

Drug information and data are provided by the Food and Drug Administration (FDA) and are located at the Orange Book site. Drug information is commercially available at eKnowledgebase. Chemical structures and links to free information is also available on the web.

ICD and DRG

Diseases are classified by ICD-9 codes. These ICD codes are aggregated into approximately 500 diagnosis-related groupss (DRG) expected to have similar hospital use.

In 1991, the top 10 DRGs overall were:

- normal newborn,

vaginal delivery,
heart failure,
psychoses,
cesarean section,
neonate with significant problems,
angina pectoris,
specific cerebrovascular disorders,
pneumonia, and
hip/knee replacement.

These DRGs comprised nearly 30% of all hospital discharges.

Revenues

Industry revenues

2004 global dollar volume was $550 billion, a 7% increase over 2003—which in turn represented a 9% increase over 2002. US sales grew to $235.4 billion, a growth rate of 8.3% compared with 11.5% growth from 2002 to 2003. The United States accounts for 46% of the world's pharmaceutical market.

According to Teradata Magazine "By 2007, $40 billion in U.S. sales will be lost at the top 10 pharma companies as a result of the slowdown in R&D innovation and the expiry of patents on major products," ... "Taking a broader look across the industry, no fewer than 19 blockbuster drugs are expected to hit patent crisis by 2008. Analysis suggests that 150 mid-sized new compounds will be needed by 2007-2008 in the U.S. alone to plug this gap."

Top 10 pharmaceutical companies by sales

The top 10 pharmaceutical companies by 2004 sales are:

Rank	Company	Revenues (USD billions)	R&D Spend (USD billions)
1	Pfizer	50.9	7.5
2	GlaxoSmithKline	32.7	5.2
3	Sanofi-Aventis	27.1	3.9
4	Johnson & Johnson	24.6	5.2
5	Merck	23.9	4.0
6	Novartis	22.7	3.5
7	AstraZeneca	21.6	3.8
8	Hoffmann-La Roche	17.7	5.1
9	Bristol-Myers Squibb	15.5	2.5
10	Wyeth	14.2	2.5

Patents and Generics

Drugs are patentable. A typical patent lasts for 20 years. However, it often takes as long as 12 years to approve a drug for patient use. Patent protection allows the owner of the patent to charge high margins for the branded drug. When the patent for the drug runs out, a generic drug is usually created by a competing company and released, causing the price to drop markedly. Often the owner of the branded drug will introduce a generic version before the patent runs out in order to get a head start in the generic market.

Medicare Part D

In 2003 the United States enacted the Medicare Prescription Drug, Improvement, and Modernization Act (MMA), a program to provide prescription drug benefits to the elderly and disabled. This program is a component of Medicare (United States) and is known as "Medicare Part D." This program, set to begin in January 2006, will significantly alter the revenue models for pharmaceutical companies. Revenues from the program are expected to be $724 Billion between 2006 and 2015

Pharmaceuticals developed by biotechnological processes often must be injected in a physician's office rather than be delivered in the form of a capsule taken orally. Medicare payments for these drugs are usually made through Medicare Part B (physician office) rather than Part D (prescription drug plan).

Sales and marketing

The pharmaceutical industry is different

In most industries the purchaser, the payer and the user are the same person. The pharmaceutical industry is different from most industries in that the products are usually not chosen by the consumers or paid for by the consumers. Physicians control the choice of many drugs through prescription writing. Private insurance or public health bodies (e.g. the NHS in the UK) often pays for most of the drugs. Moreover, insurance companies and government health agencies restrict the drugs that can be prescribed through the use of formularies. This along with the high margins companies can realise for their most successful medicines make pharmaceutical marketing a complex discipline. There are a number of firms that specialize in data and analytics for pharmaceutical marketing

Advertising to physicians

Physicians are perhaps the most important players in pharmaceutical sales. They write the prescriptions that determine which drugs will be used by the patient. Influencing the physician is key to pharmaceutical sales. Historically, this was done with large pharmaceutical sales forces. A medium-sized pharmaceutical company might have a sales force of 1000 representaives. The largest companies have tens of thousands of representatives. Currently, there are approximately 100,000 pharmaceutical sales reps in the United States pursuing some 120,000 pharmaceutical prescribers. Drug companies spend $5 billion annually sending representatives to physician offices.

Direct to consumer

Since the 1980s new methods of marketing for prescription drugs to consumers have become important. Patients are far less deferential to doctors and will inquire about, or even demand, to receive a medication they have seen advertised on television. In the United States recent years have seen an increase in mass media advertisements for pharmaceuticals.

In almost all European countries, direct to consumer advertising is banned. This also reflects the more social health systems that operate that side of the Atlantic. US-style DTC advertising is hugely controversial in Europe and some of the excesses seen in the US have undoubtedly caused significant damage to the reputation of the industry.

The payers

Public and private insurers affect the writing of prescriptions by physicians through formularies that restrict the number and types of drugs that the insurer will cover. Not only can the insurer affect drug sales by including or excluding a particular drug from a formulary, they can affect sales by tiering, or placing bureaucratic hurdles to prescribing certain drugs. In January 2006, the U.S. instituted a new public prescription drug plan through its Medicare

program. Known as Medicare Part D, this program engages private insurers to negotiate with pharmaceutical companies for the placement of drugs on tiered formularies.

Regulation of Pharmaceutical Marketing and Distribution

The safety and effectiveness of prescription drugs in the U.S. is regulated by the federal Prescription Drug Marketing Act of 1987.

Mergers, acquisitions, and co-marketing of drugs

A merger, acquisition, or co-marketing deal between pharmaceutical companies can occur if the companies have complementary capabilities. A small biotechnology company might have a new drug but no sales or marketing capability. Conversely, a large pharmaceutical company might have unused capacity in a large sales force due to a gap in the company pipeline of new products. It may be in both company's interest to enter into a deal to capitalize on the synergy between the companies. The difference between the value of the two companies after the deal and before the deal is known as the synergy value of the deal.

Controversy

- Accusations of forging or suppressing clinical trial results to maximise sales of some medications.
- Accusations of manipulating the market for their products by excessive gifts to doctors
- Too much advertising materials in the doctor's office, such as clocks, poster ads, etc.
- Reluctance of the industry to fabricate treatments of diseases in less capable countries, such as malaria.
- Aggressive representation by pharmaceutical companies' salespeople (detailmen).
- Sponsorship of medical schools, with influence on the curriculum
- Increased number of drug tests on animals before FDA approval
- Criticism for the price of patented AIDS medication, which could limit therapeutic options for patients in the Third World, where the most people have AIDS. Under World Trade Organization rules, a developing country has options for obtaining needed medications under compulsory licensing or importation of cheaper versions of the drugs, even before patent expiration (WTO Press Release). Pharmaceutical companies often offer much needed medication at no or reduced cost to the developing countries. Proposals to allow the manufacture generic AIDS drugs are not without controversy; it is sometimes claimed that this might cause pharmaceutical companies to move away from AIDS drug research and focus their research on other, more profitable areas. In March of 2001, South Africa was sued by 41 pharmaceutical companies for their Medicines Act, which

allowed the import and generic production of cheap AIDS drugs. The case was later dropped after protest around the world.

- Between 1980 and 1997, drug industry funding for academic research rose eight fold, as research costs rose, and the rate of federal support fell. Drug researchers not employed by pharmaceutical companies often look to companies for grants, and companies often look to researchers for studies that will make their products look good. 79% of papers written by independent researchers are favorable to new drugs. 98% of papers written by researchers sponsored by the drug companies are favorable. Sponsored researchers are rewarded by drug companies by putting them on symposium circuits to lecture, with the lecture scripts written by pharmaceutical companies. Some researchers who have tried to publish papers that show harmful effects of new drugs or cheaper alternatives have been threatened by drug companies with lawsuits.
- Drug companies spent $900 million on consumer ads in the first half of 1999 alone. Pharmaceutical companies often fund non-profit "patient groups" that consume their drugs. Patient groups can advertise for the drug companies, and are unregulated by the FDA. Advertising directly to consumers, however, is strictly regulated in the United States by the FDA, as described in FDA Guidance for Industry on Consumer-Directed Broadcast Advertisements.
- Where pharmaceutics have been shown to cause side-effects, civil action has occurred, especially in countries where tort payouts are likely to be large. Due to high-profile cases leading to large compensations, most pharmaceutical companies endorse tort reform.
- According to the 2002 study "The price of innovation: new estimates of drug development costs" average out-of-pocket expenses for a single drug are US$ 403 million.

Pharmaceutical companies and the developing world

The role of pharmaceutical companies in the developing world is a matter of some debate, ranging from those arguing in favor of the billions of dollars of aid provided to the developing world to criticisms of the use of the poorest amongst us in human clinical trials, often without adequate protections, particularly in states lacking a strong rule of law.

In popular culture

Recent books and movies have been written in the west criticizing the western pharmaceutical companies role, or lack thereof, in healthcare in Africa. The most prominent of these is probably The Constant Gardener, a novel by John le Carré that was also turned into a movie.

Supporters of the plot of the movie arguing that it is realistic. However, detractors including staunch critics of the industry point out its flaws.

Tragedies in developing countries

An example of a tragedy is described in a Washington Post article from December 2000, in which a clinical trial conducted by a corrupt MD in Pfizer's name in Nigeria in 1996. That study allegedly used children to test Trovan, which had been proven efficacious in adults but not in children.

Charitable measures

There are innumerable charitable programs and drug discovery & development efforts undertaken by the industry without expectation of profit. Some prominent examples include:

- "Merck's Gift," wherein billions of free drugs were donated to cure River Blindness in Africa
- Pfizer's gift of free/discounted fluconazole and other drugs in AIDS-ravaged South Africa
- *GSK's development of a treatment for chloroquine-resistant malaria, despite the lack of profit potential* and their commitment to give free albendazole tablets to the WHO for, and until, the elimination of lymphatic filariasis worldwide.

Approved drug

In the United States, the FDA approves drugs. Before a drug can be prescribed, it must undergo an extensive FDA approval process. This process involves first testing the drug on animals or in medical labs. If found to be safe by the FDA and approved for the next phase of study, the drug is then tested for safety and effectiveness in humans (clinical trials). The drug manufacturer then files a New Drug Application to the FDA, which reviews the application and either approves or rejects it.

The U.S. and Canadian systems of new drug approvals are perhaps the most rigorous in the world. On average, it costs a company $359 million to get one new medicine from the laboratory to the pharmacist's shelf, according to a February 1993 report by the Congressional Office of Technology Assessment. It takes 12 years on average for an experimental drug to travel from lab to medicine chest. Only five in 5,000 compounds that enter preclinical testing make it to human testing. One of these five tested in people is approved.

Blockbuster drug

A *blockbuster drug* is a drug generating more than $1 billion of revenue for its owner each year. The search for blockbusters has been the foundation of the R&D strategy adopted by big pharmaceutical companies, but this looks set to change. New advances in genomics, and the promise of personalized medicine, are likely to fragment the pharmaceutical market.

A recent report from Urch Publishing estimated that about one third of the pharma market by value is accounted for by blockbusters. About 100 products are blockbusters. The top seller was Lipitor a cholesterol-lowering medication marketed by Pfizer with sales of US$12,187 million

Leading blockbuster drugs

- Atorvastatin (Lipitor) from Pfizer
- celecoxib (Celebrex) from Pfizer
- omeprazole (Losec/Prilosec) from AstraZeneca (2003 sales $2.6bn)
- esomeprazole (Nexium) from AstraZeneca (2003 sales $3.3bn)
- Fexofenadine (Telfast/Allegra) from Aventis (2004 sales $1.87bn)
- quetiapine (Seroquel) from AstraZeneca (2003 sales $1.5bn)
- metoprolol (Seloken/Toprol) from AstraZeneca (2003 sales $1.3bn)
- budesonide (Pulmicort/Rhinocort) from AstraZeneca (2003 sales $1.3bn, plus some fraction of the $0.6bn sales of Symbicort)

Counterfeit drug

A *counterfeit drug* or a *counterfeit medicine* is a medication which is produced and sold with the intent to deceptively represent its origin, authenticity or effectiveness. The common street term for counterfeit drug is "beat bag." A counterfeit drug may be one which does not contain active ingredients, contains an insufficient quantity of active ingredients, or contains entirely incorrect active ingredients (which may or may not be harmful), and which is typically sold with inaccurate, incorrect, or fake packaging. Fake medicines and generic drugs which are deliberately mislabeled in order to deceive consumers are therefore counterfeit, while a drug which has not received regulatory approval is not necessarily so.

Overview

An individual who applies a counterfeit medication may experience a number of dangerous consequence to their health, such as unexpected side effects, allergic reactions, or a worsening of their medical condition. A number of counterfeits do not contain any active ingredients, and instead contain inert substances, which do not provide the patient any treatment benefits. Counterfeit medications may also contain incorrect ingredients, improper dosages of the correct ingredients, or they may contain hazardous ingredients.

The extent of the problem of counterfeit drugs is unknown. Counterfeiting is difficult to detect, investigate, and quantify. So, it is hard to know or even estimate the true extent of the problem. What is known is that they occur worldwide and are more prevalent in developing countries. It is estimated that upwards of 10% of drugs worldwide are counterfeit, and in some countries more than 50% of the drug supply is made up of counterfeit drugs. Furthermore, the World Health Organization estimates that the annual earnings of counterfeit drugs are over 32 Billion U.S. Dollars.

There are several technologies that may prove helpful in combating this problem, such as radio frequency identification, which uses electronic devices to track and identify items, such as pharmaceutical products, by assigning individual serial numbers to the containers holding each product. This technology may prevent the diversion or counterfeiting of drugs by allowing wholesalers and pharmacists to determine the identity and dosage of individual products. More recent innovative technology includes the use of mobile phone cameras to verify the source and authenticity of drugs within a world wide market through use of unique identifying unbreakable codes. video clip of mobile phone verification of authenticity of drugs

On May 6, 2005, the Chinese press agency Xinhua reported that the World Health Organization had established Rapid Alert System (RAS), the world's first web-based system for tracking the activities of drug cheats, in light of the increasing severity of the problem of counterfeit drugs.

Bacterial Resistance

Fake antibiotics with a low concentration of the active ingredients can do damage world wide. Courses of antibiotics that are not seen through to completion allow bacteria to regroup and develop resistance.

Television

A cable TV report featured a lady in Nigeria, Dr Dora, who was appointed to deal with fake drugs. According to these reports, many of the fake drugs came from the same countries that make normal drugs, especially China and India. In the case of India, while it is against the law to make fake drugs for internal use, it is not against the law to make fake drugs for export.

Drug development

Drug Development or *Preclinical Development* is defined in many pharmaceutical companies as the process of taking a new chemical lead through the stages necessary to allow it to be tested in human clinical trials, although a broader definition would encompass the entire process of drug discovery and clinical testing of novel drug candidates.

New Chemical Entities (*NCEs*) are compounds which emerge from the process of drug discovery. These will have promising activity against a particular biological target thought to be important in disease, however little will be known about the safety, toxicity, pharmacokinetics and metabolism of this NCE in human. It is the function of drug development to assess all of these parameters prior to human clinical trials. A further major objective of drug development is to make a recommendation of the dose and schedule to be used the first time an NCE is used in a human clinical trial ("First-in-Man", FIM).

In addition, drug development is required to establish the physicochemical properties of the NCE: its chemical makeup, stability, solubility. The process by which the chemical is made will be optimized so that from being made at the bench on a milligram scale by a synthetic chemist, it can be manufactured on the kilogram and then on the ton scale. It will be further examined for its suitability to be made into capsules, tablets or intravenous formulations. Together these processes are known in preclinical development as *CMC*: Chemistry, Manufacturing and Control.

Many aspects of drug development are focused on satisfying the regulatory requirements of drug licensing authorities. These generally constitute a number of tests designed to determine the major toxicities of a novel compound prior to first use in man. It is a legal requirement that an assessment of major organ toxicity be performed (effects on the heart and lungs, brain, kidney, liver and digestive system), as well as effects on other parts of the body that might be affected by the drug (e.g. the skin if the new drug is to be delivered through the skin). While, increasingly, these tests can be made using in vitro methods (e.g. with isolated cells), many tests can only be made by using experimental animals, since it is only in an intact organism that the complex interplay of metabolism and drug exposure on toxicity can be examined.

The process of drug development does not stop once an NCE begins human clinical trials. In addition to the tests required to move a novel drug into the clinic for the first time it is also important to ensure that long-term or chronic toxicities are determined, as well as effects on systems not previously monitored (fertility, reproduction, immune system, etc). The compound will also be tested for its ability to cause cancer (carcinogenicity testing).

If a compound emerges from these tests with an acceptable toxicity and safety profile, and it can further be demonstrated to have the desired effect in clinical trials, then it can be submitted for marketing approval in the various countries where it will be sold. In the US,

this process is called a New Drug Application or NDA. Most NCEs, however, will fail during drug development, either because they have some unacceptable toxicity, or because they simply do not work in clinical trials.

Generic drug

A *generic drug* (pl. generic drugs, short: generics) is a drug which is bioequivalent to a brand name drug with respect to pharmacokinetic and pharmacodynamic properties. These drugs are usually sold at a lower price than the brand name drug. Generic medicines must contain the same active ingredient at the same strength as the "innovator" brand, be bioequivalent, and are required to meet the same pharmacopoeial requirements for the preparation. By extension, therefore, generics are assumed to be identical in dose, strength, route of administration, safety, efficacy, and intended use.

Reasons for cheaper price

The principal reason for the reduced price of generic medicines is that these companies incur less costs in creating the generic drug and are therefore able to offer a lower price and still maintain profitability.

Manufacturers of generic drugs are mainly able to avoid the following three costs that brand name pharmaceutical companies incur: (1) costs associated with the research and development of the drug; (2) costs associated with the navigating governmental bureaucracy for getting a drug onto the market as safe and effective; and (3) marketing costs.

First, Generic manufacturers do not have to incur the costs of searching and finding a new drug to treat an illness because they have access to adequate information regarding the brand name drug to allow them to manufacture a bioequivalent version of the brand name drug that will do the same thing.

Second, generic manufacturers do not have to prove that their product is safe and effective through clinical trials, only that their drug is bioequivalent.

Third, these companies receive the large benefit of the marketing that goes into pushing the innovator drug. The drugs that generic manufacturers are selling have been on the market for usually a decade or more and do not need additional advertising. For the same reason, generic manufacturers also do not give away sample doses to promote their products. The significant research and development and marketing costs incurred by the large pharmaceutical companies in bringing a new drug to the market is often cited as the

reason for the high cost of new agents - they wish to recover these costs before the patent expires. Generic manufacturers do not incur these costs, with bioequivalence testing and the actual manufacturing process costing relatively little, and are able to charge significantly less than the "innovator" brand.

When can a generic drug be produced

Generic drugs can be legally produced for drugs where: 1) the patent has expired, 2) the generic company certifies the brand company's patents are either invalid, unenforceable or will not be infringed, 3) for drugs which have never held patents, or 4) in countries where a patent(s) is/are not in force. The expiration of a patent removes the monopoly of the patent holder on drug sales licensing. It is also becoming popular for the large pharmaceutical companies to preempt the expiry of their patent by producing their own generic product, or license their own product to be branded by generic companies. Thus, in some cases, the "generic" product is actually the brand product but inside a different box.

Enacted in 1984, the U.S. Drug Price Competition and Patent Term Restoration Act, informally known as the "Hatch-Waxman Act", standardized U.S. procedures for recognition of generic drugs. An applicant files an Abbreviated New Drug Application (or "ANDA") with the Food and Drug Administration (FDA) and seeks to demonstrate therapeutic equivalence to a specified, previously approved "reference listed drug." When an ANDA is approved, the FDA adds the drug to its Approved Drug Products list, also known as the "Orange Book", and annotates the list to show equivalence between the reference listed drug and the approved generic. The FDA also recognizes drugs using the same ingredients with different bioavailability and divides them into therapeutic equivalence groups. For example, as of 2006 diltiazem hydrochloride had four equivalence groups all using the same active ingredient but considered equivalent only within a group. For an explanation of FDA terms and procedures, see "Approved Drug Products with Therapeutic Equivalence Evaluations, Preface."

Patent lifetime and research cost issues

Pharmaceutical companies may produce a generic drug when the patent expires on the innovator drug. Patent lifetime differs from country to country. The length of time before a patent expires varies for different drugs. Usually, there is no way to renew a patent after it expires. A new version of the drug with significant changes to the compound could be patented but this will require new clinical trials and will not prevent the generic versions of the original drug. Usually, generic drugs are much less expensive than the brand-name product. Some patients and physicians will hesitate to select these medications because of concerns about the quality of generic drugs. When a pharmaceutical company first markets a drug, it is usually under a patent that allows only the pharmaceutical company that developed the drug to sell it. This allows the company to recoup the cost of developing that particular drug. It costs on average around $800,000,000 to develop and test a new drug before it is approved for use. After the patent on a drug expires, any pharmaceutical company can manufacture and sell that drug. Since the drug has already been tested and approved, the cost of simply manufacturing the drug will be a fraction of the original cost of testing and

developing that particular drug. The brand-name drug companies have tended to litigate aggressively to extend patent protection on their medicines and keep generic versions off the market, a process referred to by critics as "evergreening."

Ensuring bioequivalence

In the USA the Food and Drug Administration (FDA) is responsible for making sure that generic drugs are "safe and effective." The approval process for generic drugs began in the late 1960s. Generic drug manufacturers were required to prove that their formulation exhibits bioequivalence to the innovator product. Over the past several years there have been studies that have shown the effectivness and safety of some generic drugs. Generic drugs are always less expensive and can save patients and insurance companies thousands of dollars supposedly without compromising the quality of care. The FDA must approve generic drugs just as innovator drugs must be approved. Bioequivalence, however, does not mean that generic drugs are exactly the same as their innovator product counterparts, as chemical differences do exist. Some doctors and patients emphatically believe that certain generic drugs are not as effective as the products they are meant to replace (ie. Prozac, Oxycontin), and consumers would undoubtedly benefit from more clinical studies done on drug by drug basis.

180 Day Generic Drug Exclusivity

The US FDA offers a 180 day exclusivity period to generic drug manufacturers in specific cases. During this period only one (or sometimes a few) generic manufacturers can produce the generic version of a drug. This exclusivity period is only used when a generic manufacturer argues that a patent is invalid or is not violated in the generic production of a drug, and the period acts as a reward for the generic manufacturer who is willing to risk liability in court and the cost of patent court litigation. There is often contention around these 180 day exclusivity periods because a generic producer does not have to produce the drug during this period and can file an application first to prevent other generic producers from selling the drug.

Large pharmaceutical companies often spend thousands of dollars protecting their patents from generic competition. Apart from litigation, companies use other methods such as reformulation or licensing a subsidiary (or another company) to sell generics under the original patent. Generics sold under license from the patent holder are known as *authorized generics*; they are not affected by the 180 day exclusivity period as they fall under the patent holder's original drug application.

A prime example of how this works is simvastatin (Zocor), a popular drug created and manufactured by U.S. based pharmaceutical Merck & Co., which lost its US patent protection on June 23, 2006. India-based Ranbaxy Laboratories (at the 80-mg strength) and Israel-based Teva Pharmaceutical Industries (at all other strengths) received 180 day exclusivity periods for simvastatin; due to Zocor's popularity, both companies began marketing their products immediately after the patent expired. However, Dr. Reddy's Laboratories also markets an authorized generic version of simvastatin under license from Zocor's

manufacturer, Merck & Co.; some packages of Dr. Reddy's simvastatin even show Merck as the actual manufacturer and have Merck's logo on the bottom.

Pharmaceutical marketing

Pharmaceutical marketing is the business of advertising or otherwise promoting the sale of pharmaceuticals or drugs.

History

The marketing of medication has a long history. The sale of miracle cures, many with little real potency, has always been common. Marketing of legitimate non-prescription medications, such as pain relievers or allergy medicine, has also long been practiced. Mass marketing of prescription medications was rare until recently, however. It was long believed that since doctors made the selection of drugs, mass marketing was a waste of resources; specific ads targeting the medical profession were thought to be cheaper and just as effective. This would involve ads in professional journals and visits by sales staff to doctor’s offices and hospitals. An important part of these efforts was marketing to medical students.

Direct and indirect marketing to health care providers

Physicians are perhaps the most important players in pharmaceutical sales. They write the prescriptions that determine which drugs will be used by the patient. Influencing the physician is the key to pharmaceutical sales. Historically, this was done by a large pharmaceutical sales force. A medium-sized pharmaceutical company might have a sales force of 1000 representatives. The largest companies have tens of thousands of representatives. Sales representatives called upon physicians regularly, providing information and free drug samples to the physicians. This is still the approach today; however, economic pressures on the industry are causing pharmaceutical companies to rethink the traditional sales process to physicians.

Pharmaceutical companies are developing processes to influence the people who influence the physicians. There are several channels by which a physician may be influenced, including self-influence through research, peer influence, direct interaction with pharmaceutical companies, patients, and public or private insurance companies.

There are a number of firms that specialize in data and analytics for pharmaceutical marketing

Individual research

Physicians discover pharmaceutical information from such sources as the Physician's Desk Reference and online sources, as well as via PDAs with applications.

They also rely upon pharmaceutical-branded e-detailing sites, pharmaceutical sales and non-sales representatives, and scholarly literature. Scholarly literature can be in the form of medical journal article reprints, often delivered by sales representatives at their place of employment or at conference exhibitions.

Journal article reprints are available from companies.

Peer influence

- Key opinion leaders

Key opinion leaders (KOL), or "thought leaders", are respected individuals, such as prominent medical school faculty, who influence physicians through their professional status. Pharmaceutical companies generally engage key opinion leaders early in the drug development process to provide advocacy and key marketing feedback Some pharmaceutical companies identify key opinion leaders through direct inquiry of physicians (primary research).

- Colleagues

Physicians acquire information through informal contacts with their colleagues, including social events, professional affiliations, common hospital affiliations, and common medical school affiliations. Some pharmaceutical companies identify influential colleagues through commercially available prescription writing and patient level data (see list of data providers in this article).

Direct contact with pharmaceutical sales representatives

Currently, there are approximately 100,000 pharmaceutical sales reps in the United States pursuing some 200,000 pharmaceutical prescribers. A pharmaceutical representative will often try to see a given physician every few weeks. Representatives often have a call list of about 200 physicians with 120 targets that should be visited in 4-6 week cycles.

Because of the large size of the pharmaceutical sales force, the organization, management, and measurement of effectiveness of the sales force are significant business challenges. Management tasks are usually broken down into the areas of physician targeting, sales force size and structure, sales force optimization, call planning, and sales forces effectiveness.

Physician targeting

Marketers attempt to identify the universe of physicians most likely to prescribe a given drug. Historically, this was done by measuring the number of total prescriptions (TRx) and new prescriptions (NRx) per week that each physician writes. This information is collected by commercial vendors (see list in this article). The physicians are then "deciled" into ten

groups based on their writing patterns. Higher deciles are more aggressively targeted. Some pharmaceutical companies use additional information such as:

- profitability of a prescription (script),
- accessibility of the physician,
- tendency of the physician to use the pharmaceutical company's drugs,
- effect of managed care formularies on the ability of the physician to prescribe a drug,
- the adoption sequence of the physician (that is, how readily the physician adopts new drugs in place of older, established treatments), and
- the tendency of the physician to use a wide palette of drugs
- influence that physicians have on their colleagues.

Data for drugs prescribed in a hospital are not usually available at the physician level. Advanced analytic techniques are used to value physicians in a hospital setting.

Sales force size and structure

Marketers must decide on the appropriate size of a sales force needed to sell a particular portfolio of drugs to the target universe. Design the optimal reach (how many physicians to see) and frequency (how often to see them) for each individual physician. Decide how many sales representatives to devote to office and group practice and how many to devote to hospital accounts.

Patients

Since the 1980s, new methods of marketing prescription drugs to consumers have become important. Patients are far less deferential to doctors and will inquire about, or even demand to receive, a medication they have seen advertised on television. In the United States, recent years have seen an increase in mass media advertisements for pharmaceuticals. Expenditures on direct-to-consumer (DTC pharmaceutical advertising) have more than quintupled in the last seven years since the FDA changed the guidelines, from $700 million in 1997 to more than $4 billion in 2004.

Private and public insurers

Public and private insurers affect the writing of prescriptions by physicians through formularies that restrict the number and types of drugs that the insurer will cover. Not only can the insurer affect drug sales by including or excluding a particular drug from a formulary, they can affect sales by tiering, or placing bureaucratic hurdles to prescribing certain drugs. In January 2006, the U.S. instituted a new public prescription drug plan through its Medicare program. Known as Medicare Part D, this program engages private insurers to negotiate with pharmaceutical companies for the placement of drugs on tiered formularies.

Regulation

In the United States, marketing and distribution of pharmaceuticals is regulated by the federal Prescription Drug Marketing Act of 1987.

Controversy

- The mass marketing to consumers of pharmaceuticals is controversial. It is banned in every western country except the US and New Zealand, which is considering a ban. Some feel it is better to leave the decision wholly in the hands of medical professionals; others feel that consumer education and participation in health is useful, but consumers need independent, comparative information about drugs (not promotional information)[4]. For these reasons, most countries impose limits on pharmaceutical mass marketing that are not placed on the marketing of other products. In some areas it is required that ads for drugs include a list of possible side effects, so that consumers are informed of both facets of a medicine. Canada's limitations on pharmaceutical advertising ensure that commercials that mention the name of a product cannot in any way describe what it does. Commercials that mention a medical problem cannot also mention the name of the product for sale; at most, they can direct the viewer to a website or telephone number operated by the pharmaceutical company.
- The number and persistence of pharmaceutical representatives has placed a burden on the time of physicians. "As the number of reps went up, the amount of time an average rep spent with doctors went down—so far down, that tactical scaling has spawned a strategic crisis. Physicians no longer spend much time with sales reps, nor do they see this as a serious problem."
- Recent legal cases and US congressional hearings have provided access to pharmaceutical industry documents revealing new marketing strategies for drugs. Activities once considered independent of promotional intent, including continuing medical education and medical research, are used, including paying to publish articles about promoted drugs for the medical literature, and alleged suppression of unfavorable study results.

Standard treatment

Standard treatment (Active Control). The treatment that is normally provided to people with a given condition. In many studies, a control group receives the standard treatment while a treatment group receives the experimental treatment. After the clinical trial, researchers compare the outcomes of the two groups to see if the experimental treatment is better than, as good as or not as beneficial as the standard treatment.

Active (Positive) Concurrent Control

In an active control (or positive control) trial, subjects are randomly assigned to the test treatment or to an active control treatment. Such clinical trial s are usually double-blind, but this is not always possible; many oncology trials, for example, are considered difficult or impossible to blind because of different regimens, different routes of administration, and different toxicities. Active control trials can have two distinct objectives with respect to showing efficacy: (1) to show efficacy of the test treatment by showing it is as good as a known effective treatment or (2) to show efficacy by showing superiority of the test treatment to the active control. They may also be used with the primary objective of comparing the efficacy and/or safety of the two treatments . Whether the purpose of the trial is to show efficacy of the new treatment or to compare two treatments, the question of whether the trial would be capable of distinguishing effective from less effective or ineffective treatments is critical .

Pharmacy

Pharmacy (from the Greek Æ¬Á¼±º¿½ = drug) is a transitional field between health sciences and chemical sciences and a profession charged with ensuring the safe use of medication. Traditionally, pharmacists have compounded and dispensed medications on the orders of physicians. More recently, pharmacy has come to include other services related to patient care including clinical practice, medication review, and drug information. Some of these new pharmaceutical roles are now mandated by law in various legislatures. Pharmacists, therefore, are drug therapy experts, and the primary health professionals who optimise medication management to produce positive health-outcomes.

The symbols most commonly associated with pharmacy are the mortar and pestle and the (recipere) character. Pharmacy organisations often employ other elements, such as the Bowl of Hygieia, conical measures, and caduceuses in their logos. Other symbols are common in different countries such as the green Greek cross in France and Great Britain, the increasingly-rare Gaper in The Netherlands, and a red stylised letter A in Germany and Austria, Apotheke being the German word for pharmacy.

Disciplines

The field of Pharmacy can generally be divided into three main disciplines:

- Pharmaceutics
- Pharmaceutical chemistry **and Pharmacognosy**
- Pharmacy practice

The boundaries between these disciplines and with other sciences, such as biochemistry, are not always clear-cut; and often, collaborative teams from various disciplines research together.

Pharmacology is sometimes considered a fourth discipline of pharmacy. Although pharmacology is essential to the study of pharmacy, it is not specific to pharmacy. Therefore it is usually considered to be a field of the broader sciences.

There are various specialties of pharmacy practice. Some specialisation is based on the place of practice including: community, hospital, consultant, locum, drug information, regulatory affairs, industry, and academia. Other specialisations are based on clinical roles including: nuclear, oncology, cardiovascular, infectious disease, diabetes, nutrition, geriatric, and psychiatric pharmacy.

Pharmacists

Main article: Pharmacist

Pharmacists are highly-trained and skilled healthcare professionals who perform various roles to ensure optimal health outcomes for their patients. Many pharmacists are also small-business owners, owning the pharmacy in which they practice. This unique dichotomy is often the subject of debate within the profession—in part due to the perception of pharmacists as "common shopkeepers" by many in the community.

Pharmacists are represented internationally by the International Pharmaceutical Federation (FIP). They are represented at the national level by professional organisations such as the Royal Pharmaceutical Society of Great Britain (RPSGB), the Pharmaceutical Society of Australia (PSA), the American Pharmacists Association (APhA), and the American Society of Health-System Pharmacists (ASHP).

In some cases, the representative body is also the registering body, which is responsible for the ethics of the profession. Since the Shipman Inquiry, there has been a move in the UK to separate the two roles.

Separation of prescribing from dispensing

In most jurisdictions (such as the United States), pharmacists are regulated separately from physicians. Specifically, the legislation stipulates that the practice of prescribing must be separate from the practice of dispensing. These jurisdictions also usually specify that only pharmacists may supply scheduled pharmaceuticals to the public, and that pharmacists cannot form business partnerships with physicians or give them "kickback" payments. However, the American Medical Association (AMA) Code of Ethics provides that physicians may dispense drugs within their office practices as long as there is no patient exploitation and patients have the right to a written prescription that can be filled elsewhere. 7 to 10 percent of American physician practices reportedly dispense drugs on their own.[1]

In other jurisdictions (particularly in Asian countries such as China, Hong Kong, Malaysia, and Singapore), doctors are allowed to dispense drugs themselves and the practice of pharmacy is sometimes integrated with that of the physician, particularly in traditional Chinese medicine.

In Canada it is common for a medical clinic and a pharmacy to be located together and for the ownership in both enterprises to be common, but licensed separately.

The reason for the majority rule is the high risk of a conflict of interest. Otherwise, the physician has a financial self-interest in "diagnosing" as many conditions as possible, and in exaggerating their seriousness, because he or she can then sell more medications to the patient. Such self-interest directly conflicts with the patient's interest in obtaining cost-effective medication and avoiding the unnecessary use of medication that may have side-effects.

A campaign for separation has begun in many countries and has already been successful (like in Korea). As many of the remaining nations move towards separation, resistance and lobbying from dispensing doctors who have pecuniary interests may prove a major stumbling block (e.g. in Malaysia).

Community pharmacy

A *pharmacy* (commonly the *chemist* in Australia, New Zealand and the UK; or *drugstore* in North America; or Apothecary, historically) is the place where most pharmacists practise the profession of pharmacy. It is the community pharmacy where the dichotomy of the profession exists—health professionals who are also retailers.

Community pharmacies usually consist of a retail storefront with a dispensary where medications are stored and dispensed. The dispensary is subject to pharmacy legislation;

with requirements for storage conditions, compulsory texts, equipment, etc., specified in legislation. Where it was once the case that pharmacists stayed within the dispensary compounding/dispensing medications; there has been an increasing trend towards the use of trained pharmacy technicians while the pharmacist spends more time communicating with patients.

All pharmacies are required to have a pharmacist on-duty at all times when open. In many jurisdictions, it is also a requirement that the owner of a pharmacy must be a registered pharmacist (R.Ph.). This latter requirement has been revoked in many jurisdictions, such that many retailers (including grocery stores and mass merchandisers) now include a pharmacy as a department of their store.

Likewise, many pharmacies are now rather grocery store-like in their design. In addition to medicines and prescriptions, many now sell a diverse arrange of additional household items such as shampoo, bandages, office supplies, candy, and snack foods.

Hospital pharmacy

Pharmacies within hospitals differ considerably from community pharmacies. Some pharmacists in hospital pharmacies may have more complex clinical medication management issues whereas pharmacists in community pharmacies often have more complex business and customer relations issues. Because of the complexity of medications including specific indications, effectiveness of treatment regimens, safety of medications (i.e., drug interactions) and patient compliance issues (in the hospital and at home) many pharmacists practising in hospitals gain more education and training after pharmacy school through a pharmacy practice residency and sometimes followed by another residency in a specific area. Those pharmacists are often referred to as clinical pharmacists and they often specialize in various disciplines of pharmacy. For example, there are pharmacists who specialize in haematology/oncology, HIV/AIDS, infectious disease, critical care, emergency medicine, toxicology, nuclear pharmacy, pain management, psychiatry, anticoagulation clinics, herbal medicine, neurology/epilepsy management, paediatrics, neonatal pharmacists and more.

Hospital pharmacies can usually be found within the premises of the hospital. Hospital pharmacies usually stock a larger range of medications, including more specialized medications, than would be feasible in the community setting. Most hospital medications are unit-dose, or a single dose of medicine. Hospital pharmacists and trained pharmacy technicians compound sterile products for patients including total parenteral nutrition (TPN), and other medications given intravenously. This is a complex process that requires adequate training of personnel, quality assurance of products, and adequate facilities. Some hospital pharmacies have decided to outsource high risk preparations and some other compounding functions to companies who specialize in compounding.

Consultant pharmacy

Consultant pharmacy practice focuses more on medication regimen review (i.e. "cognitive services") than on actual dispensing of drugs. Consultant pharmacists most typically work in nursing homes, but are increasingly branching into other institutions and

non-institutional settings. Traditionally consultant pharmacists were usually independent business owners, though in the United States many now work for several large pharmacy management companies (primarily Omnicare, Kindred Healthcare, and PharMerica[2]). This trend may be gradually reversing as consultant pharmacists begin to work directly with patients, primarily because many elderly people are now taking numerous medications but continue to live outside of institutional settings. Some community pharmacies employ consultant pharmacists and/or provide consulting services.

Internet pharmacy

Since about the year 2000, a growing number of Internet pharmacies have been established worldwide. Many of these pharmacies are similar to community pharmacies, and in fact, many of them are actually operated by brick-and-mortar community pharmacies that serve consumers online and those that walk in their door. The primary difference is the method by which the medications are requested and received. Some customers consider this to be more convenient and private method rather than traveling to a community drugstore where another customer might overhear about the drugs that they take. Internet pharmacies (also known as Online Pharmacies) are also recommended to some patients by their physicians if they are homebound.

While most Internet pharmacies sell prescription drugs and require a valid prescription, some Internet pharmacies sell prescription drugs without requiring a prescription. Many customers order drugs from such pharmacies to avoid the "inconvenience" of visiting a doctor or to obtain medications which their doctors were unwilling to prescribe. However, this practice has been criticized as potentially dangerous, especially by those who feel that only doctors can reliably assess contraindications, risk/benefit ratios, and an individual's overall suitability for use of a medication. There also have been reports of such pharmacies dispensing substandard products. Of course as history has shown, substandard products can be dispensed by both Internet and Community pharmacies, so it is best that the buyer beware.

Canada is home to dozens of licensed Internet pharmacies, many which sell their lower-cost prescription drugs to U.S. consumers, who pay the world's highest drug prices. However, there are Internet pharmacies in many other countries including Israel, Fiji and the UK that serve customers worldwide.

In the United States, there has been a push to legalize importation of medications from Canada and other countries, in order to reduce consumer costs. While in most cases importation of prescription medications violates Food and Drug Administration (FDA) regulations and federal laws, enforcement is generally targeted at international drug suppliers, rather than consumers. There is no known case of any U.S. citizens buying Canadian drugs for personal use with a prescription, who has ever been charged by authorities.

The future of pharmacy

In the coming decades, pharmacists are expected to become more integral within the health care system. Rather than simply dispensing medication, pharmacists expect to be paid for their cognitive skills.[3]

This paradigm shift has already commenced in some countries; for instance, pharmacists in Australia receive remuneration from the Australian Government for conducting comprehensive Home Medicines Reviews. In Great Britain, pharmacists (and nurses) who undertake additional training are obtaining prescribing rights. In the United States, consultant pharmacists, who traditionally operated primarily in nursing homes are now expanding into direct consultation with patients, under the banner of "senior care pharmacy."[4]

Many universities are altering their programs to increase emphasis in fields such as pharmacotherapeutics, clinical pharmacy, nuclear pharmacy, disease state management, etc.

Adverse drug reaction

An *adverse drug reaction* (abbreviated *ADR*) is a term to describe the unwanted, negative consequences sometimes associated with the use of medications. ADR is a particular type of adverse effect. The term is preferred over the colloquial and imprecise "side effect", as the term "side effect" implies the potential for beneficial consequences and that the effects are not explained by the pharmacological actions of the drug. The focused study of ADRs is the concern of the field known as *pharmacovigilance*

While ADR is probably the most precise term to describe the concept, it is not widely used in the community since it may be perceived as jargon and because of the negative-associations with the term "drug". Alternative terms with equivalent meaning to ADR include: *side effect*, adverse event, adverse effect, etc.

There are many types of ADRs:

- Type A, pharmacologically predictable
- Type B, bizarre and unpredictable
- Type C, arising from chronic use
- Type D, delayed reaction
- Type E, end of dose reaction
- Type F, Failure of therapy

Why do Adverse Drug Reactions (ADRs) matter and how do they happen?

ADRs matter because pharmaceutical products and other substances taken for medical purposes have the potential for harming patients, even killing them. ADRs happen for many reasons, some inevitable and unavoidable, some preventable.

The inevitable reasons are:

- The effects of any medical intervention cannot be predicted with absolute certainty
- There is no drug or medical intervention which will not have some negative and undesirable effect on someone, somewhere at some time
- Information about rare events may, by their very nature, not be available until they happen.

The preventable reasons include:

- An error in diagnosing the disease
- Prescription of the wrong drug for the disease
- Prescription of the wrong dose of the right drug
- Choice of the right drug for the disease, but maybe the wrong drug for the patient, because of some genetic or ethnic predisposition, age, some other illness or medication, some allergy or intolerance
- Choice of an appropriate drug but without taking into account potentially harmful interactive effects with other drugs or substances being taken
- In relation to all the above, the full indications, contraindications and risks of the drug may not have been read or fully understood
- The patient may not comply with the doctor's advice or manufacturer's advice in the patient information leaflet
- People choosing drugs and other substances for their own medication may cause problems.

The remedies for these hugely challenging problems:'

- A higher priority in medical training in taking case-histories, diagnostic skills, pharmacology, and the recognition and reporting of adverse effects
- Greater awareness by healthcare professionals and the public about the complexities and benefit-harm-risk profiles of medical interventions
- More effective communication and openness about the nature of drugs and their effects and the degree of uncertainty associated with them
- Public education and debate about the benefits, harm and risks of medical interventions and agreement about the balance of benefit, harm and risk which is acceptable, given that there will always be some uncertainty.
- Wider discussion and education in the nature of risk in general and its communication, and in the individual variables affecting perception and acceptance of risk.

Regulatory authorities and guidelines

Monitoring of ADRs is highly regulated and is being monitored by regulatory authorities during clinical trials and after a new drug is on the market:

- European Medicines Agency (EMEA)

Food and Drug Administration (FDA)
Ministry of Health, Labour and Welfare (Japan)
Uppsala Monitoring Centre (WHO)
CIOMS Guidelines
Pharmacovigilance
EudraVigilance (European Union)
Yellow Card Scheme (UK)

Chinese herbology

Herbology is the Chinese art of combining medicinal herbs.

Herbology is traditionally one of the more important modalities utilized in traditional Chinese medicine (TCM). Each herbal medicine prescription is a cocktail of many herbs tailored to the individual patient. One batch of herbs is typically decocted twice over the course of one hour. The practitioner usually designs a remedy using one or two main ingredients that target the illness. Then the practitioner adds many other ingredients to adjust the formula to the patient's yin/yang conditions. Sometimes, ingredients are needed to cancel out toxicity or side-effects of the main ingredients. Some herbs require the use of other ingredients as catalyst or else the brew is ineffective. The latter steps require great experience and knowledge, and make the difference between a good Chinese herbal doctor and an amateur. Unlike western medications, the balance and interaction of all the ingredients are considered more important than the effect of individual ingredients. A key to success in TCM is the treatment of each patient as an individual.

Chinese herbology often incorporates ingredients from all parts of plants, the leaf, stem, flower, root, and also ingredients from animals and minerals. The use of parts of endangered species (such as seahorses, rhinoceros horns, and tiger bones) has created controversy and resulted in a black market of poachers who hunt restricted animals. Many herbal manufacturers have discontinued the use of any parts from endangered animals.

History of Chinese herbology

Chinese herbs have been used for centuries. The first herbalist in Chinese tradition is Shennong, a mythical personage, who is said to have tasted hundreds of herbs and imparted

his knowledge of medicinal and poisonous plants to the agricultural people. The first Chinese manual on pharmacology, the Shennong Bencao Jing (Shennong Emperor's Classic of Materia Medica), lists some 365 medicines of which 252 of them are herbs, and dates back somewhere in the 1st century C.E. Han dynasty. Earlier literature included lists of prescriptions for specific ailments, exemplified by a manuscript "Recipes for 52 Ailments", found in the MaWangDui tomb, sealed in 168 B.C.E.

Succeeding generations augmented on this work, as in the Yaoxing Lun (o'º; also spelled Yao Xing Lun; literally "Treatise on the Nature of Medicinal Herbs"), a 7th century Tang Dynasty Chinese treatise on herbal medicine.

Arguably the most important of these was the Compendium of Materia Medica (Bencao Gangmu) compiled during the Ming dynasty by Li Shizhen, which is still used today for consultation and reference.

The history of this literature is presented in Paul U. Unschuld's "Medicine in China: a History of Pharmaceutics"; Univ. of Calif. Press, 1986.

Categorizing Chinese herbs

Chinese physicians used several different methods to classify traditional Chinese herbs:

- The Four Natures
- The Five Tastes
- The Meridians

The earlier (Han through Tang eras) Ben Cao (Materia Medicae) began with a three-level categorization:

Low level -- drastic acting, toxic substances Middle level -- medicinal physiological effects High level -- health and spirit enhancement

During the neo-Confucian Song-Jin-Yuan era (10th to 12th Centuries), the theoratical framework from acupuncture theory (which was rooted in Confucian Han theory) was formally applied to herbal categorization (which was earlier more the domain of Daoist natural science). In particular, alignment with the Five Phases (Tastes) and the 12 channels (Meridians theory) came to be used after this period.

The Four Natures

This pertains to the degree of yin and yang, ranging from cold (extreme yin), cool, neutral to warm and hot (extreme yang). The patient's internal balance of yin and yang is taken into account when the herbs are selected. For example, medicinal herbs of "hot", yang nature are used when the person is suffering from internal cold that requires to be purged, or when the patient has a general cold constituency. Sometimes an ingredient is added to offset the extreme effect of one herb.

The Five Tastes

The five tastes are pungent, sweet, sour, bitter and salty, each of which their functions and characteristics. For example, pungent herbs are used to generate sweat and to direct and

vitalize qi and the blood. Sweet-tasting herbs often tonify or harmonize bodily systems. Some sweet-tasting herbs also exhibit a bland taste, which helps drain dampness through diuresis. Sour taste most often is astringent or consolidates, while bitter taste dispels heat, purges the bowels and get rid of dampness by drying them out. Salty tastes soften hard masses as well as purge and open the bowels.

The Meridians

The Meridians refer to which organs the herb acts upon. For example, menthol is pungent, cool and is linked with the lungs and the liver. Since the lungs is the organ which protects the body from invasion from cold and influenza, menthol can help purge coldness in the lungs and invading heat toxins caused by hot "wind".

50 fundamental herbs

In Chinese herbology, there are 50 "fundamental herbs." These include:

- Agastache rugosa

Alangium chinense
Anemone or Pulsatilla chinensis
Anisodus tanguticus
Ardisia japonica
Aster tataricus
Astragalus membranaceus
Camellia sinensis
Cannabis sativa
Carthamus tinctorius
Cinnamomum cassia
Cissampelos pareira
Coptis chinensis
Corydalis ambigua
Croton tiglium
Daphne genkwa
Datura metel
Datura tatula
Dendrobium nobile
Dichroa febrifuga
Ephedra sinica
Eucommia ulmoides
Euphorbia pekinensis
Flueggea suffruticosa (formerly Securinega suffruticosa)
Forsythia suspensa
Gentiana loureiroi
Gleditsia sinensis
Glycyrrhiza uralensis

Hydnocarpus anthelmintica (syn. H. anthelminthicus)
Ilex purpurea
Leonurus japonicus
Ligusticum wallichii
Lobelia chinensis
Phellodendron amurense
Platycladus orientalis (formerly Thuja orientalis)
Pseudolarix amabilis
Psilopeganum sinense
Pueraria lobata
Rauwolfia serpentina
Rehmannia glutinosa
Rheum officinale
Rhododendron tsinghaiense
Saussurea costus
Schisandra chinensis
Scutellaria baicalensis
Stemona tuberosa
Stephania tetrandra
Styphnolobium japonicum (formerly Sophora japonica)
Trichosanthes kirilowii
Wikstroemia indica

Drug reaction testing

Drug reaction testing uses a genetic test to predict how a particular person will respond to various prescription and non-prescription medications. It checks for genes that code for specific liver enzymes which activate, deactivate, or are influenced by various drugs.

There are currently four genetic markers commonly tested for: 2D6, 2C9, 2C19, and 1A2.

This testing has been done for some time by drug companies working on new drugs, but is relatively newly available to the general public. Strattera is the first drug to mention the test in the official documentation, although it doesn't specifically recommend that patients get the test before taking the medication.

There are four possible categories for each marker: poor metabolizer, intermediate metabolizer, extensive metabolizer, or ultra-extensive metabolizer. Different testing companies may call these by different names. Extensive metabolizers (that is, people who are extensive metabolizers of a given type) are the most common, and are the type of people for which drugs are designed. Up to 7% of Caucasians are poor metabolizers of drugs metabolized by the CYP2D6 enzyme.[1]

People who can't metabolize a drug will require a much lower dose than is recommended by the manufacturer, and those who metabolize it quickly may require a higher dose. Some drugs, such as codeine, will not be effective in people without the requisite enzymes to activate them.

People who are poor metabolizers of a drug may overdose while taking less than the recommended dose.

Essential medicines

Essential medicines, as defined by the World Health Organization are "those drugs that satisfy the health care needs of the majority of the population; they should therefore be available at all times in adequate amounts and in appropriate dosage forms, at a price the community can afford."

The WHO has published a model list of essential medicines. Each country is encouraged to prepare their own lists taking into consideration local priorities. At present over 150 countries have published an official essential medicines list.The WHO List contains a core list and a complementary list.

The core list presents a list of minimum medicine needs for a basic health care system, listing the most efficacious, safe and cost-effective medicines for priority conditions. Priority conditions are selected on the basis of current and estimated future public health relevance, and potential for safe and cost-effective treatment.

The complementary list presents essential medicines for priority diseases, for which specialized diagnostic or monitoring facilities are needed. In case of doubt medicines may also be listed as complementary on the basis of consistent higher costs or less attractive cost-effectiveness in a variety of settings.

The compilation of an essential medicines list enables health authorities, especially in developing countries, to optimize pharmaceutical resources.

Pharmacist

Pharmacists are health professionals who practice the art and science of pharmacy. In their traditional role, pharmacists typically take a request for medicines from a prescribing health care provider in the form of a medical prescription and dispense the medication to the patient and counsel them on the proper use and adverse effects of that medication. In this role, pharmacists ensure the safe and effective use of medications. Pharmacists also participate in disease state management, where they optimise and monitor drug therapy – often in collaboration with physicians and/or other health professionals. Pharmacists have many areas of expertise and are a critical source of medical knowledge in clinics, hospitals, and community pharmacies throughout the world.

Pharmacists are sometimes small-business owners, owning the pharmacy in which they practice. They are also very skilled and specialized individuals with specific knowledge that makes them a vital part of any healthcare team. They act as a learned intermediary between patients and physicians to ensure that proper medical therapy is chosen and implemented in the best way possible.

Pharmacists are sometimes referred to as *chemists* (or *dispensing chemists*), which sometimes causes confusion with scientists in the field of chemistry. This term is a historical one, since pharmacists originally were required to complete an undergraduate degree in Pharmaceutical Chemistry (PhC) and were known as "Pharmaceutical Chemists".

Qualifications and registration

The basic requirement for pharmacists to be considered for registration is an undergraduate or postgraduate Pharmacy degree from a recognised university. In most countries this involves a four-year course to attain a Bachelor of Pharmacy (BPharm) degree.

In order to practise as a pharmacist, the person must be registered with the relevant statutory body, which governs the registration and practice of pharmacy within the territory of its jurisdiction. There is often a requirement for the pharmacy graduate to have completed a certain number of hours of experience in a pharmacy, under the supervision of a registered pharmacist. The statutory body will usually administer a written and oral examination to the prospective pharmacist prior to registration.

Pharmacists are trained in fields including pharmacology, chemistry, pharmaceutical chemistry, pharmacy practice (including drug interactions, medicine monitoring, medication management), pharmaceutics, pharmacy law, physiology, anatomy, biochemistry, kinetics, nephrology, hepatology, and compounding medications. Additional curriculum covers basic diagnosis with emphasis on disease state management, therapeutics and prescribing (selecting the most appropriate medication for a given patient).

Australia

In Australia, apart from the four-year BPharm course, there is the option of a postgraduate two-year Master of Pharmacy (MPharm) course for those with undergraduate science degree background.

Pharmacists are registered by Pharmacy Boards in individual states such as the Pharmacy Board of New South Wales. In Western Australia, pharmacists are registered by the Pharmaceutical Council of Western Australia. Individual states have differing requirements for pharmacy graduates for registration, but generally graduates are required to complete approximately one year of practice under the supervision of a registered pharmacist. In addition, graduates are required to complete an approved graduate training course for that state, for example the Pharmacist Graduate Training Course (PGTC) offered by the Pharmaceutical Society of Australia NSW Branch is required in New South Wales. On meeting these requirements, graduates are eligible to sit the registration examination which may involve both written and oral components.

Greece

In Greece, a five-year University course must be completed. This course is offered by the University of Athens, the University of Thessaloniki and the University of Patras. The course comprises 4 years of theory and laboratory practice and a 5th year of compulsory, full-time in-service training in a community pharmacy and the pharmaceutical department of a hospital. An additional trimester placement in a pharmaceutical industry is also an option, however it does not count towards the acquisition of the licence to practice. Upon successful completion of the course, a Degree in Pharmacy is awarded.

The pharmacy graduate may pursue a career in the industry after graduation. A career in this field does not require a licence to practise pharmacy. However, pharmacists wishing to open a pharmacy, work in hospitals or in the National Organization of Medicines must first successfully participate in board examinations organized by the Greek Ministry of Health, in order to obtain a License to Practice Pharmacy.

New Zealand

In New Zealand, as with other western nations, a four year BPharm must be completed, followed by an internship at a pharmacy. Pharmacists are registered at the Pharmaceutical Society Of New Zealand. The degree can be taken at University Of Otago in Dunedin and University Of Auckland in Auckland.

Republic of Ireland

In the Republic of Ireland, a 4-year BPharm degree must be completed followed by one year of post-registration training. Trinity College, Dublin was the only university offering the BPharm course in the Irish Republic until recently. In 2003 two new Schools of Pharmacy were opened. A Pharmacy department was created at University College, Cork on the southern coast of Ireland as well as another Pharmacy school in the Irish capital, Dublin. (Royal College of Surgeons in Ireland)

Spain

In Spain, the Degree in Pharmacy (called licenciatura en farmacia) is consisting of 5 years. Last one is divided into two semesters, first one is similar as previous years (theory and laboratory practice) but second one is a full-time in-service training in a community pharmacy or at the pharmaceutical department of a hospital. This estructure is changing by another according to European Higher Education Area's System.

After obtaining degree certificate, there is the chance of opening a pharmacy sitting an examination in order to achieve a licence. There is also the chance of postgraduate programs as Masters and Doctorates and of carrying hospital/industry speciality programs out (FIR or farmacéutico interno-residente, pharmacist intern-resident) by means of an examination like medical specialities (MIR). These specialities are: "Hospital pharmacist", "Clinical microbiology and parasitology", "Clinical biochemistry", "Clinical immunology", "Clinical analysis", "Radiopharmacy", "Galenical and industrial pharmacy" and "Drug and medicines' control and analysis".

There are 15 universities with licenciatura in Pharmacy in Spain, three of them are private universities.

United Kingdom

In the United Kingdom, integration with the European Union has resulted in the BPharm course being superseded by a four-year course for the qualification Master of Pharmacy (MPharm). In Great Britain the Royal Pharmaceutical Society of Great Britain is responsible for regulation of pharmacy affairs and in Northern Ireland it is the Pharmaceutical Society of Northern Ireland. Graduates must complete one year of practical training and pass a registration examination before they can be entered on the register of pharmacists, known as the register of pharmaceutical chemists.

Pharmacists registered in other countries can also register in the UK. Overseas pharmacists are required to undertake the Overseas Pharmacists Assessment Programme (OSPAP), a one year intensive course focused on pharmacy practice in Great Britain. OSPAP authorisation can be given by Royal Pharmaceutical Society of Great Britain and the course is undertaken either the University of Sunderland, Aston University or the University of Brighton. However, pharmacists that have obtained their qualifications and are registered in other countries of the European Economic Area can register with the Royal Pharmaceutical Society of Great Britain without undergoing additional or pre-registration training.

The term pharmacist is protected in the United Kingdom. It can only be used by individuals that are registered with the Royal Pharmaceutical Society of Great Britain.

United States

Traditionally in the United States, the bachelor's degree in pharmacy was the first-professional degree for pharmacy practice. However, in 1990, the American Association of Colleges of Pharmacy (AACP) mandated that a doctor of pharmacy would be the new first-

professional degree. As of the year 2000, all pharmacy schools in the U.S. have discontinued the B.S. Pharm. (Bachelor of Science in Pharmacy) degree program.

Today, individuals seeking to become pharmacists must first complete a pre-pharmacy undergraduate program. This program consists of a minimum of 60-70 semester credit hours (90-100 quarter credit hours) of undergraduate coursework in basic and advanced sciences; however many students go on to complete a four year program (between 120-130 semester credit hours) leading to a Bachelor of Science degree in biology, chemistry, or a similar field. In addition, a high PCAT (Pharmacy College Admission Test) score is required at most colleges and schools of pharmacy.

After admission, a student will complete a four year pharmacy program and will be awarded the Doctor of Pharmacy (PharmD) degree upon graduation. A pharmacy graduate may choose to complete an optional post-graduate residency (one to three years) or enter directly into pharmacy practice, e.g., community (retail), compounding, consultant (nursing home), hospital, nuclear, etc.

Pharmacy school graduates must complete internship requirements and pass the North American Pharmacist Licensure Examination, or NAPLEX, and an additional state exam before they can acquire a license to practice pharmacy in that state. The NAPLEX was created by the National Association of Boards of Pharmacy (NABP).

Roles

Pharmacists are often the first point-of-contact for patients with health inquiries. This means that pharmacists have large roles in the primary healthcare of patients.

These roles include, but are not limited to :

- clinical medication management
- specialized monitoring of simple and complex disease states
- reviewing medication regimens
- monitoring of treatment regimens
- general health monitoring
- compounding medicines
- general health advice
- providing specific education to patients about disease states and medications
- oversight of dispensing medicines on prescription
- provision of non-prescription medicines
- counseling and advice on optimal use of medicines
- advice and treatment of common ailments
- referral to other health professionals if necessary
- dosing drugs in renal and hepatic failure
- pharmacokinetic evaluation
- education of physicians on medications and their proper use
- prescribing medications in collaboration with other healthcare professionals
- providing pharmaceutical information

Specialities

Practice specialisation

Specialties exist within the pharmacy profession, with the place of occupation being the major differentiator. Specialities include:

- Academic pharmacist
- Clinical pharmacist
- Community pharmacist
- Compounding pharmacist
- Consultant pharmacist
- Drug information pharmacist
- Home Health pharmacist
- Hospital pharmacist
- Industrial pharmacist
- Locum pharmacist
- Regulatory-affairs pharmacist
- Veterinary pharmacist

Specialty Practice accreditation

In the United States, a pharmacist can become certified in recognized specialty practice areas by passing an examination administered by the Board of Pharmaceutical Specialties. There are five specialties in which a pharmacist can become Board-certified. The Pharmacotherapy specialty also has two subspecialties, as follows:

- Nuclear Pharmacy
- Nutrition Support Pharmacy
- Oncology Pharmacy
- Pharmacotherapy
  - Cardiology
  - Infectious disease
- Psychiatric Pharmacy

Additionally, other certifications are available from smaller credentialing boards, such as the Certified Geriatric Pharmacist (CGP) designation, administered by the Commission for Certification in Geriatric Pharmacy (CCGP).

In Australia, accreditation exists only for certain specialties and is provided by professional bodies for the following:

- Consultant Pharmacist (AACPA), by the Australian Association of Consultant Pharmacy (AACP)
- Certified Geriatric Pharmacist (CGP), by the Society of Hospital Pharmacists of Australia (SHPA)

Self-medication

Self-medication is the use of drugs, sometimes illicit, to treat a perceived or real malady, often of a psychological nature.

Over-the-counter drugs are a form of self medication. The buyer diagnoses their own illness and buys a specific drug to treat it. The World Self-Medication Industry (WSMI) define self-medication as the treatment of common health problems with medicines especially designed and labeled for use without medical supervision and approved as safe and effective for such use.

A person may also self-medicate by taking more or less than the recommended dose of a drug.

Some mental illness sufferers attempt to correct their illnesses by use of tobacco, cannabis, or other mind-altering drugs. While this may provide immediate relief of some symptoms such as anxiety, it may evoke and/or exacerbate some symptoms of several kinds of mental illnesses that are already latently present, and may lead to addiction/dependence, among other side effects of long-term use of the drug. The theory that drug dependence or addiction results from self-medication for the distress caused by a pre-existing condition was introduced in 1974 by David F. Duncan and Edward J. Khantzian in independent publications. This theory has come to be known as the self-medication hypothesis. For example, sufferers of post-traumatic stress disorder are prone to self-medication, as well as many individual without this diagnosis which have suffered from (mental) trauma.

Occasionally an individual will attempt self-medication for physical illnesses. For example, it is believed that Kurt Cobain's use of heroin partially stemmed from a painful stomach condition.

The current phenomenon in many Western societies of the widespread usage of vitamins, herbs, and other over-the-counter "supplements"--usually without the advice, supervision, or even knowledge of any licensed health professional--is another possible example of self-medication. Some observers of health behavior and medical affairs have speculated that this trend may arise from the desire of laymen to feel more in control of their own health--rather than relying on the traditional medical establishment, whose motives are sometimes seen as suspect. The extraordinary increases in the cost of traditional health care in recent decades--doctors, hospitals, prescriptions, etc.-- causes some individuals to desperately try to find more affordable alternatives to treat or prevent their own afflictions, though this pursuit sometimes proves to be ineffective and expensive.

Adverse effect

In medicine, an *adverse effect* is an abnormal, harmful, undesired and/or unintended side-effect, although not necessarily unexpected, which is obtained as a result of a therapy or other medical intervention, such as drug/chemotherapy, physical therapy, surgery, medical procedure, use of a medical device, etc. Iatrogenesis (literally, generated by a physician) is a common cause of adverse effects, as well as medical error. Using a drug or other medical intervention which is contraindicated may increase the risk of adverse effects. Adverse effects may cause medical complications of a disease or procedure and negatively affect its prognosis.

The harmful outcome is usually indicated by some result such as morbidity, mortality, alteration in body weight, levels of enzymes, loss of function or as a pathological change detected at the microscopic, macroscopic or physiological level. They may cause a reversible or irreversible change, including an increase or decrease in the susceptibility of the individual to other chemicals, foods, or procedures (e.g. drug interaction).

Reporting systems

In many countries, adverse effects are required by law to be reported, researched in clinical trials and included into the patient information accompanying medical devices and drugs for sale to the public.

UK

The Yellow Card Scheme is a UK initiative run by the Medicines and Healthcare products Regulatory Agency (MHRA) and the Commission on Human Medicines (CHM) to gather information on adverse effects to medicines. This includes all licensed medicines from medicines issued on prescription to medicines bought over the counter from a supermarket. The Scheme also includes all herbal preparations and unlicensed medicines found in cosmetic treatments. ADRs can be reported by a number of healthcare professionals including doctors, pharmacists and nurses, as well as patients.

For further information see the Yellow Card Scheme website, or find copies of the Yellow Card in the appedices of a BNF.

To read reports from the UK Yellow Card Scheme you can download here.

USA

In the USA several reporting systems have been built, such as the Vaccine Adverse Event Reporting System (VAERS), the Manufacturer and User Facility Device Experience Database (MAUDE) and the Special Nutritionals Adverse Event Monitoring System. MedWatch is the main reporting center, operated by the Food and Drug Administration.

Australia

In Australia, adverse effect reporting is administered by the Adverse Drug Reactions Advisory Committee (ADRAC), a subcommittee of the Australian Drug Evaluation Committee (ADEC). Reporting is voluntary, and ADRAC requests health professionals to report all adverse reactions to its current drugs of interest, and serious adverse reactions to any drug. ADRAC publishes the Australian Adverse Drug Reactions Bulletin every 2 months.

Adverse effects of medical procedures

Surgery, of course, may have a number of undesirable or harmful after effects, such as infection, hemorrhage, inflammation, scarring, loss of function, changes in local blood flow, and so on. They can be reversible or irreversible, and a compromise must be found by the physician and the patient between the beneficial or life-saving consequences of surgery versus its adverse effects. For example, a limb may be lost to amputation in case of untreatable gangrene, but life is saved. Presently, one of the greatest advantages of minimally invasive surgery, such as laparoscopic surgery is the reduction of adverse effects.

Other non-surgical physical procedures such as high intensity radiotherapy may cause burns and alterations in the skin. In general, these therapies try to avoid damage to healthy tissues while maximizing the therapeutic effect.

Vaccination is a medical procedure which is particularly prone to adverse effects, due to the nature of its biological preparation (sometimes using attenuated pathogens and toxins). Common adverse effects may be fever, malaise and local reactions in the vaccination site, such as eczema vaccinatum, a severe, sometimes fatal complication which may result in persons who have eczema or atopic dermatitis, and, as such, those persons should not be vaccinated, even if the condition is currently not active.

Diagnostic procedures may also have adverse effects, depending much on whether they are invasive, non-invasive or minimally invasive. For example, allergic reactions to x-ray contrasting material often occur, a colonoscopy may cause the perforation of the intestine wall, etc.

Adverse effects of drugs

Main article: adverse drug reaction

Adverse effects can occur as a collateral or side effect of many interventions, but they are particularly important in pharmacology, due to its wider, and sometimes uncontrollable, use by way of self-medication. Thus, responsible drug use becomes an important issue here.

Adverse effects, like intended effects of drugs, are a function of dosage or drug levels at the target organs, so they may be avoided or decreased by means of careful and precise pharmacodynamics (the change of drug levels in the organism in function of time after administration).

Adverse effects may also be caused by drug interaction, i.e., when physicians fail to check for all medicaments a patient is taking and prescribe new ones which interact agonistically or antagonistically (potentiate or decrease the intended therapeutic effect). Significant morbidity and mortality is caused around the world because of this. Drug-drug and food-drug interactions may occur, and even so-called "natural drugs" used in alternative medicine may have dangerous adverse effects. For example, extracts of St. John's wort (Hypericum perforatum), a phytotherapic used for treating mild depression are known to cause an increase in the cytochrome P450 enzymes responsible for the metabolism and elimination of many drugs, so that patients taking it are likely to experience a reduction in blood levels of drugs that they are taking for other purposes, such as cancer chemotherapeutic drugs, protease inhibitors for HIV and oral contraceptives.

The scientific field of activity associated with drug safety is increasingly government-regulated and is of major concern for the public as well as to drug manufacturers. The distinction between adverse and non-adverse effects is a major undertaking when a new drug is developed and tested before marketing it. This is done in toxicity studies to determine the non-adverse effect level (NOAEL). These studies are used to define the dosage to be used in human testing (phase I) as well as to calculate the maximum admissible daily intake. Imperfections in clinical trials, such as insufficient number of patients or short duration, sometimes lead to public health disasters such as those of fenfluramine (the so-called fen-phen episode), thalidomide and, more recently, of cerivastatin (Baycol®, Lipobay®) and

rofecoxib (Vioxx®), where drastic adverse effects were observed, like teratogenesis, pulmonary hypertension, stroke, heart disease, neuropathy, etc., and a significant number of deaths, causing the forced or voluntary withdrawal of the drug from the market.

Most drugs have a large list of non-severe or mild adverse effects which do not rule out the interruption of usage. These effects have widely variable incidence, according to individual sensitivity. They comprise nausea, dizziness, diarrhea, malaise, vomit, headache, dermatitis, dry mouth, etc.

Controversies

Sometimes, putative medical adverse effects are regarded as controversial and generate heated discussions in society and lawsuits against drug manufacturers. One example is the current controversy whether autism may be caused by the MMR vaccine (or by thimerosal, a mercury-based preservative used in some vaccines). No significant link has been decisively found so far; nevertheless lawsuits have been brought. Another instance is the potential adverse effects of silicone breast implants, which lead to hundreds of thousands of litigations against manufacturers of gel-based implants, due to allegations of damage to the immune system which have not yet been conclusively proven.

Due to the exceedingly high impact on public health of widely used medications, such as oral contraceptives and hormone replacement therapy, which may affect millions of users, even marginal probabilities of adverse effects of a severe nature, such as breast cancer, have led to public outcry and changes in medical therapy, although its benefits largely surpassed the statistical risks.

Limitations of adverse effects reporting

In principle, medical professionals are required to report all adverse effects related to a specific form of therapy. In practice, it is at the discretion of the professional to determine whether a medical event is at all related to the therapy. For example, a leg fracture in a skiing accident in a patient who years before took antibiotics for pneumonia is not likely to get reported.

As a result, routine adverse effects reporting may often not include long-term and subtle effects that may ultimately be attributed to a therapy.

Examples of adverse effects

- Abortion, miscarriage or uterine hemorrhage associated with misoprostol (Cytotec®), a labor-inducing drug (this is a case where the adverse effect has been used legally and illegally for performing abortions)

Addiction to many sedatives and analgesics such as diazepam, morphine, etc.
Bleeding of the intestine associated with aspirin therapy
Deafness and kidney failure associated with gentamicin (an antibiotic)
Death, following sedation in children using propofol (Diprivan®)
Dementia associated with heart bypass surgery
Depression or hepatic injury caused by interferon

Diabetes caused by atypical antipsychotic medications (neuroleptic psychiatric drugs)
Diarrhea caused by the use of orlistat (Xenical®)
Erectile dysfunction associated with many drugs, such as antidepressants
Fever associated with vaccination (in the past, imperfectly manufactured vaccines, such as BCG and poliomyelitis, have caused the very disease they intended to fight).
Glaucoma associated with corticosteroid-based eye drops
Hair loss and anemia may be caused by chemotherapy against cancer, leukemia, etc.
Headache following spinal anesthesia
Hypertension in ephedrine users, which prompted FDA to remove the status of dietary supplement of ephedra extracts
Insomnia caused by stimulants, Ritalin®, Adderall®, etc.
Lactic acidosis associated with the use of stavudine (Zerit®, for anti-HIV therapy) or metformin (for diabetes)
Melasma and thrombosis associated with oral contraceptive use
Rhabdomyolysis associated with statins (anti-cholesterol drugs)
Seizures caused by withdrawal from benzodiazepine
Sleepiness or increase in appetite due to antihistamine use
Stroke or heart attack associated with sildenafil (Viagra®) when used with nitroglycerine
Suicide, increased tendency associated to the use of fluoxetine and other SSRI antidepressants
Tardive dyskinesia associated with long-term use of metoclopramide and many antipsychotic medications

Agonist

An *agonist* is a molecule that selectively binds to a specific receptor and triggers a response in the cell. It mimicks the action of an endogenous biochemical molecule (such as hormone or neurotransmitter) that binds to the same receptor. It is a drug molecule (synthesized outside an organism) that reproduces the action of an endogenous natural biochemical (synthesized inside an organism). An agonist is the opposite of an antagonist in the sense that while an antagonist also binds to the receptor, the antagonist does not activate the receptor and actually blocks it from activation by agonists. A *partial agonist* (such as buspirone, aripiprazole, bifeprunox or norclozapine) activates a receptor, but only produces a partial physiological response compared to a *full agonist*. A *co-agonist* works with other co-agonists to produce the desired effect together. Receptors can be activated or inactivated by

endogenous (such as hormones and neurotransmitters) or exogenous (such as drugs) agonists and antagonists, resulting in stimulating or inhibiting the cell. To see how an agonist may activate a receptor see this link. Recently a novel theory called Functional Selectivity has been proposed that broadens the conventional definition of pharmacology.

Etymology

Stems from the Greek agonistes, 'contestant', from agon, 'contest'. An agonist is a chemical contestant or contender.

- Receptor antagonist

Placebo

A *placebo*, from the Latin for "I shall please", is an inactive substance (pill, liquid, etc.), which is administered as if it were a therapy, but which has no therapeutic value other than the placebo effect.

Early use of placebos

Originally, a placebo was a substance that a well-meaning doctor would give to a patient, telling him that it was a powerful drug (e.g., a painkiller), when in fact it was nothing more than a sugar pill. Thus, Hooper's medical dictionary of 1811 says placebo is "an epithet given to any medicine adapted more to please than benefit the patient." The subsequent reduction of the patient's symptoms was attributed to the patient's belief in the drug.

Placebos are themselves inactive, however a patient may experience either a positive or negative clinical effect while taking one. When a placebo is administered to mimic a previously administered drug, it may also incur the same side effects as the prior authentic drug. Most of these effects are thought to be psychological in nature or due to other unrelated factors. Not all placebos are "created equal." A placebo that involves ingestion, injection, or incision is often more powerful than a non-invasive technique. Placebos administered by authority figures such as general practitioners and other experts may also be more powerful than when the psychological authority effect is absent.

A placebo which results in a worsening of symptoms is called a nocebo (Latin for "I will harm").

Modern clinical application

Experimenters typically use placebos in the context of a clinical trial, in which a "test group" of patients receives the therapy being tested, and a "control group" receives the placebo. It can then be determined if results from the "test" group exceed those due to the

placebo effect. If they do, the therapy or pill given to the "test group" is assumed to have had an effect. The first well documented use of a placebo in a clinical trial was reported in "Streptomycin treatment of pulmonary tuberculosis". BMJ 1948;2:769--782, a research paper by the Medical Research Council. Thus, if a therapy or medicine has no effect beyond placebo, then it is said to have no effect or efficacy beyond non-specific effects.

Technical challenges and pitfalls

Double-Blinding

Appropriate use of a placebo in a clinical trial often requires or at least benefits from a double-blind study design, which means that neither the experimenters nor the subjects know which subjects are in the "test group" and which are in the "control group". This sometimes causes difficulties as a double-blind design cannot be easily applied to many treatments. For example, because some drugs have clear physiological impact, an inert pill (e.g., a sugar pill) would not be an effective placebo to test against any such drug. That is, an inert pill could not be used to demonstrate whether an active drug with noticeable physical side effects has more than a strong placebo effect. For example, long before any psychoactive response most people can tell if they have ingested an active antidepressant or anti-anxiety agent because of their physiological effects. The same is true of strong pain relievers. Believing you have received the active drug can produce a markedly heightened placebo effect. To offset this heightened effect, it is necessary to use a *psychoactive placebo,* i.e., a drug that produces enough physical effects to balance the belief in the control and experimental groups that they have received the active drug. An example of the use of a psychoactive placebo can be found in the Marsh Chapel Experiment. In that double-blind study, the experimental group received psilocybin while the control group received a large dose of niacin that produces noticeable physical effects.

Measuring the Placebo Effect

Ethical challenges and concerns

Bioethicists have raised diverse concerns on the use of placebos in modern medicine and research. These have been largely incorporated into modern rules for the use of placebos in research but some issues remain subject to debate.

- Disclosure. Rules that govern modern clinical trials insist on full disclosure to subjects who take part. Today, subjects are told that they may receive the drug being tested or they may receive the placebo.
- Balancing Treatment vs. Research Objectives. Ethicists have also raised concerns on the use of placebos in those circumstances in which a standard treatment exists unless there are genuine doubts of the effectivity of such standard treatment. If standard treatments exist for the disease being studied in clinical trials, a standard treatment is always used in place of a placebo for serious diseases.

- Placebo effect

Placebo effect

The *placebo effect* (Latin placebo, "I shall please"), first mentioned in 1955 by Henry K. Beecher, M.D. (Beecher 1955) and also known as non-specific effects and the subject-expectancy effect, is the phenomenon that a patient's symptoms can be alleviated by an otherwise ineffective treatment, since the individual expects or believes that it will work. Some people consider this to be a remarkable aspect of human physiology; others consider it to be an illusion arising from the way medical experiments were conducted. The phenomenon, if it exists at all, is not fully understood by science.(New Scientist Space 19 March 2005)

In the opposite effect, a patient who disbelieves in a treatment may experience a worsening of symptoms. This nocebo effect (Latin nocebo, "I shall harm") can be measured in the same way as the placebo effect, e.g., when members of a control group receiving an inert substance report a worsening of symptoms. The recipients of the inert substance may nullify the placebo effect intended by simply having a negative attitude towards the effectiveness of the substance prescribed, which often leads to a nocebo effect, which is not caused by the substance itself, but more the patient's mentality towards her or his ability to get well.

Placebo-controlled studies

Beecher (1955) reported that about a quarter of patients who were administered a placebo, for example against back pain, reported a relief or diminution of pain. Remarkably, not only did the patients report improvement, but the improvements themselves were often objectively measurable, and the same improvements were typically not observed in patients who did not receive the placebo.

Because of this effect, government regulatory agencies approve new drugs only after tests establish not only that patients respond to them, but also that their effect is greater than that of a placebo (by way of affecting more patients, by affecting responders more strongly or both). Such a test or clinical trial is called a placebo-controlled study. Because a doctor's belief in the value of a treatment can affect his or her behaviour, and thus what his or her patient believes, such trials are usually conducted in "double-blind" fashion: that is, not only are the patients made unaware when they are receiving a placebo, the doctors are made unaware too. Recently, it has even been shown that "mock" surgery can have similar effects, and so some surgical techniques must be studied with placebo controls (rarely double blind, due to the difficulty involved). To merit approval, the group receiving the experimental treatment must experience a greater benefit than the placebo group.

Nearly all studies conducted this way show some benefit in the placebo group. For example, Khan published a meta-analysis of studies of investigational antidepressants and found a 30% reduction in suicide and attempted suicide in the placebo groups and a 40% reduction in the treated groups. (Khan 2000) However, studies generally do not include an *untreated* group, so determining the actual size of the placebo effect, compared to totally untreated patients, is difficult.

Notable placebo effect absences

In psychological treatment, two disorders are known to have very low placebo effects: schizophrenia, and obsessive compulsive disorder.

Placebo and pain

Careful studies have shown that the placebo effect can alleviate pain, although the effect is more pronounced with pre-existing pain than with experimentally induced pain. People can be conditioned to expect analgesia in certain situations. When those conditions are provided to the patient, the brain responds by generating a pattern of neural activity that produces objectively quantifiable analgesia. (Benedetti 2003, Wager 2004)

Evans argued that the placebo effect works through a suppression of the acute phase response, and as a result does not work in medical conditions that do not feature this. (Evans 2005) The acute phase response consists of inflammation and sickness behaviour:

- Four classic signs of ‘inflammation’: tumor, rubor, calor and dolor – swelling, redness, heat and pain.
- Sickness behaviour: lethargy, apathy, loss of appetite and increased sensitivity to pain.

Placebo and depression

A brain-imaging study found that depressed patients who responded to the placebo effect showed changes in cerebral blood flow, which were similar to the changes in brain function seen in patients who responded to anti-depressant medication. (Leuchter 2002) Other studies argue that up to 75% of the effectiveness of anti-depressant medication is due to the placebo-effect rather than the treatment itself. (Khan 2000)

Endogenous Opiates

Endogenous opiates are chemicals produced by the brain that suppress pain and produce analgesia and a sense of well-being. Opium and drugs derived from it (opiates) produce their "highs" by triggering the same brain receptors used by natural opiates. Increased release of endogenous opiates like endorphin is associated with pleasant experiences like exercise (the runner's high) and sex. When patients who claimed to experience pain relief after receiving a placebo were injected with naloxone (a drug that blocks the effects of opiates), their pain

returned, suggesting that the placebo effect may be partly due to the release of natural opiates. (Sauro 2005)

Objective or subjective effects?

Hrobjartsson and Götzsche published a study in 2001 and a follow-up study in 2004 questioning the nature of the placebo effect. (Hrobjartsson 2001, Hrobjartsson 2004) They performed two meta-analyses involving 156 clinical trials in which an experimental drug or treatment protocol was compared to a placebo group and an untreated group, and specifically asked whether the placebo group improved compared to the untreated group. Hrobjartsson and Götzsche found that in studies with a binary outcome, meaning patients were classified as improved or not improved, the placebo group had no statistically significant improvement over the no-treatment group. Similarly, there was no significant placebo effect in studies in which objective outcomes (such as blood pressure) were measured by an independent observer. The placebo effect could only be documented in studies in which the outcomes (improvement or failure to improve) were reported by the subjects themselves. The authors concluded that the placebo effect does not have "powerful clinical effects," (objective effects) and that patient-reported improvements (subjective effects) in pain were small and could not be clearly distinguished from bias.

These results suggest that the placebo effect is largely subjective. This would help explain why the placebo effect is easiest to demonstrate in conditions where subjective factors are very prominent or significant parts of the problem. Some of these conditions are headache, stomachache, asthma, allergy, tension, and the experience of pain, which is often a significant part of many mild and serious illnesses.

How the placebo effect works

There are three main hypotheses for how the placebo effect works, the subject-expectancy effect, conditioning and motivation.

Expectancy Effect

The subject-expectancy effect attributes the placebo effect to conscious or unconscious manipulation by patients in reporting improvement. Hrobjartsson and Götzsche argued in their article, "Most patients are polite and prone to please the investigators by reporting improvement, even when no improvement was felt." Subjective bias can also be unconscious, where the patient believes he is improving as a result of the attention and care he has received.

Conditioning

Classical conditioning is a type of associative learning where the subject learns to associate a particular stimulus with a particular response. In this case the stimulant is the substance perceived as medicine but is the placebo, and the response is the relief of

symptoms. It is difficult to tell the difference between conditioning and the expectancy effect when the outcome is subjective and reported by the patient. However, conditioning can result in measurable biological changes similar to the changes seen with the real treatment or drug. For example, studies showing that placebo treatments result in changes in brain function similar to the real drug are probably examples of conditioning resulting in objectively measurable results. (Sauro 2005, Wager 2004, Leuchter 2002)

Motivation

Motivational explanations of the placebo effect have typically considered the placebo effect to be an outcome of one's desire to feel better, reduce anxiety, or cooperate with an experimenter or health care professional (Price et al. 1999, Margo 1999). The motivational perspective is supported by recent research showing that nonconscious goals for cooperation can be satisfied by confirming expectations about a treatment (Geers et al. 2005).

The use of placebos in medical practice

The ethics of prescribing placebos in medical practice is highly debated. Some practitioners argue that the use of placebos is sometimes justified because it will do no harm and may do some good. With the publication of studies by Hróbjartsson and Götzsche and others, the proposition that placebos may do some good is under fire.

In research experimental studies, the method of establishing a proper control group to eliminate the placebo effect has also been difficult, particularly for surgical and therapy interventions that are not pharmaceutical in nature. Notably, there has been much debate of whether to use a placebo pill or conduct a sham procedure as a control.

A study of Danish general practitioners found that 48% had prescribed a placebo at least 10 times in the past year. The most frequently prescribed placebos were antibiotics for viral infections, and vitamins for fatigue. Specialists and hospital-based physicians reported much lower rates of placebo use. (Hrobjartsson 2003) A 2004 study in the British Medical Journal of physicians in Israel found that 60% used placebos in their medical practice, most commonly to "fend off" requests for unjustified medications or to calm a patient. Of the physicians who reported using placebos, only 15% told their patients they were receiving placebos or non-specific medications. (Nitzan 2004) An accompanying editorial stated,

"The placebo effect, thought of as the result of the inert pill, can be better understood as an effect of the relationship between doctor and patient. Adding the doctor's caring to medical care affects the patient's experience of treatment, reduces pain, and may affect outcome. This survey makes it clear that doctors continue to use placebos, and most think they help."

The editorial suggested there were problems with Hróbjartsson and Götzsche's methods and argued that their results show that placebos can't cure everything, but don't prove that the placebo effect cures nothing. The editorial concluded, "We cannot afford to dispense with any treatment that works, even if we are not certain how it does." (Spiegel 2004)

The editorial prompted responses on both sides of the issue.[1]

- Critics of the practice responded that it is unethical to prescribe treatments that don't work, and that telling a patient that a placebo is a real medication is deceptive and harms the doctor-patient relationship in the long run. Critics also argued that using placebos can delay the proper diagnosis and treatment of serious medical conditions.
- Defenders of the use of placebos suggested that placebos do not work in clinical trials because the subjects know they might be getting a placebo, but do work in medical practice where the patient believes he or she is getting an active drug. Other writers pointed to the empirical data showing that placebos can have measurable biological effects, especially in pain relief (see above), or argued that the use of a placebo to "please the patient" fosters real healing as part of a caring doctor-patient relationship. (Barfod 2005, Di Blasi 2005)

About 25% of physicians in both the Danish and Israeli studies used placebos as a diagnostic tool to determine if a patient's symptoms were real, or if the patient was malingering. Both the critics and defenders of the medical use of placebos agreed that this was unethical. The BMJ editorial said, "That a patient gets pain relief from a placebo does not imply that the pain is not real or organic in origin...the use of the placebo for 'diagnosis' of whether or not pain is real is misguided."

The placebo administration may prove to be a useful treatment in some specific cases where recommended drugs can not be used. For example, burn patients who are experiencing respiratory problems cannot often be prescribed opioid (morphine) or opioid derivatives (pethidine), as these can cause further respiratory depression. In such cases placebo injections (normal saline, etc.) are of use in providing real pain relief to burn patients if they (those not in delirium) are told that are being given a powerful dose of painkiller.

There is general agreement that placebo control groups are an important tool for controlling for several types of possible bias, including the placebo effect, in double blind clinical trials.

The placebo effect is an active area of research and discussion and it is possible that a clear consensus regarding the use of placebos in medical practice will emerge in the future.

Methodology of Administration

Placebos are things like sugar pills, that look like real treatments but in fact have no physical effect. They are used to create "blind" trials in which the participants do not know whether they are getting the active treatment or not, so that physical effects can be measured independently of the participants' expectations. There are various effects of expectations, and blind trials control all of these together by making whatever expectations there are equal for all cases. Placebos aren't the only possible technique for creating blindness (unawareness of the intervention): to test the effectiveness of prayer by others, you just don't tell the participants who has and has not had prayers said for them. To test the effect of changing the frequency of fluorescent lights on headaches, you just change the light fittings at night in the absence of the office workers (this is a real case).

Related to this is the widespread opinion that placebo effects exist, where belief in the presence of a promising treatment (even though it is in fact an inert placebo) creates a real

result e.g. recovery from disease. Placebos as a technique for blinding will remain important even if there is no placebo effect, but obviously it is in itself interesting to discover whether placebo effects exist, how common they are, and how large they are. After all, if they cure people then we probably want to employ them for that.

Claims that placebo effects are large and widespread go back to at least Beecher (1955). However Kienle and Kiene (1997) did a reanalysis of his reported work, and concluded his claims had no basis in his evidence; and then Hrobjartsson & Gotzsche (2001) did a meta-analysis or review of the evidence, and concluded that most of these claims have no basis in the clinical trials published to date. The chief points of their skeptical argument are:

- Only trials that compare a group that gets no treatment with another group that gets a placebo can test the effect.
- Most claims are based on looking at the size of the improvement measured in placebo groups in trials comparing only placebo and experimental (active) treatments. This is misleading since (for instance) most diseases have a substantial clearup rate with no treatment: seeing improvements doesn't mean the placebo had an effect. (Put more technically, comparing with the baseline (pretest measure) is vulnerable to regression to the mean.)

Nevertheless, even they conclude that there is a real placebo effect for pain (not surprising since this is partly understood theoretically: Wall, 1999)); and for some other continuously-valued subjectively-assessed effects. A recent experimental demonstration was reported: Zubieta et al. (2005) "Endogenous Opiates and the Placebo Effect" The journal of neuroscience vol.25 no.34 p.7754-7762

This seems to show that the psychological cause (belief that the placebo treatment might be effective in reducing pain) causes opioid release in the brain, which then presumably operates in an analogous way to externally administered morphine.

A recent and more extensive review of the overall dispute is: M. Nimmo (2005) Placebo: Real, Imagined or Expected? A Critical Experimental Exploration Final year undergraduate Critical Review, Dept. of Psychology, University of Glasgow. PDF copy.

Summary

- Placebos are used to create blind trials. They are not the only technique for this, but are a very common and important one.
- Whether or not there is a placebo effect, placebos will remain an important technique for this.
- Recent skeptical meta-analysis of placebo effects suggest that the effect does exist, but only in very limited contexts. The widespread claims are mainly misplaced, based on faulty inferences.
- Placebos are often seen as posing ethical difficulties. Essentially the issues are of two kinds, neither about placebos alone.
    - Deceiving experimental participants, or at least withholding information. This is potentially in tension with the principle of informed consent. This is most acute for experiments that wish not just to achieve blinding, but to measure the effect of expectancies, and so wish to induce expectancies by misinforming (some) participants.

- Withholding treatment from patients (or education from students). The tension here is between the greater certainty a controlled experiment will give, versus the prior guesses of people and experts. After all, you probably wouldn't do an experiment unless you had some reason to hope a treatment worked; but if you do have such grounds, then your opinion of the best treatment should be given to all patients rather than give some a placebo.

Ways of classifying and comparing such effects Can we organize these (and other) various reported effects in some useful way? What are the effects that might be related?

Confounders mistaken for placebo effect

Due to the difficulty in ascribing causation, many phenomena overlap with — and can thus mistakenly be included in — statistics on the placebo effect.

- Natural termination of the disease process.
- Regression to the mean. Cyclical presentation of the disease.
- Errant diagnosis or prognosis.
- Temporary improvement confused with cure.

Prescription drug

A *prescription drug* is a licensed medicine that is regulated by legislation to require a prescription before it can be obtained. The term is used to distinguish it from over the counter drugs which can be obtained without a prescription. Different jurisdictions have different definitions of what constitutes a prescription drug. As a general rule, over the counter drugs are used to treat conditions not necessarily requiring a doctor's care and will have been proven to meet higher safety standards for self-medication by patients. Often a lower dosage of a drug will be approved for OTC use, while higher dosages will remain the province of a doctor's prescription; a notable case is ibuprofen, which has been widely available as an OTC pain killer since the mid-1980s but is still available in doses up to four times the OTC dose for use in cases of severe orthopedic pain.

In the United States, the term "prescription drug" is most commonly used, but they are also called *legend drugs* or *Rx-only drugs*, after the requirements of Federal and state laws that all such drugs bear a "legend" prohibiting sale without a prescription; though more complex legends have been used, on most original drug packaging today the legend simply says "Rx only". In the United Kingdom, they are referred to as *Prescription Only Medicine* or *POM*.

Dispensation of prescription drugs often includes a package insert (in Europe, a Patient Information Leaflet or PIL) that gives detailed information about the drug.

Regulation in United States

In the United States, the Federal Food, Drug, and Cosmetic Act defines what requires a prescription. Prescription drugs are generally authorized by doctors, though physician assistants and nurse practitioners do an increasing amount of drug prescribing. It is generally required that an MD,DO,PA or NP write the prescription; nurses (other than nurse practitioners), emergency medical technicians, psychologists (but not psychiatrists, who are MDs), as examples, do not generally have the authority to prescribe drugs. Unlike many other countries, the United States does not have price controls for prescription drugs, and US drug prices are often perceived as inflated in comparison to other countries; therefore, most health insurance programs (generally partially or in full paid for by the patient's employer) have prescription payment plans where the patient pays only a small copayment and the pharmacy is reimbursed for the rest of the cost by the insurance company.

The safety and effectiveness of prescription drugs in the U.S. is regulated by the federal Prescription Drug Marketing Act of 1987.

Regulation in United Kingdom

In the United Kingdom, a patient visits a general practitioner who is able to prescribe medicines. If given an NHS prescription, this can be taken to a pharmacy to be dispensed. District nurses and health visitors have had limited prescribing rights since the mid-nineties where prescription for dressings and simple medicines would have had to have been signed by a doctor. Extended prescribing was introduced in late 1999, where appropriately trained nurses could prescribe from a limited list of POMs. From 2006, some nurses and pharmacists will be permitted to prescribe all medicines in the British National Formulary, except controlled drugs directly. Each item on the prescription is liable to a prescription charge of £6.65 (as of April 2006), although many patients are exempt from this charge. This includes those over 60, under 16, patients with certain medical conditions and those on certain benefits.

An HC2 ceftificate can be applied for if you are on a low income or on incapacity benefit.One bizarre element of the prescribing charges system in the UK is that if you are in reciept of "Incapacity benefit" (Due to illness)this does NOT automatically entitle you to free prescriptions.After completion of a lengthy in depth form (HC1),which means tests your ability to pay prescription charges,you may be awarded an HC2 certificate which entitles you to free prescriptons. An HC2 certificate is notoriously difficult to obtain,Why people who are on "Incapacity benefit" should pay prescription charges when they are unable to work due

to illness is a mystery.Claimants of "Jobseekers" and "Income support" automatically recieve free prescriptions and dentistry.

Those requiring regular prescriptions may make a saving by purchasing a pre-payment certificate which covers the cost of all prescriptions required for four months or a year. This charge is paid entirely to the NHS through the pharmacy, while the pharmacy claims the cost of the medicine dispensed. Each "item" can cover any prescribed item in a very large or very small quantity according to the doctor's prescription. This means that the patients perceived "value" of the charge varies enormously - the actual cost of the medicine given out will routinely vary from a few pence to hundreds of pounds.

The majority of items dispensed on NHS prescription are exempt from charges. This is because of the large number of medicines needed by, for example, the elderly or those with medical exemptions. NHS prescriptions can also be written for certain items by dentists and nurses. Some patients also receive private prescriptions, typically either from a doctor seen privately or for medicine not permitted on the NHS. For these, the patient will pay the pharmacy directly for the cost of the medicine and the pharmacy's markup.

The devolved legislature in Wales has decided to phase out prescription charges altogether; this process is expected to be completed during 2007. In January 2006, similar proposals were made by the health committee of the Scottish Parliament; however, these were rejected by Health Minister Andy Kerr on the grounds that "Executive policy remains that it is right that patients who can afford to should continue to contribute towards NHS dispensing costs".

Receptor antagonist

In medicine and biology, a *receptor antagonist* is a ligand that inhibits the function of an agonist and inverse agonist for a specific receptor.

Most drugs exert effects, both beneficial and detrimental, by interacting with specific receptors that are present on or within cells. Historically, receptors were thought to act much like light switches. Agonists were thought to turn "on" a single cellular response by binding to the receptor, thus initiating a biochemical mechanism for change within a cell. Antagonists were thought to turn "off" that response by 'blocking' the receptor from the agonist.

Recently, the discovery of inverse agonists and other concepts such as functional selectivity have blurred these definitions.

Today's current theories involving receptor antagonists center around an antagonist's ability to counteract the effects of agonists and inverse agonists (if one exists for the specific receptor). Antagonists work by binding to receptors and stopping cascades put in place by

an agonist. On their own, antagonists produce no effect by themselves to a cell, and are said to have zero intrinsic activity and zero efficacy.

There are three kinds of receptor antagonists:

- Antagonists that compete with an agonist for a binding site are competitive antagonists. They bind to the same receptor binding site as the agonist, thus competing for the same binding site. An example is the interleukin-1 receptor antagonist, IL-1Ra. High concentrations of agonist will displace the antagonist from the receptor.
- Antagonists that antagonize by other means are non-competitive antagonists. They bind to a different binding-site from the agonists, exerting their action to that receptor via the other binding site. Thus, they are called non-competitive antagonists because they do not compete for the same binding site as the agonists.
- Antagonists that bind covalently with the receptor binging site are irreversible antagonists. Unlike competitive antagonism, the covalent nature of the bond means the antagonist cannot be displaced by raising the concentration of the agonist.

Antagonists may be naturally occurring as is the case with *physiological antagonists*, or they may be synthetic and made to mimic the body's physiological antagonists. There are multiple antagonists for most receptors. A synthetic antagonist may compete with a physiological antagonist for binding sites upon receptors. Similarly, endogenous antagonists may also compete with one another. The antagonist which is bound is usually the one with the higher affinity for the receptor.

Tablet

A *tablet* is a mixture of active substances and binders, usually in powder form, pressed into a solid.

Medicines to be taken orally are very often supplied in tablet form; indeed the word tablet without qualification would be taken to refer to a medicinal tablet. Medicinal tablets are usually called pills. Other products are manufactured in the form of tablets which dissolve; e.g., for cleaning and deodorizing.

Medicinal tablets are usually intended to be swallowed, and are of a suitable size and shape. A coating may be applied to hide the taste of the tablet's components. Tablets for other purposes, e.g., effervescent medicinal tablets and non-medicinal tablets, may be larger.

Medicinal tablets were originally made in the shape of a disk of whatever colour their components determined, but are now made in many shapes and colours to help users to distinguish between different medicines that they take. Tablets are often stamped with symbols, letters, and numbers which enable them to be identified. Sizes of tablets to be

swallowed range from a few millimeters to about a centimeter. Some tablets are in the shape of capsules, and are called "caplets".

When Tylenol (paracetamol/acetaminophen) capsules were laced with cyanide (an incident referred to as the Tylenol scare), many people stopped buying capsules because they are easy to contaminate, in favor of tablets, which are not. Some makers of OTC (over-the-counter) drugs responded by starting to make what they termed "caplets", which were actually just tablets made in the shape of a capsule.

Tablets are often scored to allow them easily to be broken into equal halves for smaller doses.

Some people have difficulty swallowing tablets, this is called dysphagia. This is often caused by a gag reflex.

Tabletting formulations

In the tablet-pressing process, it is important that all ingredients be dry, powdered, and of uniform grain size as much as possible. Mixed grain sizes tend to separate out due to operational vibrations, resulting in inconsistent tableting, while any moisture in the system will tend to clog the tableting pathways.

Some substances may be tableted as pure substances, but this is usually not the case; most formulations include excipients. Normally, an inactive ingredient termed a binder is added to help hold the tablet together and give it strength. A wide variety of binders may be used, some common ones including lactose powder, sucrose powder, tapioca starch (cassava flour) and microcrystalline cellulose.

Often, an ingredient is also needed to act as an Disintegrant. This is an ingredient that dissolves readily in water to help the tablet disperse once swallowed. Some binders, such as starch, are also excellent disintegrants.

Small amounts of lubricants are usually added, as well. The most common of these are stearic acid (stearin) and magnesium stearate. These help the tablets, once pressed, to be more easily ejected from the die.

Tablet coating

Many tablets today are coated after being pressed. Although sugar-coating was popular in the past, the process has many drawbacks. Modern tablet coatings are polymer and polysaccharide based, with plasticizers and pigments included. Tablet coatings must be stable and strong enough to survive the handling of the tablet, must not make tablets stick together during the coating process, and must follow the fine contours of embossed characters or logos on tablets. Coatings can also facilitate printing on tablets, if required. Coatings are necessary for tablets that have an unpleasant taste, and a smoother finish makes large tablets easier to swallow. Tablet coatings are also useful to extend the shelf-life of components that are sensitive to moisture or oxidation. Opaque materials like titanium dioxide can protect light-sensitive actives from photodegradation. Special coatings (for example with pearlescent effects) can enhance brand recognition.

If the active ingredient of a tablet is sensitive to acid, or is irritant to the stomach lining, an enteric coating can be used, which is resistant to stomach acid and dissolves in the high

pH of the intestines. Enteric coatings are also used for medicines that can be negatively affected by taking a long time to reach the small intestine where they are absorbed. Coatings are often chosen to control the rate of dissolution of the drug in the gastro-intestinal tract. Some drugs will be absorbed better at different points in the digestive system. If the highest percentage of absorption of a drug takes place in the stomach, a coating that dissolves quickly and easily in acid will be selected. If the rate of absoprtion is best in the large intestine or colon, then a coating that is acid resistent and dissolves slowly would be used to ensure it reached that point before dispersing. The area of the Gastro-intestinal tract with the best absorption for any particluar drug is usually determined by clinical trials.

Tablet presses

Tablet presses, the machines that make the tablets, range from small, inexpensive bench-top models that make one tablet at a time, no more than a few thousand an hour, and with only around a half-ton pressure, to large, computerized, industrial models that can make hundreds of thousands of tablets an hour with much greater pressure. Some tablet presses can make extremely large tablets, such as some of the toilet cleaning and deodorizing products or dishwasher soap. Others can make smaller tablets, from regular aspirin to some the size of a bb gun pellet. Tablet presses may also be used to form tablets out of a wide variety of materials, from powdered metals to cookie crumbs. Currently the tablet press an important piece of machinery for any manufacturer who wishes to get into pharmaceutical manufacturing.

Pill-splitters

It is sometimes necessary to split pills into halves or quarters. Tablets are easier to break accurately if scored, but there are devices called pill-splitters which cut unscored (and, obviously, also scored) pills.

Medical prescription

A *medical prescription* is an order (often in written form) by a qualified health care professional to a pharmacist or other therapist for a treatment to be provided to their patient.

Format and definition

Prescriptions are typically handwritten on preprinted prescription forms that are assembled into pads, or alternatively printed onto similar forms using a computer printer. Preprinted on the form is text that identifies the document as a prescription, the name and address of the prescribing provider and any other legal requirement such as a registration number (e.g. DEA Number in the United States). Unique for each prescription is the name of the patient. In the United Kingdom the patient's name and address must also be recorded.

Each prescription is dated and some jurisdictions may place a time limit on the prescription. There is the specific "recipe" of the medication and the directions for taking it. Finally there is the doctor's signature.

The symbol "R***x***" meaning "prescription" is a transliteration of a symbol resembling a capital R with a cross on the diagonal ***()***.

There are various theories about the origin of this symbol - some note its similarity to the Eye of Horus, others to the ancient symbol for Jupiter, both gods whose protection may have been sought in medical contexts. Alternatively, it may be intended as an abbreviation of the Latin "recipe", the imperative form of "recipere", "to take", and it is quite possible that more than one of these factors influenced its form. Literally, "Recipe" means simply "Take...." and when a doctor writes a prescription beginning with "Rx", he or she is completing the command. This was probably originally directed at the pharmacist who needed to take a certain amount of each ingredient to compound the medicine, rather than at the patient who must "take" the medicine, in the sense of consuming it.

Incidentally, in an entirely unrelated context (communications), "Rx" is an abbreviation for "receiver" or "to receive" and, in the same context, "Tx" is an abbreviation for "transmitter" or "to transmit."

The word "prescription" can be decomposed into "pre" and "script" and literally means, "to write before" a drug can be prepared. Those within the industry will often call prescriptions simply "scripts".

Contents of the prescription

Both pharmacists and physicians are regulated professions in most jurisdictions. A prescription as a communications mechanism between them is also regulated and is a legal document. Regulations may define what constitutes a prescription, the contents and format of the prescription (including the size of the piece of paper - see Exhibit C paragraph 10) and how prescriptions are handled and stored by the pharmacist. Many jurisdictions will now allow faxed or phone prescriptions containing the same information. Exhibit A below illustrates the legal definition of a prescription.

Many brand name drugs have less expensive generic drug substitutes that are chemically equivalent. Prescriptions will also contain instructions on whether the prescriber will allow the pharmacist to substitute a generic version of the drug. This instruction is communicated in a number of ways. In some jurisdictions, the preprinted prescription contains two signature lines: one line has "dispense as written" printed underneath; the other line has "substitution permitted" underneath. Some have a preprinted box "dispense as written" for the prescriber to check off (but this is easily checked off by anyone with access to the prescription). Other jurisdictions the protocol is for the prescriber to handwrite one of the following phrases: "dispense as written", "DAW", "brand necessary", "do not substitute", "no substitution", "medically necessary", "do not interchange"

As a guideline, pediatric prescriptions should include the age of the child if the patient is less than twelve and the age and months if less than five. (In general, including the age on the prescription is helpful.) In some jurisdictions, it may be a legal requirement to include the age of child on the prescription. Adding the weight of the child is also helpful.

Prescriptions often have a "label" box. When checked, pharmacist is instructed to label the medication. When not checked, the patient only receives instructions for taking the medication and no information about the prescription itself.

Some prescribers further inform the patient and pharmacist by providing the indicator for the medication; i.e. what is being treated. This assists the pharmacist in checking for errors as many common medications can be used for multiple medical conditions.

Some prescriptions will specify whether and how many "repeats" or "refills" are allowed; that is whether the patient may obtain more of the same medication without getting a new prescription from the doctor. Regulations may restrict some types of drugs from being refilled.

In group practices, the preprinted portion of the prescription may contain multiple prescribers' names. Prescribers typically circle themselves to indicate who is prescribing or there may be a checkbox next to their name.

Handling of the prescription

When filled by a pharmacist, as a matter of business practice, the pharmacist may write certain information right on the prescription. This may also be mandated by legislation (see Exhibit D). Information such as the actual manufacturer of the drug and the date the medication was dispensed may be written right onto the prescription. Legislation may require the pharmacist sign the prescription. In computerized pharmacies, all such information is printed and stapled to the prescription. Sometimes such information is printed onto labels and the labels affixed right onto the prescription.

When filled by the pharmacist, prescriptions are typically assigned a "prescription number" (often abbreviated "Rx#") that is unique to the pharmacy that filled the prescription. The prescription number is written right on the prescription by the pharmacist. The prescription number has the practical purpose of uniquely identifying the prescription later on while filed (both manual and electronic). The prescription number is also put on the label on the dispensed medication. The patient may be required to reference the prescription number for refills and drug insurance claims. There may also be a legal requirement for prescription numbers for subsequent identification purposes.

As a legal document, some jurisdictions will mandate the archiving of the original paper prescription in the pharmacy. Often the patient cannot take the original prescription with them. Some jurisdictions may entitle patients to a copy. The retention period varies but can be as long as six years. See Exhibit B for sample legislation governing the archiving of prescriptions. Once the retention period has passed, privacy legislation may dictate what can be done with the original paper prescription. Legislation may also dictate what happens to the prescriptions if the pharmacy closes or is sold. For example, if the pharmacy goes out of business, the pharmacist may be required to return the prescription to the patient, to the next closest pharmacy or to the governing body for pharmacists.

Prescriptions for non-narcotic drugs may also be "transferred" from one pharmacy to another for subsequent repeats to be dispensed from another pharmacy. The physical piece of paper that is the prescription is not transferred, but all the information on it is transferred

from one pharmacy to another. Legislation may dictate the protocol by which the transfer occurs and whether the transfer needs to be noted on the original paper prescription.

It is estimated that 3 billion (3 thousand million) prescriptions were written in the United States in 2002. This number has grown from 1.5 billion in 1989 and is expected to continue to grow.

Forgeries, thefts and prevention

Prescriptions are sometimes forged because many narcotics are cheaper and safer as prescription drugs than as street drugs. Forgery takes many forms: Doctor's prescription pads are sometimes stolen, amounts may be altered on legitimate prescriptions, call back numbers may be falsified and phoned or faxed prescriptions faked

Some doctors will use prescription pads that contain similar security measures as checks to make photocopying prescriptions harder. These security measures may be mandated by law - see Exhibit C for sample legal specifications. Legislation may mandate that only certain printers may print prescriptions. New Jersey, for example, requires that only state approved printers may be used to print official "New Jersey Prescription Blanks." (See Exhibit E.) Prescribers can make it harder for amount forgeries by writing out the amounts in words. Again, this may be mandated by law

Some jurisdictions help control stolen prescriptions by requiring special "triplicate prescriptions" for certain classes of drug. Blank triplicates are only available from the regulating agency and are individually numbered. The doctor retains a copy, the second and third copies are given to the patient to give to the pharmacist. The pharmacist retains the second copy and the third copy is submitted to the regulating agency. The regulating agency can issue lists of stolen prescriptions that pharmacists can check. In this example, the prescription's validity is further limited to 72 hours from issuance. This system also has the further benefit of managing "double doctoring" where patients visit multiple doctors to get prescriptions.

States have various laws making theft of prescription blanks or forgery of prescriptions criminal offenses and/or providing special treatment for these offenses (for Example N.J. Stat. 2C:21-1. making forgery of a prescription blank a third degree rather than fourth degree offense)

When forgery is suspected, pharmacists will call the doctor to verify the prescription and will attempt to detain the suspect pending arrival of authorities. Forged prescriptions are no longer considered medical documents and doctor-patient confidentiality rules no longer apply.

Writing prescriptions

Who can write prescriptions

Who can issue prescriptions is governed by local legislation. In the United States, physicians, veterinarians, dentists, and podiatrists have full prescribing power. In all states, optometrists can prescribe medications to treat certain eye diseases, and will also issue

eyeglass prescriptions for corrective eyeglasses. [14] States allow mid-level practitioners different prescription privileges. Nurse practitioners (also known as advance practice nurses), physician assistants, optometrists, homeopathic physicians, naturopathic physicians, some registered pharmacists and doctors of oriental medicine currently represent the spectrum of mid-level practitioners. Each state regulates what (if any) prescription powers members of the above group are allowed. Advance practice nurses and physician assistants have some form of prescriptive authority in 49 states. But registered pharmacists, for example, have limited prescriptive authority in only 6 states..In some states, clinical psychologists (PhD's or PsyD's) who have also undergone specialized training in script-writing may prescribe a limited number of drugs to treat nervous and mental disorders.

Legibility of prescriptions

Prescriptions, when handwritten, are notorious for being often illegible (5% according to an Irish study). Contrary to popular belief, pharmacists do not have special deciphering skills. When in doubt, they call the doctor. At other times, even though some of the individual letters are illegible, the position of the legible letters and length of the word is sufficient to distinguish the medication based on the knowledge of the pharmacist. For doctors that the pharmacist deals with regularly, they learn to read the doctor's handwriting. Patients are advised to ensure that the prescription is legible before leaving the doctor's office. Some jurisdictions have made legible prescriptions a law (e.g. Florida). Some have advocated the elimination of handwritten prescriptions altogether and computer printed prescriptions are becoming increasingly common in some places.

Writing good prescriptions

Independent of the actual prescribing decision, elements of a good prescription writing include:

- careful use of decimal points to avoid ambiguity:
  - avoid unnecessary decimal points: 5 mL instead of 5.0 mL to avoid possible misinterpretation of 5.0=50
  - always zero prefix decimals: e.g. 0.5 instead of .5 to avoid misinterpretation with .5=5
  - never have trailing zeros on decimals: e.g. use 0.5 instead of .50 to avoid misinterpretation with .50=50
  - avoid decimals altogether by changing the units: 0.5 g =500 mg
- "mL" is used instead of "cc" or "cm^3" even though they are technically equivalent
- directions should be written out in full in English although some common Latin abbreviations are listed below
- quantities can be given directly or implied by the frequency & duration of the directions

- where the directions are "as needed" the quantity should always be specified
- where possible, usage directions should specify times (7 am, 3 pm, 11 pm) rather than simply frequency (3 times a day) and especially relationship to meals for orally consumed medication
- use permanent ink
- avoid prn "as needed" - limits & indicators should be specified e.g. "q 3h prn pain"
- for refills - minimum duration between repeats & number of repeats should be specified

Abbreviations

See Appendix 1 for a complete list of common abbreviations found on prescriptions. Many abbreviations are derived from Latin phrases. Hospital pharmacies have more abbreviations, some specific to the hospital. Different jurisdictions follow different conventions on what is abbreviated or not. Prescriptions that don't follow area conventions may be flagged as possible forgeries.

Some abbreviations which are ambiguous, or which in their written form might be confused with something else, are not recommended and should be avoided. These are included in a separate list in Appendix 1.

Non prescription drug prescriptions

Prescriptions are also used for things that are not strictly regulated as a prescription drug. Prescribers will often give non-prescription drugs out as prescriptions because drug benefit plans may reimburse the patient only if the over-the-counter medication is taken under the direction of a doctor. Conversely, if a medication is available over-the-counter, doctors may ask patients if they want it as a prescription and possibly incur a pharmacist's dispensing fee or whether they want to get it themselves at a lower price. If the patient wants the medication not under prescription, the prescriber is usually careful to give the medication name to the patient on a blank piece of paper to avoid any confusion with a prescription. This is applied to non-medications as well. For example, crutches, and registered massage therapy may be reimbursed under some health plans, but only if given out by a prescriber as a prescription.

Prescribers will often use blank prescriptions as general letterhead. A "doctor's note" for absent days from school or work for minor illnesses will often be written on a blank prescription.

Legislation may define certain equipment as "prescription devices". Such prescription devices can only be used under the supervision of authorized personnel and such authorization is typically documented using a prescription. Examples of prescription devices include dental cement (for affixing braces to tooth surfaces), various prothesis, gut sutures, sickle cell tests, cervical cap and ultrasound monitor.

In some jurisdictions, hypodermic syringes are in a special class of its own, regulated as illicit drug use accessories separate from regular medical legislation. Such legislation will often specify a prescription as the mean by which one may legally possess syringes.

Related usage of the term prescription

Prescription may also be used as a short form for prescription drugs to distinguish from over-the-counter drugs. It may also be used in reference to the entire system of controlling drug distribution (as opposed to illicit drugs). "Prescription" is often used as a metaphor for healthy directions from authority. A "green prescription" is direction from a doctor to a patient for exercise and healthy diet.

History

The concept of prescriptions date back to the beginning of history. So long as there were medications and a writing system to capture directions for preparation and usage, there were prescriptions

Modern prescriptions are actually "extemporaneous prescriptions" from the Latin (ex tempore) for "instant". "Extemporaneous" means the prescription is written on the spot for a specific patient with a specific ailment. This is distinguished from the a non-extemporaneous prescription which is a generic recipe for a general ailment. Modern prescriptions evolved with the separation of the role of the pharmacists from that of the physician. Today the term "extemporaneous prescriptions" is reserved for "compound prescriptions" which requires the pharmacist to mix or "compound" the medication in the pharmacy for the specific needs of the patient.

Predating modern legal definitions of a prescription, a prescription traditionally is composed of four parts: a "superscription", "inscription", "subscription" and "signature"

The superscription section contains the date of the prescription and patient information (name, address, age, etc). The symbol "Rx" separates the superscription from the inscriptions sections. In this arrangement of the prescription, the "Rx" is a symbol for recipe or literally "take thou". This is most likely an exhortation to the pharmacist by the doctor, "I want the patient to have the following medication". It should not be interpreted as instructions to the patient to "take thou" as patient instructions are in a later section. Some the literal exhortation to the pharmacist is "take thou this recipe".

The inscription section defines what is the medication. The inscription section is further composed of one or more of

- a "basis" or chief ingredient indended to cure (curare)
- an "adjuvant" to assist its action and make it cure quickly (cito)
- a "corrective" to prevent or lessen any undesirable effect (tuto)
- a "vehicle" or "excipient" to make it suitable for administration and pleasant to the patient (jucunde)

The "subscription" section contains dispensing directions to the pharmacist. This may be compounding instructions or quantities.

The "signature" section contains directions to the patient and is often abbreviated "Sig." or "Signa." It also obviously contains the signature of the prescribing doctor though the word "signature" has two distinct meanings here and the abbreviations are sometimes used to avoid confusion.

Thus sample prescriptions in modern textbooks are often presented as:

Rx: medication *Disp.:* dispensing instructions *Sig.:* patient instructions

Future directions of prescriptions

As a prescription is nothing more than information among a doctor, pharmacist and patient, information technology can be applied to it. Existing information technology is adequate to print out prescriptions. Medical information systems in some hospitals do away with prescriptions within the hospital. There are proposals to securely transmit the prescription from the doctor to the pharmacist using smartcards and the internet. In the UK a project called the Electronic Transfer of Prescriptions (ETP) within the National Programme for IT (NPfIT) is currently piloting such a scheme between doctors and pharmacies.

Within computerized pharmacies, the information on the piece of paper that is the prescription is captured immediately. Thereafter, the prescription is simply an entry within the pharmacy's information system and the paper prescription is stored for legal reasons only.

In cases where a pharmacy is part of a chain of pharmacies, the pharmacies are often linked together through their corporate headquarters with computer technology. Walgreens, for example, uses satellite technology to share patient information. A person who has a prescription filled at one Walgreens can get a refill of that prescription at any other store in the chain, as well as have their information available for new prescriptions at any Walgreens.

Some pharmacies also offer services to customers over the internet. Walgreens' web site, for example, allows customers to order refills for medicine over the internet, and allows them to specify the store that they will pick up the medicine from. Their web site also allows consumers to lookup their prescription history, and to print it out.

Pharmacy information systems are a potential source of valuable information for pharmaceutical companies as it contains information about doctor's prescribing habits. Prescription data mining of such data is a developing, specialized field.

Although computerized information systems offer attractive improvements to paper-based prescriptions, they are not yet available in many prescribers' practices. To reduce prescribing errors, some investigators have developed modified prescription forms that prompt the prescriber to provide all the desired elements of a good prescription. The modified forms also contain pre-defined choices such as common quantities, units and frequencies that the prescriber may circle rather than write out. Such forms are thought to reduce errors (especially omission and handwriting errors) and are actively under evaluation. (See: Kennedy AG, Littenberg B. A Modified Outpatient Prescription Form to Reduce Prescription Errors. Joint Commission Journal of Quality and Safety 2004; 30:480-487.)

Appendix 1: Partial list of abbreviations

This appendix is a list of some abbreviations used in prescriptions. Its listing here does not mean such abbreviations should be used. See main article for discussion on the use of abbreviations. This listing does not include abbreviations for actual pharmaceuticals (which is a separate article in itself). Capitalization and the use of a period is a matter of style. In the attached list, Latin is not capitalized whereas English acronyms are. The period is used wherever there are letters omitted in the abbreviation.

Partial list of prescription abbreviations

Abbreviation (Latin) Meaning

aa (ana) of each

ad (ad) up to

a.c. (ante cibum) before meals

a.d. (aurio dextra) right ear

ad lib. (ad libitum) use as much as one desires; freely

admov. (admove) apply

agit (agita) stir/shake

alt. h. (alternis horis) every other hour

a.m. (ante meridiem) morning, before noon

amp () ampule
amt () amount

aq (aqua) water

a.l., a.s. (aurio laeva, aurio sinister) left ear

A.T.C. () around the clock

a.u. (auris utrae) both ears

bis (bis) twice

b.i.d. (bis in die) twice daily

B.M. () bowel movement

bol. (bolus) as a large single dose (usually intravenously)

B.S. () blood sugar

B.S.A () body surface areas

cap., caps. (capsula) capsule

c (cum) with (usually written with a bar on top of the "c")
To avoid ambiguity, the following abbreviations are not recommended

- *a.u., a.s., a.d.* - Latin for both, left and right ears; the "a" can be misread to be an "o" and interpreted to mean both, right or left eyes
- *d/c* - can mean "discontinue" or "discharge"
- *h.s.* - can mean half strength or "hour of sleep"
- *q.d.* - meant "every day" but the "." after the "q" is interpreted to be an "i" thus "q.i.d." or quadrupling the dose to 4 times a day
- *q.o.d.* - meant "every other day" but the "o" can be interpreted as "." or "i" resulting in double or eight times the frequency
- *SC/SQ* - meant "subcutaneaous" but mistaken for "SL" for "sublingual"
- *T.I.W* - meant 3 times a week but mistaken for twice a week
- *U* - meant "units" but mistaken for "0", "4" or "cc" when poorly written; conversely *cc* can be mistaken for "U"
- *¼g* - meant "microgram" but mistaken for "mg"; this 1000-fold error can cause potentially fatal misunderstandings

Exhibit A: sample legal definition of a prescription

Taken from California's Business and Professions Code Section 4040

4040. (a) "Prescription" means an oral, written, or electronic transmission order that is both of the following: (1) Given individually for the person or persons for whom ordered that includes all of the following:
(A) The name or names and address of the patient or patients.
(B) The name and quantity of the drug or device prescribed and the directions for use.
(C) The date of issue.
(D) Either rubber stamped, typed, or printed by hand or typeset, the name, address, and telephone number of the prescriber, his or her license classification, and his or her federal registry number, if a controlled substance is prescribed.
(E) A legible, clear notice of the condition for which the drug is being prescribed, if requested by the patient or patients.
(F) If in writing, signed by the prescriber issuing the order, or the certified nurse-midwife, nurse practitioner, or physician assistant who issues a drug order pursuant to Section 2746.51,2836.1, or 3502.1.

(2) Issued by a physician, dentist, optometrist, podiatrist, or veterinarian or, if a drug order is issued pursuant to Section 2746.51, 2836.1, or 3502.1, by a certified nurse-midwife, nurse practitioner, or physician assistant licensed in this state.
(b) Notwithstanding subdivision (a), a written order of the prescriber for a dangerous drug, except for any Schedule II controlled substance, that contains at least the name and signature of the prescriber, the name and address of the patient in a manner consistent with paragraph (3) of subdivision (b) of Section 11164 of the Health and Safety Code, the name and quantity of the drug prescribed, directions for use, and the date of issue may be treated as a prescription by the dispensing pharmacist as long as any additional information required by subdivision (a) is readily retrievable in the pharmacy. In the event of a conflict between this subdivision and Section 11164 of the Health and Safety Code, Section 11164 of the Health and Safety Code shall prevail.
(c) "Electronic transmission prescription" includes both image and data prescriptions. "Electronic image transmission prescription" means any prescription order for which a facsimile of the order is received by a pharmacy from a licensed prescriber. "Electronic data transmission prescription" means any prescription order, other than an electronic image transmission prescription, that is electronically transmitted from a licensed prescriber to a pharmacy.
(d) The use of commonly used abbreviations shall not invalidate an otherwise valid prescription.
(e) Nothing in the amendments made to this section (formerly Section 4036) at the 1969 Regular Session of the Legislature shall be construed as expanding or limiting the right that a chiropractor, while acting within the scope of his or her license, may have to prescribe a device.

Exhibit B: sample legal requirement for storage of prescriptions

From the Mississippi Board of Pharmacy

ARTICLE XIII PRESCRIPTIONS TO BE FILED
1. All prescriptions shall be filed in one of the following ways:
A. Three separate files may be maintained; a file for Schedule II prescriptions dispensed; a file for Schedule III, IV and V prescriptions dispensed; and a file for all other prescriptions dispensed.
B. Two files may be maintained; a file for all Schedule II prescriptions dispensed and another file for all other prescriptions dispensed, including those in Schedule III, IV and V. If this method is used, the prescriptions for Schedule III, IV and V substances must be stamped with the letter "C" in red ink, not less than one inch high, in the lower right-hand corner. This distinctive marking makes the records readily retrievable for inspection. Pharmacies with automatic data processing systems are exempted from marking Schedule III, IV and V controlled substance prescriptions with the red "C".
2. A hard copy of original prescriptions, whether records are maintained manually or in a data processing system, shall be assigned a serial number and maintained by the pharmacy in numerical and chronological order. All prescriptions shall be maintained for at least five years from the date of original dispensing.

3. If a pharmacy utilizes a data processing system for record keeping, all computer generated labels should be affixed to the prescription document in such a manner as not to obscure information on the face of the document.

Exhibit C: sample legal requirements for security and format

From Indiana Board of Pharmacy

856 IAC 1-34-2 Security feature requirements
Authority: IC 35-48-7-8
Affected: IC 16-42-19-5

Sec. 2. (a) All controlled substance prescriptions written by licensed Indiana practitioners, as defined by IC 16-42-19-5, must contain the following security features: (1) A latent, repetitive "void" pattern screened at five percent (5%) in reflex blue must appear across the entire face of the document when the prescription is photocopied. (2) There shall be a custom artificial watermark printed on the back side of the base paper so that it may only be seen at a forty-five (45) degree angle. The watermark shall consist of the words "Indiana Security Prescription", appearing horizontally in a step-and-repeated format in five (5) lines on the back of the document using 12-point Helvetica bold type style. (3) An opaque RX symbol must appear in the upper right-hand corner, one-eighth (c) of an inch from the top of the pad and five-sixteenths (5 /16) of an inch from the right side of the pad. The symbol must be three-fourths (3/4) inch in size and must disappear if the prescription copy is lightened. (4) Six (6) quantity check-off boxes must be printed on the form and the following quantities must appear and the appropriate box be checked off for the prescription to be valid: (A) 1-24 (B) 25-49 (C) 50-74 (D) 75-100 (E) 101-150 (F) 151 and over. (5) No advertisements may appear on the front or back of the prescription blank. (6) Logos, defined as a symbol utilized by an individual, professional practice, professional association, or hospital, may appear on the prescription blank. The upper left one (1) inch square of the prescription blank is reserved for the purpose of logos. Only logos, as defined by this subdivision, may appear on the prescription blank. (7) Only one (1) prescription may be written per prescription blank. The following statement must be printed on the bottom of the pad: "Prescription is void if more than one (1) prescription is written per blank.". (8) Refill options that can be circled by the prescriber must appear below any logos and above the signature lines on the left side of the prescription blank in the following order: Refill NR 1 2 3 4 5 Void after_____. (9) Practitioner name and state issued professional license number must be preprinted, stamped, or manually printed on the prescription. (10) All prescription blanks printed under this rule shall be four and one-fourth (4-1/4) inches high and five and one-half (5-1/2) inches wide. (b) Nothing in this rule shall prevent licensed Indiana practitioners from utilizing security paper prescriptions for the prescribing of any legend drug. (Indiana Board of Pharmacy; 856 IAC 1-34-2; filed Jul 5, 1995, 9:45 a.m.: 18 IR 2782, eff Jan 1, 1996)

Exhibit D: sample requirements on information added by the pharmacist

Taken from the Ontario's Drug and Pharmacies Regulation Act, paragraph 156.

(1) Every person who dispenses a drug pursuant to a prescription shall ensure that the following information is recorded on the prescription, (a) the name and address of the

person for whom the drug is prescribed; (b) the name, strength (where applicable) and quantity of the prescribed drug; (c) the directions for use, as prescribed; (d) the name and address of the prescriber; (e) the identity of the manufacturer of the drug dispensed; (f) an identification number or other designation; (g) the signature of the person dispensing the drug and, where different, also the signature of the person receiving a verbal prescription; (h) the date on which the drug is dispensed; (i) the price charged. R.S.O. 1990, c. H.4, s. 156 (1).

Exhibit E: New Jersey requirements for prescription blanks

From New Jersey official statutes

45:14-55 Use of New Jersey Prescription Blanks. 16. a. A practitioner practicing in this State shall use non-reproducible, non-erasable safety paper New Jersey Prescription Blanks bearing that practitioner's license number whenever the practitioner issues prescriptions for controlled dangerous substances, prescription legend drugs or other prescription items. The prescription blanks shall be secured from a vendor approved by the Division of Consumer Affairs in the Department of Law and Public Safety. b. A licensed practitioner practicing in this State shall maintain a record of the receipt of New Jersey Prescription Blanks. The practitioner shall notify the Office of Drug Control in the Division of Consumer Affairs as soon as possible but no later than 72 hours of being made aware that any New Jersey Prescription Blank in the practitioner's possession has been stolen. Upon receipt of notification, the Office of Drug Control shall take appropriate action, including notification to the Department of Human Services and the Attorney General. 45:14-56 Health care facility prescriptions. 17. a. Prescriptions issued by a health care facility licensed pursuant to P.L.1971, c.136 (C.26:2H-1 et seq.) shall be written on non-reproducible, non-erasable safety paper New Jersey Prescription Blanks. The prescription blanks shall be secured from a vendor approved by the Division of Consumer Affairs in the Department of Law and Public Safety. The New Jersey Prescription Blanks shall bear the unique provider number assigned to that health care facility for the issuing of prescriptions for controlled dangerous substances, prescription legend drugs or other prescription items. b. A health care facility shall maintain a record of the receipt of New Jersey Prescription Blanks. The health care facility shall notify the Office of Drug Control in the Division of Consumer Affairs as soon as possible but no later than 72 hours of being made aware that any New Jersey Prescription Blank in the facility's possession has been stolen. Upon receipt of notification, the Office of Drug Control shall take appropriate action including notification to the Department of Human Services and the Attorney General. 45:14-57 Requirements for prescription to be filled. 18.A prescription issued by a practitioner or health care facility licensed in New Jersey shall not be filled by a pharmacist unless the prescription is issued on a New Jersey Prescription Blank bearing the practitioner's license number or the unique provider number assigned to a health care facility. 45:14-59 Format for New Jersey Prescription Blanks. 20.The Division of Consumer Affairs in the Department of Law and Public Safety shall establish the format for uniform, non-reproducible, non-erasable safety paper prescription blanks, to be known as New Jersey Prescription Blanks, which format shall include an identifiable logo or symbol that will appear on all prescription blanks. The division shall

approve a sufficient number of vendors to ensure production of an adequate supply of New Jersey Prescription Blanks for practitioners and health care facilities statewide.

Medication

A *medication* is a licenced drug taken to cure or reduce symptoms of an illness or medical condition. Medications are generally divided into two groups by the United States and similar laws -- Over-the-counter drug (OTC) medications, which are available in pharmacies and supermarkets without special restrictions, and Prescription only medicines (POM), which must be prescribed by a physician, physician assistant, nurse practitioner, or dentist. The International Narcotics Control Board of the United Nations imposes a world law of prohibition or censorship of certain medications. They publish a lengthy list of chemicals and plants whose trade and consumption (where applicable) is forbidden. Most OTC medication is generally considered to be safe enough that most persons will not hurt themselves accidentally by taking it as instructed. Many countries, such as the UK have a third category of pharmacy medicines which can only be sold in registered pharmacies, by or under the supervision of a pharmacist. However, the precise distinction between OTC and prescription depends on the legal jurisdiction. Medications are typically produced by pharmaceutical companies and are often patented. Those that are not patented are called generic drugs.

Classification

Medication can be usually classified in various ways, e.g. by its chemical properties, mode of administration, or biological system affected. An elaborate and widely used classification system is the Anatomical Therapeutic Chemical Classification System.

Types of medication

For the gastrointestinal tract or digestive system

- Upper digestive tract: antacids, reflux suppressants, antiflatulents, antidopaminergics, proton pump inhibitors, H2-receptor antagonists, cytoprotectants, prostaglandin analogues
- Lower digestive tract: laxatives, antispasmodics, antidiarrhoeals, bile acid sequestrants, opioids

For the cardiovascular system

- General: beta-receptor blocker, calcium channel blockers, diuretics, cardiac glycosides, antiarrhythmics, nitrate, antianginals, vasoconstrictor, vasodilator, peripheral activator

- **Affecting** Blood pressure**:** ACE inhibitors**,** angiotensin receptor blockers**,** alpha blocker

- Coagulation: anticoagulant, heparin, antiplatelet drug, fibrinolytic, anti-hemophilic factor, haemostatic drugs
- Atherosclerosis/cholesterol agents: hypolipidaemic agents, statins.

For the central nervous system

See also: Psychoactive drug

hypnotic, **anaesthetics**, **antipsychotic**, **antidepressant** (including tricyclic antidepressants, **monoamine oxidase inhibitor**, lithium salt, **selective serotonin reuptake inhibitor**), **anti-emetic**, **anticonvulsant** and antiepileptic, **anxiolytic**, **barbiturate**, movement disorder drug, **stimulant** (including Amphetamine), **benzodiazepine**, cyclopyrrolone, dopamine antagonist, **antihistamine**, cholinergic, **anticholinergic**, emetic, **cannabinoids**, 5-HT antagonist

For pain & consciousness (analgesic drugs)

Further information: Analgesic

The main classes of painkillers are NSAIDs, opioids and various orphans such as paracetamol, tricyclic antidepressants and anticonvulsants.

For musculo-skeletal disorders

NSAIDs (including COX-2 selective inhibitors), muscle relaxant, neuromuscular drug anticholinesterase

For the eye

- General: adrenergic neurone blocker, astringent, ocular lubricant
- Diagnostic: topical anesthetics, sympathomimetics, parasympatholytics, mydriatics, cycloplegics
- Anti-bacterial: antibiotics, topical antibiotics, sulfa drugs, aminoglycosides, fluoroquinolones
- Anti-viral:
- Anti-fungal: imidazoles, polyenes
- Anti-inflammatory: NSAIDs, corticosteroids

- Anti-allergy: mast cell inhibitors
- Anti-glaucoma: adrenergic agonists, beta-blockers, carbonic anhydrase inhibitors/hyperosmotics, cholinergics, miotics, parasympathomimetics, prostaglandin agonists/prostaglandin inhibitors. nitroglycerin

For the ear, nose and oropharynx

sympathomimetic, **antihistamine**, **anticholinergic**, NSAIDs, steroid, **antiseptic**, **local anesthetic**, **antifungal**, cerumenolytic

For the respiratory system

bronchodilator, NSAIDs, anti-allergic, antitussive, mucolytic, decongestant corticosteroid, beta-receptor antagonist, anticholinergic, steroid

For endocrine problems

androgen, antiandrogen, gonadotropin, corticosteroid, growth hormone, insulin, antidiabetic (sulfonylurea, biguanide/metformin, thiazolidinedione, insulin), thyroid hormones, antithyroid drugs, calcitonin, diphosponate, vasopressin analogues

For the reproductive system or urinary system

antifungal, alkalising agent, quinolones, antibiotic, cholinergic, anticholinergic, anticholinesterase, antispasmodic, 5-alpha reductase inhibitor, selective alpha-1 blocker, sildenafil

For contraception

contraceptive, oral contraceptives, spermicide, depot contraceptives

For obstetrics and gynaecology

NSAIDs, anticholinergic, haemostatic drug, antifibrinolytic, Hormone Replacement Therapy, bone regulator, beta-receptor agonist, follicle stimulating hormone, luteinising hormone, LHRH gamolenic acid, gonadotropin release inhibitor, progestogen, dopamine agonist, oestrogen, prostaglandin, gonadorelin, clomiphene, Tamoxifen, Diethylstilbestrol

For the skin

emollient, anti-pruritic, antifungal, disinfectant, scabicide, pediculicide, tar products, vitamin A derivatives, vitamin D analogue, keratolytic, abrasive, systemic antibiotic, topical

antibiotic, hormones, desloughing agent, exudate absorbent, fibrinolytic, proteolytic, sunscreen, antiperspirant, corticosteroid

For infections and infestations

antibiotic, antifungal, antileprotic, antituberculous drug, antimalarial, anthelmintic, amoebicide, antiviral, antiprotozoal, antiserum

For immunology

vaccine, immunoglobulin, immunosuppressant, interferon, monoclonal antibody

For allergic disorders

anti-allergic, antihistamine, NSAIDs

For nutrition

tonic, iron preparation, electrolyte, parenteral nutritional supplement, vitamins, anti-obesity drug, anabolic drug, haematopoietic drug, food product drug

For neoplastic disorders

cytotoxic drug, sex hormones, aromatase inhibitor, somatostatin inhibitor, recombinant interleukins, G-CSF, erythropoietin

For diagnostics

contrast media

For euthanasia

A euthanaticum is used for euthanasia and physician-assisted suicide, see also barbiturates.

Other/related topics

Polypharmacy: suggests that multiple use of prescribed and non-prescribed medications, (use of 5 or more), can have adverse effects on the recipient.

Zoopharmacognosy: Animal usage of drugs and non-foods.

Phosphate binders

Phosphate binders are a group of medications used to reduce the absorption of phosphate and taken with meals and snacks. They are typically used in patients with chronic renal failure (CRF) as they cannot get rid of the phosphate that gets into their blood (i.e. the serum phosphate in chronic renal failure is typically elevated).

Clinical use

For patients with chronic renal failure, controlling serum phosphate is important because it is associated with bone pathology and regulated together with serum calcium by the parathyroid hormone (PTH). High (serum) phosphate levels (known as hyperphosphatemia) normally results in an elevation of the PTH level, which then leads to more phosphate excretion into the urine.[1] If the kidneys do not function properly the phosphate level increases. Also, the serum calcium levels tend to be low. This is because the kidneys in chronic renal failure do not produce the active form of vitamin D (1,25-dihydroxycholecalciferol), which is important for calcium absorption from food. Low serum calcium levels, like high phosphate, also lead to a high PTH.

A high PTH leads to a large mobilization of calcium from the bone and, if it is not replaced, bone is lost. Bone loss and damage due to CRF is called renal osteodystrophy. To avoid a high PTH and bone loss in patients with CRF, CRF patients typically avoid high phosphate intake and take calcium supplements, vitamin D and phosphate binders.

Mechanism of action

These agents work by binding to phosphate in the GI tract, thereby making it unavailable to the body for absorption. Hence, these drugs are usually taken with meals to bind any phosphate that may be present in the ingested food. Phosphate binders may be simple molecular entities (such as aluminum, calcium, or lanthanum salts) that react with phosphate and form an insoluble compound. Phosphate binders, such as sevelamer, may also be polymeric structures which bind to phosphate and are then excreted.

Adverse effects

With regard to phosphate binders, aluminum-containing compounds (such as aluminum hydroxide) are the least preferred because prolonged aluminum intake can cause encephalopathy and osteomalacia. If calcium is already being used as a supplement, additional calcium used as a phosphate binder may cause hypercalcemia and tissue-damaging calcinosis. One may avoid these adverse effects by using phosphate binders that do not contain calcium or aluminum as active ingredients, such as lanthanum carbonate or sevelamer.

Common phosphate binders

- Aluminum hydroxide (Alucaps®)
- Calcium carbonate (Calcichew®, Titralac®)
- Calcium acetate (Phosex®) Lanthanum carbonate (Fosrenol®) Sevelamer (Renagel®)

Calcium carbonate

Systematic name Calcium carbonate

Other names Limestone, calcite, aragonite, chalk, marble

Molecular formula $CaCO_3$

Molar mass 100.087 g/mol

Appearance White powder.
CAS number [471-34-1]

Properties

Density and phase 2.83 g/cm^3, solid.

Solubility in water Insoluble

Melting point 825°C (1098 K)

Boiling point Decomposes

Thermochemistry

”$_f$H$^0_{liquid}$ -1154 kJ/mol

”$_f$H$^0_{solid}$ -1207 kJ/mol
S$^0_{solid}$ 93 J/mol·K

Structure

Molecular shape Linear

Coordination geometry Tetrahedral

Related compounds Calcium oxide

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

Calcium carbonate is a chemical compound, with chemical formula $CaCO_3$. It is commonly used medicinally as a calcium supplement or as an antacid. Calcium carbonate is the active ingredient in agricultural lime. It is a common substance found as rock in all parts of the world and is the main component of seashells and the shell of snails. It is usually the principal cause of hard water.

Occurrence

Calcium carbonate is found naturally as the following minerals and rocks:

- Aragonite
- Calcite
- Chalk
- Limestone
- Marble
- Travertine

Eggshells are composed of approximately 95% calcium carbonate.

To test whether a mineral or rock contains calcium carbonate, strong acids, like hydrochloric acid, can be dropped with a dropper onto it. If it does contain the chemical, it will fizz and produce carbon dioxide; otherwise, it probably wouldn't react vigorously. For example, all of the rocks/mineral mentioned above will react with acid.

Preparation

The vast majority of calcium carbonate used in industry is extracted by mining or quarrying. Pure calcium carbonate (e.g. for food or pharmaceutical use), can be produced from a pure quarried source (usually marble) or it can be prepared by passing carbon dioxide into a solution of calcium hydroxide: the calcium carbonate precipitates out, and this grade of product is referred to as a precipitate (abbreviated to PCC).

$Ca(OH)_2 + CO_2 \rightarrow CaCO_3 + H_2O$

Chemical properties

Calcium carbonate shares the typical properties of other carbonates. Notably:

1. it reacts with strong acids, releasing carbon dioxide:
   $CaCO_3 + 2HCl \rightarrow CaCl_2 + CO_2 + H_2O$
2. it releases carbon dioxide on heating (to above 825 °C in the case of $CaCO_3$), to form calcium oxide, commonly called burnt lime:
   $CaCO_3 \rightarrow CaO + CO_2$

Calcium carbonate will react with water that is saturated with carbon dioxide to form the soluble calcium bicarbonate.

$CaCO_3 + CO_2 + H_2O \rightarrow Ca(HCO_3)_2$

This reaction is important in the erosion of carbonate rocks, forming caverns, and leads to hard water in many regions.

Uses

The main use of calcium carbonate is in the construction industry, either as a building material in its own right (e.g. marble) or limestone aggregate for roadbuilding or as an ingredient of cement or as the starting material for the preparation of builder's lime by burning in a kiln . A common contaminate is magnesium carbonate.

Calcium carbonate is widely used as an extender in paints, in particular matte emulsion paint where typically 30% by weight of the paint is either chalk or marble.

Calcium carbonate is also widely used as a filler in plastics. Some typical examples include around 15 to 20% loading of chalk in uPVC drain pipe, 5 to 15% loading of stearate coated chalk or marble in uPVC window profile. Fine ground calcium carbonate is an essential ingredient in the microporous film used in babies nappies and some building films as the pores are nucleated around the calcium carbonate particles during the manufacture of the film by biaxial stretching.

Calcium carbonate is also used in a wide range of trade and DIY adhesives, sealants and decorating fillers. Ceramic tile adhesives typically contain 70 to 80% limestone. Decorating crack fillers contain similar levels of marble or dolomite. It is also mixed with putty in setting Stained glass windows, and as a resist to prevent glass from sticking to kiln shelves when firing glazes and paints at high temperature.

Calcium carbonate is widely used medicinally as an inexpensive dietary calcium supplement,[1] antacid, and/or phosphate binder. It is also used in the pharmaceutical industry as a base material for tablets of other pharmaceuticals.

Calcium carbonate is known as whiting in ceramics/glazing applications, where it is used as a common ingredient for many glazes in its white powdered form. When a glaze containing this material is fired in a kiln, the whiting acts as a flux material in the glaze.

It is commonly called chalk as it has been a major component of blackboard chalk. Chalk may consist of either calcium carbonate or gypsum, hydrated calcium sulfate $CaSO_4 \cdot 2H_2O$.

In North America, calcium carbonate has begun to replace kaolin in the production of glossy paper. Europe has been practicing this as alkaline papermaking or acid-free papermaking for some decades. Carbonates are available in forms: ground calcium carbonate (GCC) or precipitated calcium carbonate (PCC). The latter has a very fine and controlled particle size, on the order of 2 micron in diameter, useful in coatings for paper.

As a food additive, it is used in some soy milk products as a source of dietary calcium.

In 1989, Dr. Simmons introduced $CaCO_3$ into the Whetstone Brook in Massachusetts. His hope was that the calcium carbonate would counter the acid in the stream from acid rain and save the trout that had ceased to spawn. Although his experiment was a success, it did increase the amounts of aluminum ions in the area of the brook that was not treated with the limestone. This shows that $CaCO_3$ can be added to neutralize the effects of acid rain in river ecosystems. Nowadays, calcium carbonate is used to neutralise acidic conditions in both soil and water.

Calcination Equilibrium

Equilibrium Pressure of CO_2 over $CaCO_3$	
550 °C	0.055 kPa
587 °C	0.13 kPa
605 °C	0.31 kPa
680 °C	1.80 kPa
727 °C	5.9 kPa
748 °C	9.3 kPa
777 °C	14 kPa
800 °C	24 kPa
830 °C	34 kPa
852 °C	51 kPa
871 °C	72 kPa
881 °C	80 kPa
891 °C	91 kPa
898 °C	101 kPa
937 °C	179 kPa
1082 °C	901 kPa
1241 °C	3961 kPa

Calcination of limestone using charcoal fires to produce quicklime has been practiced since antiquity by cultures all over the world. The answer to the question, "how hot does the fire have to be?" is usually given as 825 °C, but stating an absolute threshold is misleading. Calcium carbonate exists in equilibrium with calcium oxide and carbon dioxide at any temperature. At each temperature there is a partial pressure of carbon dioxide that is in equilibrium with calcium carbonate. At room temperature the equilibrium overwhelmingly favors calcium carbonate, because the equilibrium CO***2*** pressure is only a tiny fraction of the partial CO***2*** pressure in air, which is about 0.035 kPa. At temperatures above 550 °C the equilibrium CO2 pressure begins to exceed the CO2 pressure in air. So above 550 °C, calcium

carbonate begins to outgas CO2 into air. But in a charcoal fired kiln, the concentration of CO2 will be much higher than it is in air. Indeed if all the oxygen in the kiln is consumed in the fire, then the partial pressure of CO2 in the kiln can be as high as 20 kPa. The table shows that this equilibrium pressure is not achieved until the temperature is nearly 800 °C. For the outgassing of CO2 from calcium carbonate to happen at an economically useful rate, the equilibrium pressure must significantly exceed the ambient pressure of CO2. And for it to happen rapidly, the equilibrium pressure must exceed total atmospheric pressure of 101 kPa, which happens at 898 °C.

Solubility of calcium carbonate in water

Calcium carbonate is poorly soluble in water.

Calcium Ion Solubility as a function of CO_2 partial pressure at 25 °C		
P_{CO2} (atm)	pH	$[Ca^{2+}]$ (mol/L)
10^{-12}	12.0	5.19×10^{-3}
10^{-10}	11.3	1.12×10^{-3}
10^{-8}	10.7	2.55×10^{-4}
10^{-6}	9.83	1.20×10^{-4}
10^{-4}	8.62	3.16×10^{-4}
3.5×10^{-4}	**8.27**	**4.70×10^{-4}**
10^{-3}	7.96	6.62×10^{-4}
10^{-2}	7.30	1.42×10^{-3}
10^{-1}	6.63	3.05×10^{-3}
1	5.96	6.58×10^{-3}
10	5.30	1.42×10^{-2}

The table on the right shows the result for [Ca^{2+}] and [H^{+}] (in the form of pH) as a function of ambient partial pressure of CO_2. At atmospheric levels of ambient CO_2 the table indicates the solution will be slightly alkaline. The trends the table shows are

1) As ambient CO_2 partial pressure is reduced below atmospheric levels, the solution becomes more and more alkaline. At extremly low P_{CO_2}, dissolved CO_2, bicarbonate ion, and carbonate ion largely evaporate from the solution, leaving a highly alkaline solution of calcium hydroxide, which is more soluble than $CaCO_3$. 2) As ambient CO_2 partial pressure increases to levels above atmospheric, pH drops, and much of the carbonate ion is converted to bicarbonate ion, which results in higher solubility of Ca^{2+}.

The effect of the latter is especially evident in day to day life of people who have hard water. Water in aquifers underground can be exposed to levels of CO2 much higher than atmospheric. As such water percolates through calcium carbonate rock, the CaCO3 dissolves according to the second trend. When that same water then water emerges from the tap, in time it comes into equilibrium with CO2 levels in the air by outgassing its excess CO2. The calcium carbonate becomes less soluble as a result and the excess precipitates as lime scale. This same process is responsible for the formation of stalactites and stalagmites in limestone caves.

Psychoactive drugs

A *psychoactive drug* or *psychotropic substance* is a chemical substance that acts primarily upon the central nervous system where it alters brain function, resulting in temporary changes in perception, mood, consciousness and behavior.

These drugs may be used recreationally to purposefully alter one's consciousness (such as coffee, alcohol or cannabis), as entheogens for spiritual purposes (such as the mescaline-containing peyote cactus or psilocybin-containing mushrooms), and also as medication (such as the use of narcotics in controlling pain, stimulants to treat narcolepsy and attention disorders, as well as anti-depressants and anti-psychotics for treating neurological and psychiatric illnesses).

Many of these substances (especially the stimulants and depressants) can be habit-forming, causing chemical dependency and may lead to substance abuse. Conversely, others (namely the psychedelics) can help to treat and even cure such addictions.

A brief history of drug use

Drug use is not a new phenomenon by any means. There is archaeological evidence of the use of psychoactive substances dating back at least 10,000 years, and historical evidence of cultural use over the past 5,000 years.[4]

While medicinal use plays a very large role, it has been suggested that the urge to alter one's consciousness is as primary as the drive to satiate thirst, hunger or sexual desire.[5]

Some may point a finger to marketing, availability or the pressures of modern life as to why humans use so many psychoactives in their daily lives, but one only has to look back at history, or even to children with their desire for spinning, swinging, sliding amongst other activities to see that the drive to alter one's state of mind is universal.[6]

This relationship is not limited to humans. A surprising number of animals consume different psychoactive plants and animals, berries and even fermented fruit, clearly becoming intoxicated. Traditional legends of sacred plants often contain references to animals that introduced humankind to their use.[7]

Biology suggests an evolutionary connection between psychoactive plants and animals, as to why these chemicals and their receptors exist within the nervous system.[8]

The 20th century has seen governments initially responding to many drugs by banning them and making their use, supply or trade a criminal offence. During the Prohibition era in America, alcohol had this approach used for 13-ish years. However, globalization has made many governments realize that the use of illicit drugs can no longer truly be eradicated. In many countries, there has been a move toward harm reduction by health services, where the use of illicit drugs is neither condoned nor promoted, but services and support are provided to ensure users have the negative effects of their illicit drug use minimised. This often goes hand-in-hand with supply reduction strategies by law enforcement agencies.

Other psychoactive drugs

- Aphrodisiacs
  - Bremelanotide
- In a broader sense also:
  - Antiemetics
  - Analgesics
  - Antiepileptics

Ways psychoactive drugs affect the brain

There are many ways in which psychoactive drugs can affect the brain. While some drugs affect neurons presynaptically, others act postsynaptically and some drugs don't even affect the synapse, working on neural axons instead. Here is a general breakdown of the ways psychoactive drugs can work.

1. Prevent The Action Potential From Starting
   - Lidocaine, TTX (they bind to voltage-gated sodium channels, so no action potential begins even when a generator potential passes threshold)
2. Neurotransmitter Synthesis
   - Increase - L-Dopa, tryptophan, choline (precursors)
   - Decrease - PCPA (inhibits synthesis of 5HT)
   - Causes increased sensitivity to the five senses, due to an increasing number of signals being sent to the brain.
3. Neurotransmitter Packaging
   - Increase - MAO Inhibitors
   - Decrease - Reserpine (pokes holes in the synaptic vesicles of catecholamines)
4. Neurotransmitter Release
   - Increase - Black Widow Spider venom (ACh)
   - Decrease - Botulinum Toxin (ACh), Tetanus (GABA)
5. Agonists - Mimic the original neurotransmitters and activate the receptors
   - Muscarine, Nicotine **(ACh)**
   - AMDA, NMDA (Glu)
   - Alcohol, Benzodiazepines (GABA)
6. Antagonists - Bind to the receptor sites and block activation
   - Atropine, Curare **(ACh)**
   - PCP (Glu)

- Caffeine **(**adenosine**)**

7. Prevent ACh Breakdown

- Insecticides**, Nerve Gas**

8. Prevent Reuptake

- Cocaine **(**DA**),**
    - Tricyclics, SSRIs (5-HT, NE)

- based on information taught in NSC 201, Vanderbilt University

Philosophy and morality of psychoactive drugs

For thousands of years, people have studied psychoactive drugs, both by observation and ingestion. However, humanity remains bitterly divided regarding psychoactive drugs, and their value and use has long been an issue of major philosophical and moral contention, even to the point of war (the Opium Wars being a prime example of a war being fought over psychoactives). A majority of youths and adults consume one or more psychoactive drugs. In the West, the most common by numbers of users are caffeine, alcohol, and nicotine, in that order. Most people accept restrictions on some and the prohibition of others, especially the "hard" drugs, which are generally illegal in most countries.[9][10][11]

Because so many consumers want to reduce or eliminate their own use[12], many professionals, self-help groups, and businesses specialize in that field, with varying degrees of success. Many parents attempt to influence the actions and choices of their children regarding psychoactives.

Debate continues over whether each psychoactive drug being considered is or is not spiritual, sinful, therapeutic, poisonous, ethical, immoral, effective, risky, responsible, recreational, a weapon to use against enemies, a boost to the economy, etc. These attitudes can often be deeply rooted in philosophical and/or religious beliefs, making it difficult to reach consensus or agreement on the proper moral and philosophical stance regarding psychoactive drugs. A major point of contention regards the role of government, whether it should, with respect to each drug, remain neutral, make use safer, educate for abstention, educate for moderation, regulate trade, require a prescription, restrict promotion, prohibit altogether, alter penalties, change enforcement, and so on.

Alkyl nitrites

Alkyl nitrites are compounds of structure R-ONO. Formally they are alkyl esters of nitrous acid.

The first few members of the series are volatile liquids; methyl and ethyl nitrite are gaseous at room temperature and pressure. The compounds have a distinctive fruity odor.

Preparation and use

Organic nitrites are prepared from alcohols and sodium nitrite in sulfuric acid solution. They decompose slowly on standing, the decomposition products being oxides of nitrogen, water, the alcohol, and polymerization products of the aldehyde.[1]

In the laboratory, solutions of alkyl nitrites in glacial acetic acid are sometimes used as mild nitrating agents. The nitrating species is acetyl nitrate generated in situ.

Antidepressants

An *antidepressant* is a medication designed to treat or alleviate the symptoms of clinical depression. Some antidepressants, notably the tricyclics, are commonly used off-label in the treatment of neuropathic pain, whether or not the patient is depressed. Smaller doses are generally used for this purpose, and they often take effect more quickly. Many antidepressants also are used for the treatment of anxiety disorders, and tricyclic antidepressants are used in the treatment of chronic pain disorders such as chronic functional abdominal pain (CFAP), myofascial pain syndrome, and post-herpetic neuralgia.

The main classes of antidepressants have similar efficacy, but the newer types are generally regarded to have a more benign side-effect profile and less risk of lethality if taken in overdose.

History

Like many psychiatric drugs, antidepressants were discovered by accident. The first useful antidepressants belonged to a group called MAOIs (*M*ono*A*mine *O*xidase *I*nhibitors) and were discovered in the early 1950s. The original member of this group was iproniazid, which was originally developed to treat tuberculosis.[1] The next group were the tricyclic antidepressants. The first was imipramine. They were effective and safer than the MAOI but still quite dangerous in overdose. They are still used today but have been largely replaced by another group: SSRIs (*S*elective *S*erotonin *R*euptake *I*nhibitors). The first SSRI was Zimelidine. Drugs from all three groups have been found to improve the mood of depressed patients. The SSRI antidepressants were early examples of rational drug design.

Classes and members

Antidepressants (*ATC N06A*):

Monoamine oxidase inhibitors (MAOI) - Harmaline, Iproclozide, Iproniazid, Isocarboxazid, Nialamide, Phenelzine, Selegiline, Toloxatone, Tranylcypromine

Reversible inhibitor of monoamine oxidase A (RIMA) - Brofaromine, Moclobemide

Dopamine reuptake inhibitor (DARI) - Amineptine, Phenmetrazine, Vanoxerine, Modafinil

Norepinephrine-dopamine reuptake inhibitors - Bupropion

Norepinephrine reuptake inhibitor (NRI) or (NARI) - Atomoxetine, Maprotiline, Reboxetine, Viloxazine

Serotonin-norepinephrine reuptake inhibitor (SNRI) - Duloxetine, Milnacipran, Venlafaxine

Selective serotonin reuptake inhibitor (SSRI) - Alaproclate, Etoperidone, Citalopram, Escitalopram, Fluoxetine, Fluvoxamine, Paroxetine,

Selective serotonin reuptake enhancer (SSRE) - Tianeptine

Tricyclic antidepressants (TCA) - Amitriptyline, Amoxapine, Butriptyline, Clomipramine, Desipramine, Dibenzepin, Dothiepin, Doxepin, Imipramine, Iprindole, Lofepramine, Melitracen, Nortriptyline, Opipramol, Protriptyline, Trimipramine

Tetracyclic antidepressants - Maprotiline, Mianserin, Nefazodone, Trazodone

Noradrenergic and specific serotonergic antidepressant (NaSSA) Mirtazapine

Classes

- Monoamine oxidase inhibitors **(MAOIs)**
    - Tricyclic antidepressants (TCAs)
- Selective serotonin reuptake inhibitors **(SSRIs)**
- Serotonin-norepinephrine reuptake inhibitors **(SNRIs)**
    - Norepinephrine/noradrenaline reuptake inhibitors (NRIs aka NERIs/NARIs)
    - Dopamine reuptake inhibitors (DRIs)
- Opioids
- Selective serotonin reuptake enhancers **(SSREs)**
    - Novel antidepressants
- Tetracyclic antidepressants

Prominent members

Well-known antidepressants are:

- Fluoxetine - of the SSRI class (Prozac, Sarafem, Fluctin, Fontex, Prodep, Fludep, Lovan)
- Venlafaxine - of the SSRI class (Effexor, Efexor)
- Citalopram - of the SSRI class (Celexa, Cipramil, Talohexane)
- Paroxetine - of the SSRI class (Paxil, Seroxat, Aropax)
- Escitalopram - of the SSRI class (Lexapro, Cipralex)
- Fluvoxamine - of the SSRI class (Luvox, Faverin)
- Duloxetine - of the SSRI class (Cymbalta)

- Bupropion - of the DRI and NRI classes (Wellbutrin, Zyban)
- Amitriptyline - of the TCA class (Elavil)
- Dothiepin (Dosulepin) - of the TCA class (Prothiaden, Dothapax)

Mechanism of action

The therapeutic effects of antidepressants are believed to be related to an effect on neurotransmitters, particularly by inhibiting the monoamine transporter proteins of serotonin and norepinephrine. Selective serotonin reuptake inhibitors (SSRIs) specifically prevent the reuptake of serotonin (thereby increasing the level of serotonin in synapses of the brain), whereas earlier monoamine oxidase inhibitors (MAOIs) blocked the destruction of neurotransmitters by enzymes which normally break them down. Tricyclic antidepressants (TCAs) prevent the reuptake of various neurotransmitters, including serotonin, norepinephrine, and dopamine. Although these drugs are clearly effective in treating depression, the current theory still leaves unanswered questions. For example, concentrations in the blood build to therapeutic levels in only a few days and begin affecting neurotransmitter activity immediately. Changes in mood, however, often take four weeks or more to appear. One explanation holds that the "down-regulation" of neurotransmitter receptors—an apparent consequence of excess signaling and a process that takes several weeks—is actually the mechanism responsible for the alleviation of depressive symptoms. Another theory, based on recent research published by the National Institutes of Health in the United States, suggests that antidepressants may derive their effects by promoting neurogenesis in the hippocampus.. Recent research suggests that antidepressants act on transcription factors termed "clock genes" , which also are involved in actions of drugs of abuse and possibly in obesity

Treatment strategies

On efficacy measures, a successful antidepressant trial involves at least 50% of the test subjects on the drug responding to the medication. "Response" signifies at least a 50% reduction in depression symptoms, as opposed to "remission," which indicates a virtual elimination of depression symptoms. A number of different treatment strategies, however, may produce better results.

Switching

The American Psychiatric Association 2000 Practice Guideline for the Treatment of Patients with Major Depressive Disorder advises that where no response is achieved following six to eight weeks of treatment with an antidepressant to switch to an antidepressant in the same class, then to a different class of antidepressant.

A series of open-label studies by Michael Thase MD of the University of Pittsburgh found that more than half the patients who failed on their initial antidepressant achieved a response on their second antidepressant from the same class. (Thase ME et al. "Fluoxetine

treatment of patients with major depressive disorder who failed initial treatment with sertraline." J Clin Psychiatry. 1997 Jan;58(1):16-21.)

A 2002 double-blind study by the same author found a positive benefit among treatment-resistant patients switching either from an SSRI to a tricyclic or from a tricyclic to an SSRI. (Thase ME et al. "Double-blind switch study of imipramine or sertraline treatment of antidepressant-resistant chronic depression." Arch Gen Psychiatry. 2002 Mar;59(3):233-9.)

Augmentation and combination

For a partial response, the American Psychiatric Association advises augmenting an antidepressant with a different pharmaceutical agent. These agents may include lithium, thyroid supplementation, atypical antipsychotics, and dopamine agonists, among others. Symbyax, a combination olanzapine-fluoxetine (Zyprexa-Prozac) pill, is approved in the US for treating bipolar depression, and is being investigated for other depression indications. In general, however, there are no major augmentation studies to guide psychiatrists.

Combination strategy involves using two or more antidepressants from different classes to target more than one neurotransmitter in order to hopefully achieve a more beneficial result. Again, this is a little-studied area of antidepressant treatment.

Combining with psychotherapy

A 2000 study found that those on nefazadone (Serzone) plus a form of short-term psychotherapy called Cognitive Behavioral Analysis System of Psychotherapy (CBASP) fared significantly better (85% response, 42% remission) than those on Serzone alone (55% response, 22% remission) or CBASP alone (52% response, 24% remission). (Keller MB et al. "A comparison of nefazadone, the cognitive behavioral-analysis system of psychotherapy, and their combination for the treatment of chronic depression." N Engl J Med. 2000 May 18;342(20):1462-70.

Preventing relapse

A 2003 meta-analysis of 31 placebo-controlled antidepressant trials found that continuing with antidepressants reduced the risk of relapse by 70%. (Geddes JR et al. "Relapse prevention with antidepressant drug treatment in depressive disorders: a systematic review." Lancet. 2003 Feb 22;361(9358):653-61.)

The American Psychiatric Association advises four to five months of continuation treatment on an antidepressant following the resolution of symptoms. For patients with a history of depressive episodes, the British Association for Psychopharmacology's 2000 Evidence Based Guidelines for Treating Depressive Disorders with Antidepressants advises remaining on an antidepressant for at least six months and as long as five years or indefinitely.

Tolerance and dependence

Antidepressants are not thought to produce tolerance, although sudden withdrawal may produce adverse effects. Antidepressants create little if any immediate change in mood and require between several days and several weeks to take effect.

Antidepressants do not seem to have all of the same addictive qualities as other substances such as nicotine, caffeine, cocaine, or other stimulants. (There is, however, controversy on the definition of addiction.) Some argue that antidepressants do not meet the general requirements for the commonly-established view. While some antidepressants may cause dependence and withdrawal they do not seem to cause uncontrollable urges to increase the dose due to euphoria or pleasure. For example, if an SSRI medication is suddenly discontinued, it may produce both somatic and psychological withdrawal symptoms, a phenomenon known as "SSRI discontinuation syndrome" (Tamam & Ozpoyraz, 2002). When the decision is made to stop taking antidepressants it is common practice to "wean" off of them by slowly decreasing the dose over a period of several weeks.

It is generally not a good idea to take antidepressants without a prescription. The selection of an antidepressant and dosage suitable for a certain case and a certain person is a lengthy and complicated process, requiring the knowledge of a professional. Certain antidepressants can initially make depression worse, can induce anxiety, or can make a patient aggressive, dysphoric or acutely suicidal. In certain cases, an antidepressant can induce a switch from depression to mania or hypomania, can accelerate and shorten a manic cycle (i.e. promote a rapid-cycling pattern), or can induce the development of psychosis (or just the re-activation of latent psychosis) in a patient with depression who wasn't psychotic before the antidepressant.

Side effects

Antidepressants can often cause side effects, and an inability to tolerate these is the most common cause of discontinuing an otherwise working medication.

General

Although recent drugs may have fewer side effects, patients sometimes report severe side effects associated with their discontinuation, particularly with Paroxetine and venlafaxine. Additionally, a certain percentage of patients do not respond to antidepressant drugs. Another advantage of some newer antidepressants is they can show effects within as few as five days, whereas most take four to six weeks to show a change in mood. However, some studies show that these medications might be even more likely to result in moderate to severe sexual dysfunction. However, there are medications in trials that appear to show an improved profile in regard to sexual dysfunction and other key side effects.

MAO inhibitors can produce a potentially lethal hypertensive reaction if taken with foods that contain high levels of tyramine, such as mature cheese, cured meats or yeast extracts. Likewise, lethal reactions to both prescription and over the counter medications have occurred. Any patient currently undergoing therapy with an MAO inhibiting medication should be monitored closely by the prescribing physician and always consulted before taking an over the counter or prescribed medication. Such patients should also inform emergency

room personnel and information should be kept with one's identification indicating the fact that the holder is on MAO inhibiting medications. Some doctors even suggest the use of a medical alert ID bracelet. Although the reactions in question are dramatic when they happen, the total number of deaths due to interactions and dietary concerns are comparable to over-the-counter medications.

Antidepressants should be used with great care, usually in conjunction with mood stabilisers, in the treatment of bipolar disorder, as they can exacerbate symptoms of mania. They have also been known to trigger mania or hypomania in some patients with bipolar disorder and in a small percentage of patients with depression. SSRIs are the antidepressants most frequently associated with this side effect.

Use of antidepressants should be monitored by a psychiatrist, but in countries such as New Zealand, the United Kingdom, and the United States, primary care physicians are able to prescribe antidepressants without consulting a psychiatrist. In particular, it has been noted that the most dangerous period for suicide in a patient with depression is immediately after treatment has commenced, as antidepressants may reduce the symptoms of depression such as psychomotor retardation or lack of motivation before mood starts to improve. Although this appears to be a paradox, studies indicate the suicidal ideation is a relatively common component of the initial phases of antidepressant therapy, and it may be even more prevalent in younger patients such as pre-adolescents and teenagers. It is strongly recommended that other family members and loved ones monitor the young patient's behavior, especially in the first eight weeks of therapy, for any signs of suicidal ideation or behaviors. Until the black box warnings on these drugs were issued by FDA as well as by agencies in other nations, side effects and alerting families to risk were largely ignored and downplayed by manufacturers and practitioners. This may have resulted in some deaths by suicide although direct proof for such a link is largely anecdotal. The higher incidence of suicide ideation reported in a number of studies has drawn attention and caution in how these drugs are used.

Sexual

Sexual dysfunction is a very common side effect, especially with SSRIs. Bupropion, a dual reuptake inhibitor (NE and DA), in many cases results in a moderately increased libido, due to increased dopamine activity. This effect is also seen with dopamine reuptake inhibitors, CNS stimulants and dopamine agonists, and is due to increases in testosterone production (due to inhibition of prolactin) and increased nitric oxide synthesis. Apomorphine, nefazodone and nitroglycerin have been shown to reverse some sexual dysfunction via increased nitric oxide activity. MAOIs are reported to have fewer negative effects on sexual function and libido, particularly moclobemide at a 1.9% rate of occurrence. Betanechol has been reported to reverse MAOI-induced sexual dysfunction via its cholinergic agonist properties **(Gross 1982)**.

In order for the physician to select the appropriate response, the patient should provide the physician with information to distinguish between reduced libido (little or no desire for sex), reduced sexual function (impotence, vaginal dryness) and anorgasmia, as these have separate causes and prompt different treatment.

REM Sleep

It is well recognized that virtually all major antidepressant drugs suppress REM sleep and it has, in fact, been proposed that the clinical efficacy of these drugs largely derives from their suppressant effects on REM sleep. The three major classes of antidepressant drugs, monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs), profoundly suppress REM sleep The MAOIs virtually completely abolish REM sleep, while the TCAs and SSRIs have been shown to produce immediate (40-85%) and sustained (30-50%) reductions in REM sleep. Ironically, a common side effect of most antidepressants is an increase in vivid dreams, and nightmares are a common result of rapid withdrawal from MAOIs.

Opioids

Opium has long been known as an antidepressant. Various Opiates were commonly used as antidepressants until the mid-1950s, when they fell out of favor with medical orthodoxy due to their addictive nature, the tolerance buildup issues and their side-effect profile.

Today the use of opioids in treating depression is a large taboo in the medical field due to associations with drug abuse; hence, research has proceeded at a very slow rate.

A small clinical trial conducted at Harvard Medical School in 1995, demonstrated that a majority of treatment-refractory, unipolar, non-psychotic, major depression patients could be successfully treated with an opioid medication called Buprenorphine, which is a partial mu agonist and potent kappa antagonist. The exact mechanism of its action in depression is not known, as kappa antagonists are antidepressants in their own right. After the release of this paper, use of buprenorphine against depression in the clinical setting has increased. The lack of large-scale clinical trials has been a deterrent to widespread use.

While opioids have been proven to substantially relieve symptoms of depression for a large class of patients, re-acceptance of this fact has been severely hampered by governmental narcotic prohibition efforts, and the (until buprenorphine) lack of alternatives with low risk of tolerance and addiction.

Buprenorphine is generally preferred as the first-line opiate in depression treatment, as managing the tolerance buildup of other opiates can be complicated.

Gamma-Hydroxybutyric acid

Gamma-Hydoxybutyric acid (GHB) has been used by some as an antidepressant. Claude Rifat, a French biologist, conducted some early research into GHB's antidepressant potential. Rifat noted that GHB did not cause the emotional blunting effects caused by conventional antidepressants, but instead intensified pleasurable and rewarding feelings in the user while powerfully suppressing depression. Unfortunately, GHB has now been outlawed, except for use as a prescription treatment for narcolepsy.

Controversy

Several studies have stimulated doubt about the effectiveness of antidepressants. The studies cite that the difference between antidepressants and placebo is negligible (Kirsch I, Moore TJ, Scoboria A, Nicholls SS (2002a), The emperor's new drugs: an analysis of antidepressant medication data submitted to the U.S. Food and Drug Administration. Prevention & Treatment 5:Article 23).

The paper in question has been severely criticized by independent researchers, however. One reason for this is that it deals almost exclusively with the SSRI class of medication. In leveling criticism against the efficacy of SSRIs, critics state, it is not the best paper, merely the most widely known one. Also, other classes of antidepressants have demonstrated superior efficacy, and it has been argued that this paper is "throwing the baby out with the bathwater", while its thrust should in fact be levelled at the serotonin hypothesis of depression.

Through a Freedom of Information Act request, two psychologists obtained 47 studies used by the FDA for approval of the six antidepressants prescribed most widely between 1987-99. Overall, antidepressant pills worked 18% better than placebos, a statistically significant difference, "but not meaningful for people in clinical settings," says University of Connecticut psychologist Irving Kirsch. He and co-author Thomas Moore released their findings in "Prevention and Treatment," an e-journal of the American Psychological Association.

More than half of the 47 studies found that patients on antidepressants improved no more than those on placebos, Kirsch says. "They should have told the American public about this. The drugs have been touted as much more effective than they are." He says studies finding no benefit have been mentioned only on labeling for Celexa, the most recently approved drug. The others included in his evaluation: Prozac, Paxil, Zoloft, Effexor and Serzone.

Additional papers have been published regarding the benefits of atypical vs. typical antidepressants. These are timely papers given the need for evidence based medicine, as well as the cost of health care. Discussion of a key paper reviewing this topic titled "Quantitative analysis of sponsorship bias in economic studies of antidepressants" can be found at an on-line journal club.

Peter Glenmullen, a Harvard psychiatrist, has written a book on the subject for the layperson; see link below.

Alternative medicines

Alternative treatments for depression such as the herbal remedy St John's wort and the amino acid derivative SAM-e have gained popularity in recent years. Clinical trials have shown the effect of acupuncture to be comparable with amitriptyline; in addition, acupuncture has been found to be more effective in depressive patients with decreased excretion of 3-methyl-4-hydroxy-phenylglycol (the principal metabolite of the central neurotransmitter norepinephrine), while amitriptyline is more effective for those with inhibition in the dexamethasone suppression test (World Health Organisation, Acupuncture: Review and Analysis of Reports on Controlled Clinical Trials, 2002). Acupuncture has also been proven to prompt the body to produce greater levels of endorphins.Clinical trials have shown SAM-e to be as effective as standard antidepressant medication, with many fewer side

effects (Delle Chiaie et al., 2002; Mischoulon and Fava, 2002). Most studies conclude that St. John's wort is usually as effective against depressions as other modern medication, again with fewer side effects, and it is widely prescribed for depression in Europe. However, a recent study showed St. John's wort to be no more effective than a placebo in cases of severe depression (Hypericum Depression Trial Study Group, 2002). Tryptophan dietary supplements, although banned in many countries due to impurities that caused a blood disease, have also been used as natural antidepressants. Dietary supplements of 5-HTP, a chemical the body forms from tryptophan and uses to make serotonin, have shown some promising research results but need further study.

Developments

NMDA antagonists such as ketamine and dextromethorphan have recently gained some interest in this field as their apparent ability to reverse endogenous opioid tolerance can give fast-acting dramatic effects. However, their acute psychoactive effects have been a problem.[1]

Memantine, a moderate affinity NMDA antagonist, has been used to avoid tolerance buildup, and has seen use in opioid tolerance reversal. Proglumide is used to induce acute reversal of tolerance prior to this maintenance strategy; it does not work by itself in the long term, due to tolerance to its effects.

Bicyclic antidepressants

Bicyclic antidepressants are a class of antidepressant drugs. They are named after the drugs' molecular structure, which contains two rings of atoms (compare tetracyclic and tricyclic antidepressants). The term 'bicyclic antidepressant' is of lesser usage than the terms tricyclic or tetracyclic subtypes since for most bicyclic structured antidepressant drugs their pharmacological identity is largely defined not by their structure but their mode of action. An example of this is Fluoxetine, though structurally bicyclic, is categorized among selective serotonin reuptake inhibitors.

Monoamine oxidase inhibitors

Monoamine oxidase inhibitors (*MAOIs*) are a class of antidepressant drugs prescribed for the treatment of depression. They are particularly effective in treating atypical depression, and have also shown efficacy in helping smokers to quit. Due to potentially lethal dietary and drug interactions they had been reserved as a last line of defense, used only when other classes of antidepressant drugs (for example tricyclic antidepressants and selective serotonin reuptake inhibitors) had been tried unsuccessfully. Recently however, a patch form of the drug (known as Emsam) was invented. (Emsam was approved for use by the FDA on February 28, 2006.) When applied transdermally the drug does not enter the gastro-intestinal system as it does when taken orally, thereby decreasing the dangers of dietary interactions associated with MAOI pills.

Uses

Therapeutic use

In the past they were prescribed for those resistant to tricyclic antidepressant therapy, but newer MAOIs are now sometimes used as first-line therapy. They are also used for treating agoraphobia and social anxiety. Currently, the availability of Selegiline and moclobemide provides a safer alternative, although not always as effective as the old types.

Traditional and entheogenic use

Monoamine oxidase inhibitors can be used to potentiate the effect of a number of hallucinogenic drugs, notably phenethylamines, tryptamines and several others.

Ayahuasca, an entheogenic brew traditionally used in strict ritual context by South American native tribes, is a mixture of Banisteriopsis caapi, a vine containing various

harmala alkaloids, and another plant containing N,N-DMT or 5-MeO-DMT alkaloids, usually Psychotria viridis or Diplopterys cabrerana. Modern, western analogues to ayahuasca often substitute Syrian Rue for B. caapi and Mimosa hostilis as a DMT source. As DMT is inactive orally on its own, it must be combined with an MAOI when taken orally in order to cause psychedelic effects.

Mode of action

MAOIs act by inhibiting the activity of monoamine oxidase preventing the breakdown of monoamine neurotransmitters and so increasing the available stores. There are two isoforms of monoamine oxidase, MAO-A and MAO-B. MAO-A preferentially deaminates serotonin, melatonin, adrenaline and noradrenaline. MAO-B preferentially deaminates phenylethylamine and trace amines. Dopamine is equally deaminated by both types. Many formulations use forms of fluoride attached to assist getting past the blood-brain barrier and is suspected as a factor in pineal gland effects.

Reversibility

The early MAOIs inhibited monoamine oxidase irreversibly. When they react with monoamine oxidase, they permanently deactivate it, and the enzyme cannot function until it has been replaced by the body, which can take about two weeks. A few newer MAOIs, notably moclobemide, are reversible, meaning that they can inhibit the enzyme for a time, but eventually detach, allowing the enzyme to function once more.

Selectivity

In addition to reversibility, MAOIs differ by their selectivity of the MAO receptor. Older MAOIs inhibit both MAO-A and MAO-B equally, but newer MAOIs have been developed that target one over the other. For example, a 300 mg dose of moclobemide (Manerix, Aurorix) causes 80% inhibition of MAO-A and 20-30% inhibition of MAO-B.

Dangers

When ingested orally, MAOIs inhibit the catabolism of dietary amines. Sufficient intestinal MAO-A inhibition can lead to hypertensive crisis, when foods containing tyramine are consumed (so-called "cheese reaction"), or hyperserotonemia if foods containing tryptophan are consumed. The amount required to cause a reaction exhibits great individual variation and depends on the degree of inhibition, which in turn depends on dosage and selectivity.

The exact mechanism by which tyramine causes a hypertensive reaction is not well understood, but it is assumed that tyramine displaces norepinephrine from the storage vesicles. This may trigger a cascade in which excessive amounts of norepinephrine can lead to a hypertensive crisis. Another theory suggests proliferation and accumulation of catecholamines causes hypertensive crises. Because tyramine is the building block of

catecholamines (including dopamine, norepinephrine, and epinephrine), intake promotes production of these neurotransmitters. Excessive accumulation can result when MAO is inhibited, producing SNS effects of increased heart rate and vasoconstriction that lead to hypertension. Hypertensive crises can sometimes result in stroke or cardiac arrhythmia if not treated. This risk is generally not present with RIMAs. Both kinds of intestinal MAO-inhbition can cause hyperpyrexia, nausea and psychosis if foods high in levodopa are consumed.

Examples of foods and drinks with potentially high levels of tyramine include fermented substances, such as Chianti and other aged wines, and aged cheeses. Liver is also a well-known source. (See a list of foods containing tyramine). Examples of levodopa-containing foods include broad beans. These diet restrictions are not necessary for those taking selective MAO-B inhibitors.

It deserves separate mention that some meat extracts and yeast extracts (Bovril, Marmite, Vegemite) contain extremely high levels of tyramine, and should not be used with these medications.

When MAOI's were first introduced, these risks were not known, and over the following four decades, less than 100 people have died from hypertensive crisis. Presumably due to the sudden onset and violent appearance of the reaction, MAOI's gained a reputation for being so dangerous that, for a while, they were taken off the market in America entirely. It is now known that, used as directed under the care of a qualified psychiatrist, this class of drugs remains the safest alternative for intermediate- to long-term use.

The most significant risk associated with the use of MAOIs, is the potential for interactions with over-the-counter and prescription medicines, illicit drugs and certain supplements (e.g. St. John's Wort). It is vital that a doctor supervise such combinations to avoid adverse reactions. For this reason, many users carry an MAOI-card, which lets emergency medical personnel know what drugs to avoid. (E.g. adrenaline dosage should be reduced by 75%, and duration is extended)

MAOIs should not be combined with other psychoactive substances (antidepressants, illicit drugs, painkillers, stimulants, etc.) except under expert care. Certain combinations can cause lethal reactions, common examples including SSRIs, tricyclics, meperidine and tramadol. Agents with actions on epinephrine, norepinephrine or dopamine must be administered at much lower doses due to potentiation and prolonged effect. Purely opiate-acting analgesics, such as morphine and buprenorphine may be used safely with MAOIs, but may require a dosage adjustment.

List of MAOIs

Monoamine oxidase inhibitors include:

- Isocarboxazid (Marplan)

Moclobemide (Aurorix, Manerix, Moclodura®)
Phenelzine (Nardil)
Tranylcypromine (Parnate)
Selegiline (Selegiline, Eldepryl), and Emsam
Nialamide
Iproniazid (Marsilid, Iprozid, Ipronid, Rivivol, Propilniazida)

Iproclozide
Toloxatone
Many tryptamines have MAOI properties. Harmine (present in Harmal, Banisteriopsis caapi, and tobacco) is a powerful MAOI, which is often used as one of the ingredients of ayahuasca. Certain others as AMT, 5-MeO-DMT or 5-MeO-AMT provide only minor MAO inhibition.

Reversible inhibitors of MAO-A

*RIMA*s (reversible inhibitors of monoamine oxidase type-A) are a family of psychiatric drugs that inhibit monoamine oxidase, temporarily and reversibly. They are mostly used for alleviating depression and dysthymia.

Because their action is short-lived and selective, they have a better safety profile than the older MAOI drugs (monoamine oxidase inhibitors). A special diet does not need to be so strictly adhered to, although eating excessively large amounts of tyramine-containing foods is not advisable.

Combining a RIMA or MAOI with an SSRI is dangerous since it can lead to serotonin syndrome and possible fatality.

Moclobemide and Brofaromine are RIMAs.

Harmala alkaloid

The *Harmala alkaloid* "Harmine", also known as *Telepathine* and *Banisterine*, is a naturally occurring beta-carboline alkaloid that is structurally related to harmaline. Harmine and harmaline are reversible monoamine oxidase inhibitors. They can stimulate CNS by inhibiting the metabolism of serotonin and other monoamines.

Some harmala alkaloids, particularly harmine and harmaline, are found in the seeds of the Middle Eastern plant Harmal (Peganum harmala, from which the name derives), commonly known as Syrian Rue. They occur in the seeds in concentrations of roughly 3%, though tests have documented anywhere from 2-7%, as natural sources tend to vary widely in chemical makeup. Harmala alkaloids are also found in the vine Banisteriopsis caapi in concentrations that range between 0.31-8.43% for harmine, 0.03-0.83% for harmaline and 0.05-2.94% for tetrahydroharmine [THH].[1] Banisteriopsis caapi is the key plant ingredient in the sacramental beverage Ayahuasca. Leaves from "Psychotria viridis", a source of DMT, are often added to Ayahuasca to achieve visionary states of consciousness. Many other psychoactive plants are known to be added to , as the harmala alkaloids are not significantly psychoactive on its own.

Harmala alkaloids are also found in many other plants, such as tobacco and passion flower.

Telepathine

Telepathine was originally thought to be the active chemical constituent of Banisteriopsis caapi, a key plant ingredient in the preparation of Ayahuasca; a sacremental beverage from the Amazon. This isolated chemical was so named because of the reported effects of Ayahuasca among the indigenous users, including: collective contact with and/or visions of jaguars, snakes, and jeweled birds, and ancestral spirits; the ability to see future events; and as the name suggests, telepathic communication among tribal members. It was assumed to be a newly discovered chemical at the time, however, it was soon realized that Telepathine was already more widely known as Harmine from its previous discovery in Syrian Rue (Peganum harmala).

Uses

As mentioned above, some harmala alkaloids can be used as an MAOI (*M*ono*A*mine *O*xidase *I*nhibitor) to facilitate the oral ingestion of DMT and other tryptamines; it is not hallucinogenic on its own. In high doses, it acts a purgative. Harmala alkaloids from Banisteriopsis caapi have been used to treat Parkinson's disease. Additionally, Harmaline is used as a model for Essential Tremor when injected to animals. Rats being treated with Harmaline exhibit severe tremors after 5-7 minutes. In-Vitro research showed that Harmaline increased subthreshold oscillations in neuronal membrane potential in a brainstem slice preparation containing the Inferior Olive.

List of foods containing tyramine

This is a *list of foods containing tyramine*. Tyramine is an amine which causes elevated blood pressure and tachycardia by displacing norepinephrine from storage vesicles. Tyramine is generally produced by decarboxylation of the amino acid tyrosine during fermentation of food products. All protein rich food which has been matured will contain more tyramine depending on the temperature and for how long it has been stored. Properly refrigerated will not be effected.

The amount required to cause a 30mmHg increase in diastolic blood pressure is referred to as TYR30, and generally averages around 500mg in an unmedicated, healthy individual. A class of antidepressants called MAOIs (monoamine oxidase inhibitors) can increase the sensitivity to tyramine if taken orally. If sufficient quantities of tyramine are ingested, hypertensive crises may occur, potentially causing stroke or cardiac arrythmia. There is significant evidence that tyramine may trigger migraines in sensitive individuals.

This list is for informational purposes only; it is neither all-inclusive nor does it go into any particular depth. If you plan to avoid tyramine in your diet, you are urged to seek professional guidance. Note that the exact increase in sensitivity will depend on the MAOI used, and its dose.

Alcoholic Beverages

All tap beer and ale should be avoided, as lack of hygiene and proper maintenance may allow tyramine-forming bacteria to grow. Domestic bottled beers are generally safe in small quantities. Red wine and white wine are acceptable as long as no more than 120ml is ingested. Chianti and vermouth, however, should be avoided.

Cheeses

Most aged cheeses should be avoided. While there are some, such as cream cheese and cottage cheese, that have little to no notable amounts of tyramine, most aged cheeses have high concentrations of tyramine. It is therefore wise for people that are sensitive to tyramine to avoid all aged cheeses, if at all possible.

Regular cheese of the kind typically used on bread and pizza can safely be consumed in normal amounts.

Fruit

Avocados contain tyramine, especially overripe fruit. Avocados may be eaten in moderate quantities, provided that the fruit is not overripe. Banana peels contain significant levels of tyramine.

All other fruits should be eaten in moderation, since overripe and dried fruit will contain more tyramine. Common fruits that may contain relevant levels of tyramine include: eggplant, figs, grapes, oranges, pineapples, plums, prunes and raisins.

Processed Foods

Many processed foods should be avoided, due to high tyramine levels. A few processed foods that contain high amounts of tyramine include, but are not limited to: vegemite, sauerkraut, and shrimp paste.

Meat and Fish

Fresh liver has no significant levels of tyramine, but old liver contains high amounts. Like liver, fresh meat and fish are safe, and old meat is risky. Caution is recommended in restaurants or any other uncertain source of meat. Traditionally meat from game birds and wild animals, is hung in a cool place to improve the flavour and tenderness, this significantly increases the tyramine content. Processed meats, cured or pickled meats, and meat by products and broths often contain large amounts of tyramine.

Soy

All soy products contain high levels of tyramine. Aside from soybeans themselves, commonly consumed soy products include: soy sauce, tofu, miso, and teriyaki sauce. The quantities of these products should be limited.

Nuts and Chocolate

Chocolate does not contain appreciable amounts of tyramine, but does contain other active ingredients that are potentiated by MAOIs. Accordingly, chocolate should be limited to moderate quantities to avoid risk of nausea, headaches, temperature changes and psychosis.

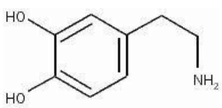
There is some evidence that large quantities of nuts, peanuts, coconuts, and brazil nuts may trigger hypertensive reactions and headaches.

Monoamine reuptake inhibitors

Dopamine reuptake inhibitors | Selective serotonin reuptake inhibitor **|** Serotonin-norepinephrine reuptake inhibitor

Dopamine

Dopamine



General

Systematic name	**4-(2-aminoethyl)benzene-1,2-diol**
Other names	**2-(3,4-dihydroxyphenyl)ethylamine; 3,4-dihydroxyphenethylamine; 3-hydroxytyramine; DA; Intropin Revivan; Oxytyramine**
Molecular formula	**$C_8H_{11}NO_2$**
SMILES	**C1=CC(=C(C=C1CCN)O)O**
Molar mass	**153.178 g/mol**
Appearance	**white powder with distinctive smell**
CAS number	**[51-61-6]**

Properties

Solubility in water	**60.0 g/100 ml (? °C), solid**
Melting point	**128 °C (401 K)**
Hazards	
R/S statement	**R: 36/37/38** **S: 26-36**
RTECS number	**UX1088000**
Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)	

Dopamine is a chemical naturally produced in the body. In the brain, dopamine functions as a neurotransmitter, activating dopamine receptors. Dopamine is also a neurohormone released by the hypothalamus. Its main function as a hormone is to inhibit the release of prolactin from the anterior lobe of the pituitary.

Dopamine can be supplied as a medication that acts on the sympathetic nervous system, producing effects such as increased heart rate and blood pressure. However, since dopamine cannot cross the blood-brain barrier, dopamine given as a drug does not directly affect the central nervous system. To increase the amount of dopamine in the brains of patients with diseases such as Parkinson's disease and Dopa-Responsive Dystonia, a synthetic precursor to dopamine such as L-DOPA can be given, since this will cross the blood-brain barrier.

Contents

Biochemistry

Dopamine has the chemical formula ($C_6H_3(OH)_2$-CH_2-CH_2-NH_2). Its chemical name is 4-(2-aminoethyl)benzene-1,2-diol and it is abbreviated "DA."

As a member of the catecholamine family, dopamine is a precursor to epinephrine (adrenaline) and norepinephrine (noradrenaline) in the biosynthetic pathways for these neurotransmitters. Arvid Carlsson won a share of the 2000 Nobel Prize in Physiology or Medicine for showing that dopamine is not just a precursor to these, but a neurotransmitter as well.

Dopamine is synthesized in the body (mainly by nervous tissue and adrenal glands) first by the hydration of the amino acid tyrosine to DOPA by tyrosine hydroxylase and then by the decarboxylation of DOPA by aromatic-L-amino-acid decarboxylase. In neurons, dopamine is packaged after synthesis into vesicles, which are then released in response to the presynaptic action potential. The inactivation mechanism of neurotransmission are 1) uptake via a specific transporter; 2) enzymatic breakdown; and 3) diffusion. Uptake back to the presynaptic neuron via the dopamine transporter is the major role in the inactivation of dopamine neurotransmission. The recycled dopamine will face either breakdown by an enzyme or be re-packaged into vesicles and reused.

Functions in the brain

Dopamine has many functions in the brain. Most importantly, dopamine is central to the reward system. Dopamine neurons may have the role to emit a teaching signal for prioritizing and learning of reward-directed behaviour and to code reward information relative to established predictions.

Movement

Dopamine affects the basal ganglia motor loop which in turn affects the way the brain controls our movements. Shortage of dopamine, particularly the death of dopamine neurons

in the nigrostriatal pathway, causes Parkinson's disease, in which a person loses the ability to execute smooth, controlled movements.

Cognition and frontal cortex

In the frontal lobes, dopamine controls the flow of information from other areas of the brain. Dopamine disorders in this region of the brain can cause a decline in neurocognitive functions, especially memory, attention and problem-solving. Reduced dopamine concentrations in the prefrontal cortex are thought to contribute to attention deficit disorder and negative schizophrenia. Conversely, anti-psychotic medications rely on their inhibition of dopamine uptake and are used in the treatment of positive symptoms in schizophrenia.

Regulating prolactin secretion

Dopamine is the primary neuroendocrine regulator of the secretion of prolactin from the anterior pituitary gland. Dopamine produced by neurons in the arcuate nucleus of the hypothalamus is secreted into the hypothalamo-hypophysial blood vessels of the median eminence, which supply the pituitary gland. The lactotrope cells that produce prolactin, in the absence of dopamine, secrete prolactin continuously; dopamine inhibits this secretion.

Motivation and pleasure

Dopamine is commonly associated with the pleasure system of the brain, providing feelings of enjoyment and reinforcement to motivate a person proactively to perform certain activities. Dopamine is released (particularly in areas such as the nucleus accumbens and striatum) by naturally rewarding experiences such as food, sex, use of certain drugs and neutral stimuli that become associated with them. This theory is often discussed in terms of drugs (such as cocaine and amphetamines), which seem to be directly or indirectly related to the increase of dopamine in these areas, and in relation to neurobiological theories of chemical addiction, arguing that these dopamine pathways are pathologically altered in addicted persons. However, cocaine and amphetamine influence separate mechanisms of action.

Cocaine is a dopamine transporter blocker that competitively inhibits dopamine uptake to increase the lifetime of dopamine and augments an overabundance of dopamine (an increase of up to 150%) within the parameters of the dopamine neurotransmitters. Like cocaine, amphetamines increase the concentration of dopamine in the synaptic gap, but by a different mechanism. Amphetamines are similar in structure to dopamine, and so can enter the terminal button of the presynaptic neuron via its dopamine transporters as well as by diffusing through the neural membrane directly. When entering inside the presynaptic neuron, amphetamines force the dopamine molecules out of their storage vesicles and expel them into the synaptic gap by making the dopamine transporters work in reverse.

Dopamine's role in experiencing pleasure has been questioned by several researchers. It has been argued that dopamine is more associated with anticipatory desire and motivation (commonly referred to as "wanting") as opposed to actual consummatory pleasure (commonly referred to as "liking"). Dopamine is released when unpleasant or aversive stimuli are encountered, and so motivates towards the pleasure of avoiding or removing the unpleasant stimuli.

Recent research suggests that the firing of dopamine neurons is a motivational chemical as a result of reward-anticipation. This is based on evidence that, when a reward is perceived to be greater than expected, the firing of certain dopamine neurons increases, which correspondingly increases desire or motivation toward the reward.

Clues to dopamine's role in motivation, desire and pleasure have come from studies performed on animals. In one such study rats were depleted of dopamine by up to 99% in the nucleus accumbens and neostriatum using 6-hydroxydopamine.[1] With this large reduction in dopamine, the rats would no longer eat by their own volition. The researchers then force fed the rats food and noted whether they had the proper facial expressions indicating whether they liked or disliked it. The researchers of this study concluded that the reduction in dopamine did not reduce the rat's consummatory pleasure, only the desire to actually eat. In another study, mutant hyperdopaminergic (increased dopamine) mice show higher "wanting" but not "liking" of sweet rewards.[2]

In humans, though, drugs that reduce dopamine activity (e.g., antipsychotics) have been shown to reduce motivation as well as cause anhedonia (the inability to experience pleasure).[3] Conversely the selective D2/D3 agonists pramipexole and ropinirole have anti-anhedonic properties as measured by the Snaith-Hamilton Pleasure Scale.[4] (The Snaith-Hamilton-Pleasure-Scale (SHAPS), introduced in English in 1995, assesses self-reported anhedonia in psychiatric patients.)

Opioid and cannabinoid transmission instead of dopamine may modulate consummatory pleasure and food palatability(liking).[5] This could explain why animals "liking" of food is independent of brain dopamine concentration. Other consummatory pleasures, however, may be more associated with dopamine. One study found that both anticipatory and consummatory measures of sexual behavior (male rats) were disrupted by DA receptor antagonists.[6] Libido can be increased by drugs that affect dopamine but not by drugs that affect opioid peptides or other neurotransmitters.

Sociability is also closely tied to dopamine neurotransmission. Low D2 receptor binding is found in people with social anxiety. Traits common to negative schizophrenia (social withdrawal, apathy, anhedonia) are thought to be related to a hypodopaminergic state in certain areas of the brain. In instances of bipolar, manic subjects can become hypersocial as well as hypersexual. This is also credited to an increase in dopamine, because mania alleviates from dopamine blocking antipsychotics.

Other theories reinforce that the crucial role of dopamine may be in desire, or anticipating pleasurable activity. Related theories [7] argue that dopamine function may be involved in the salience ('noticeableness') of perceived objects and events, with potentially important stimuli such as: 1) rewarding things or 2) dangerous or threatening things seeming more noticeable or important. This hypothesis argues that dopamine assists decision-making by influencing the priority, or level of desire, of such stimuli to the person concerned.

Pharmacological blockade of brain dopamine receptors increases rather than decreases drug-taking behavior. Since blocking dopamine decreases desire, the increase in drug taking behavior may be seen as not a chemical desire but as a deeply psychological desire to just 'feel something'.

Deficits in dopamine levels are implicated as one of several possible causes for Adult attention-deficit disorder (AADD), and some types of medications used to treat Attention-deficit hyperactivity disorder (ADHD/ADD) will help to stimulate dopaminergic systems, leading to potentially heightened sensation, for those afflicted by it and receiving treatment for it.

Links to psychosis

Disruption to the dopamine system has also been strongly linked to psychosis and schizophrenia.[8] Dopamine neurons in the mesolimbic pathway are particularly associated with these conditions. This is partly due to the discovery of a class of drugs called the phenothiazines (which block D2 dopamine receptors) that can reduce psychotic symptoms, and partly due to the finding that drugs such as amphetamine and cocaine (which are known to greatly increase dopamine levels) can cause psychosis. Because of this, most modern antipsychotic medication is designed to block dopamine function to varying degrees.

Depression

Dopamine is a neurotransmitter that is involved in depression. Amphetamines and dopamine reuptake blockers have potent anti-depressant effects but these drugs quickly lose their benefit after they deplete dopamine levels in the brain. Antidepressants appear to primarily enhance serotonergic neurotransmission during preliminary drug administration but it takes several weeks for the antidepressant effect to be noticed. The late effect of antidepressants is thought to involve the indirect serotonergic modulation of dopaminergic neurotransmission. Blocking the D***2*** dopamine receptor is known to cause relapse in patients that have achieved remission from depression, and such blocking also counteracts the effectiveness of SSRI medication.

Therapeutic use

Levodopa is a dopamine precursor used to treat Parkinson's disease. It is typically co-administered with an inhibitor of peripheral decarboxylation (DDC, dopa decarboxylase), such as carbidopa or benserazide. Inhibitors of alternative metabolic route for dopamine by catechol-O-methyl transferase are also used. These include entacapone and tolcapone.

Dopamine is also used as an inotropic drug in patients with shock to increase cardiac output and blood pressure.

Major pathways

- Mesocortical pathway
Mesolimbic pathway
Nigrostriatal pathway
Tuberoinfundibular pathway

Amphetamines

Systematic (IUPAC) name 1-phenylpropan-2-amine

Identifiers

CAS number rn=1" href="http://www.nlm.nih.gov/cgi/mesh/2006/MB_cgi?term=300-62-9&rn=1"> 300-62-9

ATC code **N06**BA01

PubChem 3007

DrugBank APRD00480

Chemical data

Formula $C_9H_{13}N$

Mol. weight 135.2084

Pharmacokinetic data

Bioavailability 4L/kg; low binding to plasma proteins (20%)

Metabolism Hepatic

Half life 10–13 hours

Excretion Renal; significant portion unaltered

Therapeutic considerations

Pregnancy cat. C (USA)

Legal status DEA Schedule II (USA), Class B (UK), Schedule III (Canada)

Routes Oral, Intravenous, Vaporized, Insufflated, Suppository

Amphetamine (*a*lpha-*m*ethyl-phenethylamine), also known as *speed* or *crank*, is a stimulant, and *club drug*, used to diminish the appetite, control weight, and treat disorders including narcolepsy and attention-deficit hyperactivity disorder. It is also used recreationally and for performance enhancement (these uses are illegal in some countries).

Illicit production and use of amphetamines occurs on a widescale basis in several European nations, typically in the form of amphetamine sulfate synthesized from phenylpropanolamine. In addition, because of the widespread use of amphetamines as a treatment for narcolepsy and ADD/ADHD, prescription amphetamines are subject to diversion and are one of the most frequently-abused drugs in high schools and colleges.

Toxicity

Patients with acute toxicity from amphetamines may have symptoms of psychosis, disorientation, temporary symptoms associated with schizophrenia, aggression, delusions, lock-jaw, diarrhea, palpitations, arrhythmia, syncope, hyperpyrexia, and hyperreflexia progressing to convulsions and coma. Patients with chronic use of amphetamines develop a rapid tolerance to the drug and may have to increase the dose to reach the desired effect and eventually develop addiction. Patients that develop addiction show symptoms of restlessness, anxiety, depression, insomnia, and suicidal behavior. A urine drug screen can be performed to determine the presence of amphetamines. Patients may need to be hospitalized. Supportive therapy is important. Cooling blankets may be used for hyperthermia. Sedation may be obtained with lorazepam or diazepam. Haloperidol may be given for agitation and delusions. Hypertension and arrhythmias should be treated.

Chemistry

Amphetamine was first synthesized in 1887 by the Romanian chemist Lazr Edeleanu at the University of Berlin, who called it "*phenylisopropylamine*". Amphetamine is a chiral compound. The racemic mixture can be divided into its optical antipodes: levo- and dextro-amphetamine. Amphetamine is the parent compound of its own structural class, comprising a broad range of psychoactive derivatives, e.g., MDMA (Ecstasy) and the N-methylated form, methamphetamine. Amphetamine is a homologue of phenethylamine.

Traditionally the medical drug came in the racemic salt-form rac-amphetamine sulfate (rac = levo- and dextro-form in equal amounts). Today, dextroamphetamine sulphate is the predominant form of the drug used; it consists entirely of the d-isomer. Attention disorders are often treated using Adderall or generic-equivalent formulations of mixed amphetamine salts that contain both d/l-amphetamine and d-amphetamine in the sulfate and saccharate forms mixed to a final ratio of 3 parts d-amphetamine to 1 part l-amphetamine.

Pharmacology

Dextroamphetamine, the eutomer of amphetamine, exhibits its mode of peripheral action via release and reuptake inhibition of the monoamine neurotransmitters acetylcholine (ACh) and histamine (H), but not glutamate. Its activity at the vesicular monoamine transporter VMAT2 is of crucial importance in the release process.[1]

Application range

Amphetamine is a synthetic drug with strong stimulant effects. In the United States, it is most commonly used for treatment of attention-deficit disorders and narcolepsy, but is also approved as a weight-loss medication in certain cases of obesity. Within the armed forces only, it is also frequently prescribed as an anti-fatigue pill for pilots and other individuals in situations requiring vigilance and alertness. Amphetamine is also used illegally to take advantage of these effects. The wanted effects stem predominantly from d-amphetamine; l-amphetamine contributes to the unwanted peripheral side effects, primarily nausea after the dose loses effect.

Medicinal use

Indicated for:

- Diet suppressant
ADD
ADHD
Narcolepsy
Treatment-resistant depression

Recreational uses:

- Stimulant

Other uses:

- Used by the US military to combat fatigue and increase wakefulness

Contraindications:

- CNS Stimulants
- MAOI **use**

Side effects:

- Dizziness
Tachycardia
Sweating
Decrease in appetite/weight loss
Euphoria followed by depression
Insomnia
Anger
Aggressiveness
Hostility

Cardiovascular:

- Bronchodilator

Ear, nose, and throat:

- Decongestant

Eye:

- Mydriasis (Pupil dilation)

Gastrointestinal:

- Diarrhoea

Musculoskeletal:

- Muscle aches/cramps

Neurological:

- Dopamine Agonist

Norepinephrine Agonist

Respiratory:

- Bronchodilator

The experimental medical use of amphetamines began in the 1920s. It was introduced in most of the world in the form of the pharmaceutical Benzedrine in the late-1920s. The drug was used by the militaries of several nations, especially the air forces, to fight fatigue and increase alertness among servicemen. After decades of reports of abuse, the FDA banned Benzedrine inhalers, and limited amphetamines to prescription use in 1959, but illegal use became common.

Along with methylphenidate (Ritalin, Concerta, etc.), amphetamine is one of the standard treatments for ADHD. Beneficial effects for ADHD can include improved impulse control, improved concentration, decreased sensory overstimulation, and decreased irritability. These effects can be dramatic, particularly in young children. The ADHD medication Adderall is composed of four different amphetamine salts, and Adderall XR is a timed release formulation of these same salt forms.

When used within the recommended doses, side-effects like loss of appetite tend to decrease over time. However, amphetamines last longer in the body than methylphenidate (Ritalin, Concerta, etc.), and tend to have stronger side-effects on appetite and sleep.

Amphetamines are also a standard treatment for narcolepsy as well as other sleeping disorders. They are generally effective over long periods of time without producing addiction or physical dependence.

Amphetamines are sometimes used to augment anti-depressant therapy in treatment-resistant depression.

Medical use for weight loss is still approved in some countries, but is regarded as obsolete and dangerous in, for example, the United States.

Effects of use

Amphetamines release stores of norepinephrine and dopamine from nerve endings by converting the respective molecular transporters into open channels. Amphetamine also releases stores of serotonin from synaptic vesicles. Like methylphenidate (Ritalin), amphetamines also prevent the monoamine transporters for dopamine and norepinephrine from recycling them (called reuptake inhibition), which leads to increased amounts of dopamine and norepinephrine in synaptic clefts.

These combined effects rapidly increase the concentrations of the respective neurotransmitters in the synaptic cleft, which promotes nerve impulse transmission in neurons that have those receptors.

Physical effects

- Short-term physiological effects include decreased appetite, increased stamina and physical energy, increased sexual drive/response, involuntary bodily movements, hyperhidrosis, hyperactivity, jitteriness, nausea, itchy, blotchy or greasy skin, Tachycardia, irregular heart rate, hypertension, and headaches. Fatigue can often follow the dose's period of effectiveness. Overdose can be treated with chlorpromazine.
- Long-term abuse or overdose effects can include tremor, restlessness, changed sleep patterns, anxiety and increase in pre-existing anxiety, poor skin condition, hyperreflexia, tachypnea, gastrointestinal narrowing, and weakened immune system. Fatigue and depression can follow the excitement stage. Erectile dysfunction, heart problems, stroke, and liver, kidney and lung damage can result from prolonged use. When snorted, amphetamine can lead to a deterioration of the lining of the nostrils.

Psychological effects

- Short-term psychological effects can include alertness, euphoria, increased concentration, rapid talking, increased confidence, increased social responsiveness, nystagmus (eye wiggles), hallucinations, and loss of REM sleep the night after use.
- Long-term psychological effects can include insomnia, mental states resembling schizophrenia, aggressiveness (not associated with schizophrenia), addiction or dependence with accompanying withdrawal symptoms, irritability, confusion, and panic. Chronic and/or extensively-continuous use can lead to amphetamine psychosis, which causes delusions and paranoia, but this is uncommon when taken as prescribed. Amphetamine is highly-psychologically addictive, and, with chronic use, tolerance develops very quickly. Withdrawal is, although not physiologically threatening, an unpleasant experience (including paranoia, depression, difficult breathing, dysphoria, gastric fluctuations and/or pain, and lethargia). This commonly leads chronic users to re-dose amphetamine frequently, explaining tolerance and increasing the possibility of addiction.

Addiction

Tolerance is developed rapidly in amphetamine use, therefore increasing the amount of the drug that is needed to satisfy the addiction. Many abusers will repeat the amphetamine cycle by taking more of the drug during the withdrawal. This leads to a very dangerous cycle and may involve the use of other drugs to get over the withdrawal process. Chronic users of amphetamines may resort to drug injection to experience the full effect of the drug in a faster and more intense way, with the added risks of bacterial and viral tranmission, vein damage and higher risk of overdose.

Legal issues

- In the United Kingdom, amphetamines are regarded as Class B drugs. The maximum penalty for unauthorised possession is three months' imprisonment and a £2,500 fine.
- In the United States, amphetamine and methamphetamine are Schedule II controlled drugs, classified as a CNS (Central Nervous System) Stimulant. A Schedule II drug is classified as one that: has a high potential for abuse, has a currently-accepted medical use and is used under severe restrictions, and has a high possibility of severe psychological and physiological dependence.

Internationally, amphetamine is a Schedule II drug under the Convention on Psychotropic Substances[2].

Popular culture

- Avant-garde rock and roll band The Velvet Underground wrote White Light/White Heat (song), about the effects of the drug.
Blues-Rock band Canned Heat wrote a song, on the album Boogie With Canned Heat called Amphetamine Annie, about a girl who takes speed regularly.
Rock and roll band Everclear (band) wrote a song called Amphetamine, about a girl named Amphetamine.
Space-rock band Hawkwind performed a song entitled "Motorhead", written by Lemmy Kilmister shortly before forming his own band of the same name. Kilmister is known for being a longtime user of speed.
Alternative Rock band The Smashing Pumpkins mention Amphetamine in a song titled "Annie Dog" from the album "Adore".
Rock and Roll band The Sisters of Mercy were (in)famous for the constant references to amphetamine throughout their career.
Industrial Rock band Marilyn Manson mention Amphetamines in a song titled "Rock is Dead".
Punk rock band Toys That Kill have a song entitled Amphetamine St. off their album The Citizen Abortion.
Alternative Metal band Seether mention Amphetamine in a song titled "I'm The One" from the album "Karma And Effect".

3,4-Methylenedioxyamphetamine

MDA

Chemical name 3,4-Methylenedioxyamphetamine or 1-(benzo[d][1,3]dioxol-5-yl)propan-2-amine

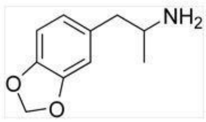
Chemical formula $C_{10}H_{13}NO_2$

Molecular mass 179.22 g/mol

Melting point 187 - 188 °C (hydrochloride)

CAS numbers 4764-17-4, 51497-09-7, 61614-60-6, 65620-66-8

SMILES NC(C)CC1=CC=C(OCO2)C2=C1



3,4-methylenedioxyamphetamine, or *MDA*, is a psychedelic hallucinogenic drug and empathogen/entactogen of the phenethylamine family. It was first synthesized by G. Mannish and W. Jacobson in 1910. There are about 20 different synthetic routes described in the literature for its preparation.

Medical use

MDA was first used in animal tests in 1939, and human trials began in 1941 in the exploration of possible therapies for Parkinson's disease. From 1949 to 1957, more than 500 human subjects were given MDA in an investigation of its potential use as an antidepressant and/or anorectic by Smith, Klein, and French. The United States Army also experimented with the drug, code named EA-1298, while working to develop a truth drug or incapacitating agent. One human subject died in January 1953 after being intravenously injected with 500mg of the drug. MDA was patented as a cough suppressant by H. D. Brown in 1958, as an ataractic by Smith, Klein, and French in 1960, and as an anorectic under the trade name “Amphedoxamine” in 1961. Several researchers, including Claudio Naranjo, have explored MDA in the field of psychotherapy.

Recreational use

MDA began to appear on the recreational drug scene around 1963 to 1964. It was then inexpensive and readily available as a research chemical from several scientific supply houses. Although now illegal, MDA continues to be bought, sold, and used for recreational purposes, often in the form of tablets purporting to contain MDMA (Ecstacy).

Effects

A recreational dose of MDA is commonly between 80 and 160mg. The “R” optical isomer is more potent than the “S” optical isomer. Although there is some debate, the duration of the drug is now generally believed to be roughly 6 to 10 hours(In the late 90s, Shulgin changed his opinion of the duration to 3-6 hours). The effects of the drug are quite similar to those of MDMA (Ecstacy), including empathogen/entactogenic effects, though typically less intense than a similar dosage of MDMA. Because of these effects, MDA was called the “hug drug” and was alleged to stand for “Mellow Drug of America” in the 1960s. Some users feel that MDA has more psychedelic or hallucinogenic qualities than MDMA.

The toxicity of MDA is not fully known. The LD50 in mice has been reported as 92mg/kg by intraperitoneal injection. Erowid lists the fatality rate at roughly 2 in 100,000 users. MDA is considered to be more potentially neurotoxic than its methylated cousin MDMA. It is a direct metabolite of MDMA.

Legality

In 1970, the Controlled Substances Act was enacted in the United States, placing MDA into Schedule I. It is similarly controlled in other nations. In Canada MDA is a Schedule III drug. Internationally, MDA is a Schedule I drug under the Convention on Psychotropic Substances[1].

Adderall

Adderall® CII is a pharmaceutical stimulant Amphetamine used to treat attention-deficit hyperactivity disorder and narcolepsy. Severe cases of depression may also be treated with Adderall or other stimulants. It was first prescribed in the 1970s as an anorectic (under the brand name Obetrol®), but such usage is now rare.

Use

- 1/4 Dextro-amphetamine Saccharate
- 1/4 Dextro-amphetamine Sulfate
- 1/4 dl-amphetamine Aspartate (racemic Amphetamine)
- 1/4 dl-amphetamine Sulfate (racemic Amphetamine)

The four component salts are claimed to be metabolised at different rates.

The average elimination half-life for dextroamphetamine is 10 hours in adults, and for levoamphetamine, 13 hours. Its effects are otherwise similar to other central nervous system stimulants (see amphetamine for details.).

The manufacturer claims that the mixture of salts makes Adderall's effects smoother, with softer highs and lows, than those of other treatments for the same disorders.

There is little evidence, however, to support this claim for immediate-release. A recent patent application for Adderall (USP #6,384,020) was a pharmaceutical composition patent listing a rapid immediate release oral dosage form. No claim of increased or smooth drug delivery was made. A recent double-blind, placebo-controlled crossover study, conducted among children, indicated that patients behaved similarly to other immediate release amphetamines. The authors found that sustained-release dexamphetamine (the main isomeric-amphetamine component of Adderall) had a longer duration of action, and cost less than Adderall, though dexamphetamine was less effective in the first few hours

Adderall is now sold in either an immediate-release tablet or an extended-release capsule, marketed as Adderall XR (for "eXtended Release"). Doses for both immediate-release and extended-release form come in 5, 10, 15, 20, 25, 30, and 35 mg increments. Adderall XR utilizes the Microtrol® delivery system to achieve the extended-release mechanism. This delivery system incorporates two beads: the first type of bead dissolves immediately and the second type releases four hours later. Maximum plasma concentration is achieved in seven hours, compared to regular Adderall IR (immediate-release) which reaches maximum plasma concentration within three hours. As a result of its high bioavailability, Adderall XR's effectiveness is not altered by food absorption in the gastrointestinal tract. However, tmax (mean plasma concentration) is prolonged by 2.5 hours (using a standard high-fat meal as the control). Acidic beverages should not be ingested with Adderall XR as they alter the pH balance of the stomach

Effects

While the exact mechanism is unknown, it is believed that Adderall works by blocking the reuptake of dopamine and norepinephrine into the presynaptic neuron and increasing their release from the presynaptic neuron into the extraneuronal space. In other words, Adderall reverses the reuptake mechanism, turning it into a pump instead of a vacuum. Sources note that amphetamine and related compounds (ephedrine, etc.) displace noradrenaline from the presynaptic neuron and do not act as reuptake inhibitors as referenced above.

The increased flow of dopamine and norepinephrine into the extraneuronal space causes the patients' brain, as one psychiatrist explains, to experience a more intense level of concentration, causing an increased ability to focus for extended periods of time, and a heightened interest in performing focus based tasks.

Though rare, it is possible for Adderall to cause psychotic episodes at recommended doses in patients with a history of psychosis.

Some patients feel they are less creative while taking Adderall, while others report that it can aid in creative work. The famous Beat generation writer Jack Kerouac, for instance, is said to have written much of his classic On The Road in a span of three weeks, aided by Amphetamine (an active ingredient in Adderall) from Benzedrine inhalers; country music star Johnny Cash had a long period of amphetamine use in the 1960s; and mathematician Paul ErdQs was noted for habitual use of prescription amphetamine throughout the final decades of his life; Smile was written by Brian Wilson and Van Dyke Parks with heavy

amphetamine use, among others. All of these probably knew the drug by its common name, speed.

Double-blind, placebo-controlled studies of dextroamphetamine in normal subjects have shown significant performance increases on cognitive tasks and decreased reaction time.

Clinical trials establishing the long term effectiveness of Adderall have not been conducted. Controlled studies have not occurred for children on Adderall for a period exceeding three weeks. Also, reviews of effectiveness for adolescents or adults on the medication for longer then four weeks have not been evaluated. Several studies on pregnant rodents have shown that exposure to amphetamines in utero or postnatal can lead to neurological damage and variance in behavior. While more controlled studies on pregnant women taking Adderall are needed, amphetamines have been shown to pass through into breast milk. Because of this, mothers taking medications containing amphetamines are advised to avoid nursing during their course of treatment.

Side effects

Common side effects of Adderall include:

- Increased heart rate
- Insomnia
- Anorexia (loss of appetite)
- Vertigo
- Headache
- Diarrhea
- Sweating
- Sexual dysfunction (impotence or changes in sex drive)
- Dry Mouth
- Irritability
- Tremor
- Euphoria

Less common side effects

- Upset stomach
- Nervousness
- Mydriasis
- Bruxism (teeth grinding)
- Formication (in excessive doses [3])
- Urinary retention
- Pyrexia
- Tachycardia
- Tics
- Urticaria
- Increased Urination (Your body's way of combating hypertension[citation

needed]])
Blunted affect
Detachment from reality

Rare side effects

- Phonic tics
- high blood pressure

- hallucinations

- Tourette's syndrome
cardiomyopathy

Contraindications

Using any Amphetamine, (including Adderall, Methamphetamine or Ecstasy) within 1-2 weeks of taking a monoamine oxidase inhibitor (MAOI) (an archaic branch of the antidepressant class) can cause a potentially fatal condition known as serotonin syndrome.

Performance-enhancing use

Because Adderall uses amphetamine stimulants to help the user concentrate for extended periods of time, many students today request Adderall from doctors in order to use it as a study aid. Thus, it is increasingly popular on college campuses. The largest benefit to students, however, is Adderall's ability to give students the power to focus on and learn what would usually be uninteresting material. Because of the appetite-suppressing properties of amphetamines, it is also sought after by those wishing to lose weight. Another less common use for students is to take Adderall before or during a night of heavy drinking in order to remain alert and active despite being intoxicated.

To add further insight to Adderall use among college students, research done by the National Institute of Drug Abuse (NIDA) shows the more competitive the college, the higher the incidence of stimulant use. An article published stated the findings of a nationwide survey of thousands of college students. The findings of this past April 2006 survey shows 5.9% use rates among the more competitive campuses, compared to 1.3% use rates among less competitive campuses. Breaking down the use pattern even further, this same sample done by NIDA reveals whites were more likely to use stimulants compared to African Americans and Asians, at rates of 4.9%, 1.6%, and 1.3% respectively. Further, students with lower grade point averages of B's or below use stimulants at a rate of 5.2%, compared to students earning B+ or above who use this medication at rates of only 3.3%. This research also specifically identified that students involved in sororities or fraternities use stimulants at a much higher rate of 8.6% compared to nonmembers who reported use at rates of only 3.3% (Whitten, 6).

In addition to the physiological risks posed by using Adderall as a way to enhance performance, the use of prescription stimulants has a direct correlation to higher levels of smoking cigarettes, binge drinking, risky behavior including driving while under the influence of drugs and the use of marijuana, ecstasy and cocaine. For example, the NIDA survey respondents revealed the likelihood that a stimulant user used cocaine in the past year was twenty times that of a non-user. Similarly, they reported being five times as likely to drive drunk (Whitten, 6).

Another major concern about the use of Adderall among college students is the psychological dependence that causes students to lose faith in their own ability to perform well and the dependence on the advantageous effects of stimulant medication. Jackie Kurta, an Alcohol and Drug Specialist at UC Santa Barbara's Student Heath Services states, "Students start out taking study drugs one time to study. The drugs work so well that the students begin to lose confidence in their own abilities to study without them," (Hirschey).

On the street, Adderall is sold illegally for $3 to $10 a pill (pills ranging from 5 to 35 mg) Slang terms for Adderall are: "slack", "zing", "fatty addy", "Blue Spanish Fly", "a.d.", "study buddies", "ralls", "headlight through fog," "smart pills", "beenies", "amps", "a-bombs", "cactus jacks", "uppies", "Freud's Love", "blasters", "corvettes" (refering to the 35 mg pill), "Duke Ellingtons", "addies", "poopy," "blue buddies", "Blue Betties", "orange tic-tacs", "the blue dutchman", "candy", "A candy", "blue boy," "nig nigs", "jollies", "smurphs", "rinky dink," "diet coke", "Thrash" by some skateboarders, "Davies"(for their founder, Dave Herrington), "team blue", "derallo," "the A train", "A+" in reference to its stimulant effect (Ambien is often referred to as "A-", the reverse effect of Adderall), and in some regions of the U.S., "railguns" and "that'da boy(s)" (from noted increase in productivity). On some college campuses taking Adderall is known as "taking the A train" or "getting some vitamin A", most likely inspired by the song "Take The A Train" by Duke Ellington. The 5 and 10 mg doses are also known in the northwest as "BBs",] which is short for "Blueberries", named for their blue color. Heavier users tend to use the term "GBs", which is short for "goof balls". Some Adderall users crush and inhale the 5 and 10 mg pills to experience a stronger "rush" and a more rapid onset of the drug's effects. This has led to the term "smurf snot," used to describe how the pills color one's mucus blue.

Aside from being used by college students as a study aide, Adderall has been used as an off label drug for weight loss. Adderall's side effect of weight loss and appetite suppression is a desired result for those trying to lose weight. It is administered as part of a "cocktail" of other off label prescription drugs that have side effects used to treat obesity. There have not been any scientific studies performed to evaluate the effectiveness of this form of treatment and is viewed a very risky and potentially dangerous way to shed pounds.

History/How it works

Adderall, formulated in the early 1990's, is the newest and most popular drug on the market for the treatment of ADHD. Due to the composure of Adderall, the four salts listed beforehand, it is superior to any other ADHD drug that has been created and used in the past. With Adderall, as opposed to drugs like Ritalin and Dexedrine, there are hardly any issues with withdraw that were clearly apparent with ADHD drugs in the past. Not only is Adderall considered a smoother ADHD drug than any other, but because of its potency there is no

need for doses to be taken throughout the day as was the case with previous drugs for treatment. Results yield that Adderall is just as effective, if not better, in treating the symptoms of ADHD in children as well as adults (about 60-70% improvement).

ADHD is a diagnosis of what is believed to be a part of the brain that insufficiently regulates brain chemicals. This irregularity causes decrease in efficiency which leads to the symptoms that define ADHD. The way Adderall works is by stimulating these areas of the brain that are considered to be working and regulating improperly. The proper dose of Adderall boosts this part of the brain to perform and function at the normal level, reverting one to normal behavior. Normal behavior is attached to a person who can maintain focus, promote calmness, and control their impulsivity.

Government warnings

On February 9, 2005, Health Canada suspended all sales of Adderall XR after data collected by manufacturer Shire Pharmaceuticals linked the drug to 12 sudden deaths in American children between the years 1999 to 2003. Further research, however, found little data suggesting use of Adderall resulted in an increased risk of cardiac defect. Of the twelve sudden deaths positively linked to pediatric Adderall users during the four year period, five had known pre-existing cardiac conditions, one died after strenuous exercise in 110 degree heat and two had levels suggestive of an overdose. Given the more than 37,000,000 prescriptions for Adderall filled during the four years, the US Food and Drug Administration could find no increased risk of sudden death among Adderall users beyond the normal rate of the general population. In August, 2005, Health Canada followed the committee report of three independent physicians and lifted the ban on Adderall XR. Given that persons with AD/HD are a high risk group, it has been suggested that stimulant medications for persons with AD/HD will actually result in lower incidence of premature death.

Currently the FDA and Health Canada advise against the use of Adderall in those persons with pre-existing cardiac or mental illnesses. They also suggest against its use in persons who have a history of drug abuse.Although FDA safety advisors voted 8 to 7 to issue a Black Box Warning, the FDA's pediatric advisory committee refused to give the drug its most severe black box warning in March, 2006. A Black Box Warning regarding amphetamine abuse potential is in place, however.Manufacturers

Adderall is manufactured by Catalytica Pharmaceuticals Inc. of Greenville, North Carolina and is distributed by Shire Pharmaceuticals. Generic equivalents (known to pharmacists as "amphetamine salts," "mixed amphetamines," or simply "amphetamines," inter alia) are also distributed in the United States by Barr Pharmaceuticals, Mallinckrodt Pharmaceuticals, Eon Labs and Ranbaxy Laboratories.

Benzedrine

Benzedrine is the trade name of the racemic variant of Amphetamine (dl-amphetamine). It was marketed under this brandname in the USA by Smith, Kline and French in the form of inhalers, starting in 1928. Benzedrine was used to enlarge nasal and bronchial passages and it is closely related to other stimulants produced later, such as Dexedrine (d-amphetamine) and methamphetamine.

Early users of the Benzedrine inhaler discovered that it had a euphoric stimulant effect, resulting in it being one of the earliest synthetic stimulants to be widely used for recreational (i.e., non-medical) purposes. Even though this drug was intended for inhalation, many people abused it by cracking the container open and swallowing the paper strip inside, which was covered in Benzedrine. The strips were often rolled into small balls and swallowed, or taken with coffee or alcohol. The drug was often referred to as "Bennies" by users and in literature.

Because of the stimulant side effect, physicians discovered that amphetamine could also be used to treat narcolepsy. This led to the production of Benzedrine in tablet form.

In the 1940s and 1950s reports began to emerge about the abuse of Benzedrine inhalers, and in 1949, doctors began to move away from prescribing Benzedrine as a bronchodilator and appetite suppressant. In 1959, the FDA made it a prescription drug in the United States.

When Benzedrine became a controlled substance, it was replaced by a less potent stimulant drug, Propylhexedrine (also known as Hexahydromethamphetamine). Propylhexedrine was also manufactured by Smith, Kline and French and was marketed under the name Benzedrex. Although Benzedrex is not as potent as Benzedrine, it still has the potential for abuse and has been the cause of death by intravenous use. The Benzedrex inhaler is still available today, but is no longer manufactured by Smith, Kline and French.

Benzedrine should not be confused with the fundamentally different substance Benzphetamine.

Influence

- Benzedrine and derived amphetamines were used as a stimulant for armed forces in World War II and Vietnam.
- This drug was very popular with the beat generation and its influence can be seen in the literature and biographies of William S. Burroughs, Jack Kerouac and Allen Ginsberg. Also, a famous user was the prolific mathematician Paul Erdös, who spent much of his restless life on psychostimulants. An article of November 1987, published in the Atlantic Monthly profiled Erdös and discussed his Benzedrine habit. Erdös said to writer Paul Hoffman that he had liked the article "...except for one thing...You shouldn't have mentioned the stuff about Benzedrine. It's not that you got it wrong. It's just that I don't want kids who are thinking about going into mathematics to think that they have to take drugs to succeed."

- Benzedrine is also prevalent in the James Bond novels by Ian Fleming. In the first novel, Casino Royale, the villain Le Chiffre inhales benzedrine during a battle of wills over a game of Baccarat with 007, earning himself the description, "filthy brute", from an American lady at the table next to Bond. In the novel Live and Let Die, Bond himself eats a benzedrine tablet before going underwater to infiltrate Mr. Big's lair. Similarly, in the novel Moonraker, 007 mixes the drug with champagne before his card game with Sir Hugo Drax in order to "keep my wits about me"; according to the book, the only side effect was overconfidence. In the novel Thunderball, rogue pilot Giuseppe Petacchi consumes two tablets while flying the British Vulcan bomber he has hijacked. This drug use has never featured in the film adaptations, until Casino Royale (2006 film), in which Le Chiffre uses a platinum inhaler, ostensibly for his asthma.
- Benzedrine is mentioned in the lyrics of the R.E.M. song "What's the Frequency, Kenneth?". The band later recorded a song with William S. Burroughs, whose late wife Joan was a notorious user of the drug.
- It is also mentioned in the song popularized by Fred Astaire known as "On the Beam."
- Former Beach Boy Brian Wilson claims that many of the songs on his album Smile were written while the lyricist Van Dyke Parks was under the influence of Benzedrine.
- The Beatles have said that in their early days in Hamburg, Germany, they used Benzedrine quite often in order to play several concerts a night without getting sleepy.
- In the novel Last Exit to Brooklyn by Hubert Selby Jr., the character Georgette, a transvestite, grapples with an addiction to Benzedrine in the face of her abusive brother and unrequited lust for a local drunk, Vinnie.
- Progressive house DJ duo, Deep Dish, opened their 2005 album George Is On with an intro track that states, "No stopping for benzedrine, no stopping for rock 'n roll stars".
- In Robert Harris's novel Enigma, Benzedrine is taken by the cryptanalysts of Bletchley Park in order to keep them awake and alert during shifts stretching over several days.
- Benzedrine was given to Judy Garland at a young age to help with her weight. She became dependent on the drug for the rest of her life. In the classic 1971 cult movie Vanishing Point, the main character Kowalski takes "Bennies" before undertaking his reckless drive through the Southwestern USA.
- Benzedrine is the preferred drug of choice amongst the flawed characters which make up the noir fiction of James Ellroy, who himself has confessed a past addiction to the drug.
- In Alice Sebold's novel The Lovely Bones, a mother and grandmother argue about whether Susie Salmon is - at fourteen - too young for benzedrine, her grandmother's "own personal savior."

- The song "Wet Sand" by Red Hot Chili Peppers contains the lyrics "The travesties that we have seen, are treating me like benzedrine".
- The song "Oh Marie" by Sheryl Crow, on her self-titled album released in 1996, contains the lyric "She's on magazines and Benzedrine and vodka."
- In the British Sitcom Fawlty Towers, during the episode entitled "The Psychiatrist", Sybil Fawlty (Prunella Scales) tells Basil Fawlty (John Cleese) that he is "spitting poison at them like some benzedrine puff-adder."
- In F. Scott Fitzgerald's unfinished final novel, The Last Tycoon, main character Monroe Stahr takes benzedrine before a date.
- In Joyce Carol Oates' Novel Blonde, a fictionalized version of Marilyn Monroe's life, Marilyn is said to have used Benzedrine "sparingly: to 'provide quick and valuable energy,' sorely needed by an exhausted actress" (418).
- The classic anime Akira opens with a character ordering benzedrine at a bar, with the well-known line "Red bennies. Three of 'em".
- Harry "The Hipster" Gibson had a novelty hit in 1944 with the song, "Who Put The Benzedrine In Mrs. Murphy's Ovaltine?"
- In addition to his addiction to heroin, the great jazz alto saxophonist Charlie "Bird" Parker, Jr. often took Benzedrine in tablet form, dissolved in cups of hot coffee. As a result, Parker often did not sleep for days at a time, and friends noted that he was always moving, "24/7".
- Jerry Reed and others have recorded a truck-driving song called "Caffeine, Nicotine, Benzedrine (and wish me luck)."
- Many truck driving songs, including "Six Days on the Road" and "Midnight Hauler," refer to "whites" which are the tablet form of benzedrine.

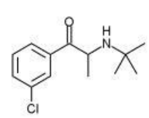
Bupropion



Systematic (IUPAC) name

(±)-1-(3-chlorophenyl)-2-[(1,1-dimethylethyl)amino]-1-propanone

Identifiers

CAS number 34841-39-9

ATC code N07**BA02**

PubChem 444

DrugBank APRD00621

Chemical data

Formula $C_{13}H_{18}NClO$

Mol. weight 239.74 g/mol

Pharmacokinetic data

Bioavailability 5 to 20% in animals; no studies in humans

Metabolism Hepatic

Half life 20 hours

Excretion Renal (87%), fecal (10%)

Therapeutic considerations

Pregnancy cat. $B_{(US)}$

Legal status -only(US)

Routes Oral

Bupropion (or *amfebutamone*, brand names *Wellbutrin* and *Zyban*) is an antidepressant of the aminoketone class, chemically unrelated to tricyclics or selective serotonin reuptake inhibitors (SSRIs). It is similar in structure to the stimulant cathinone, and to phenethylamines in general. It is a chemical derivative of diethylpropion, an Amphetamine-like substance used as an anorectic. Bupropion is both a dopamine reuptake inhibitor and a norepinephrine reuptake inhibitor. It is often used as a smoking cessation aid.

International/alternate trade names include Odranal (Colombia), Quomen (Thailand), Well (Korea), Zyban LP (France), Zyban Sustained Release (Australia)

History

Bupropion was first synthesized by Burroughs Research in 1966, and patented by Burroughs-Wellcome (later Glaxo-Wellcome, and, as of 2000, GlaxoSmithKline) in 1974. It was approved by the Food and Drug Administration (FDA) as an antidepressant in 1989 and marketed under the name *Wellbutrin*, but clinical trials indicated that incidence of seizure was two to four times greater than other antidepressants and the drug was quickly pulled

from the market. It was subsequently discovered that reducing the dose by about half greatly reduced the risk of seizures.

Glaxo then developed a sustained-release (SR) version of Wellbutrin which releases bupropion at a slower rate. The SR formulation is taken twice a day, in order to further decrease the possibility of adverse side effects and seizures. It is also available in generic form (Bupropion SR). Extended Release bupropion, Wellbutrin XL, is the most recent formulation of bupropion and is taken orally once a day. With this altered mechanism of delivery and reduced dosing, incidence of seizures is comparable to, and in some cases lower than, that of other antidepressants. Patients using Bupropion should still be checked for pre-disposing factors that might lead to a lower than normal seizure threshold. It is also important to check for other medications the patient might be using which might also work to lower the seizure threshold.

In 1997, bupropion (as bupropion hydrochloride) was approved by the FDA for use as a smoking cessation aid. Glaxo subsequently marketed the drug under the name *Zyban* to help people stop smoking tobacco by reducing the severity of nicotine cravings and addiction/withdrawal symptoms. It can be used in combination with nicotine replacement therapies. Bupropion treatment course lasts for seven to twelve weeks, with the patient halting the use of tobacco around ten days into the course.

Bupropion is also being investigated for several other disorders including overweight or obesity, attention-deficit hyperactivity disorder, restless legs syndrome and a possible treatment for increasing sexual functioning in some women. In late 2006, Wellbutrin XL was approved for use by the FDA as treatment for seasonal affective disorder.

GlaxoSmithKline's exclusivity patent ended in early 2004. Prior to this, there were several patent suits, the biggest of which involved the pharmaceutical company called Andrx in 1999. After an intitial dismissal of the case in 2003, several court appeals by Glaxo resulted in the refiling of the case. The suit is still pending.[1]

Mode of action

Bupropion is a selective catecholamine (norepinephrine and dopamine) reuptake inhibitor. It has only a small effect on serotonin reuptake. It does not inhibit MAO. The antidepressant effect of bupropion is considered to be mediated by its dopaminergic and noradrenergic action. Bupropion has also been shown to act as a competitive $\pm3^{2}4$ nicotinic antagonist, the $\pm3^{2}4$-antagonism has been shown to interrupt addiction in studies of other drugs such as ibogaine. This $\pm3^{2}4$-antagonism correlates quite well with the observed effect of interrupting addiction.

Pharmacokinetics

Bupropion is metabolised in the liver. It has at least three active metabolites: hydroxybupropion, threohydrobupropion and erythrohydrobupropion. These active metabolites are further metabolised to inactive metabolites and eliminated through excretion into the urine. The half-life of bupropion is 20 hours, as is hydroxybupropion's. Threohydrobupropion's half-life is 37 hours and erythrohydrobupropion's is 33 hours.

Chronic hepatotoxicity in animals

In rats receiving large doses of bupropion chronically, there was an increase in incidence of hepatic hyperplastic nodules and hepatocellular hypertrophy. In dogs receiving large doses of bupropion chronically, various histologic changes were seen in the liver, and laboratory tests suggesting mild hepatocellular injury were noted.

Contraindications

- Epilepsy and other conditions that lower the seizure threshold (alcohol withdrawal, active brain tumors etc.)
- Concomitant treatment with MAO inhibitors. When switching medications it is important that there be a short period of about two weeks between the medications in order to reduce risk of complications that might lead to things such as a decrease in seizure threshold.
- Caution with the concomitant use of sympathomimetic drugs (e.g. ephedrine)
- Active liver damage (e.g. cirrhosis)
- Anorexia nervosa and bulimia which might lead the patient to have a decreased seizure threshold
- Severe kidney disease
- Severe hypertension
- Anxiety disorders (caution), agitated patients
- Pediatric patients (see below)
- Use considerable caution in treating patients where suicide may be a risk (risk is no higher than any other antidepressant)

Side effects

Common side effects include dry mouth, tremors, anxiety, loss of appetite, agitation, dizziness, headache, excessive sweating such as night sweats, increased risk of seizure (Its most controversial side effect, found in 4/1000 during trials), aggressiveness, and both initial and terminal insomnia. Activation of mania and psychosis have both been encountered. Some patients may also require less than the normal dosing which usually starts at around 150 mg for the first few weeks and is then switched to the normal 300 mg dosage; these patients may be kept on the 150 mg regimen.

Suicidal thoughts and attempts have been reported in children and adolescents. Reports of increasing suicidal thoughts have occurred.

Scattered abnormalities of liver function tests are noted, without evidence of hepatotoxicity. Cases of significant liver damage with or without jaundice (icterus) have been seen rarely. In a German database covering side effects, five cases of pancreatitis with elevations of serum-amylase and lipase as well as clinical symptoms (e.g. abdominal pain, anorexia), reversible after termination of bupropion, have been reported. Currently, it is unclear whether preexisting alcohol abuse or dependence might predispose patients to develop pancreatitis.

Infrequently, dose-dependent hypertension is noted. Single cases of myocardial infarction (heart attack) have been noted, but the causal association to the use of bupropion is currently unknown.

The development of mild to moderate skin rashes associated with sensitivity to dye components within the pill coating. This can often be alleviated by simply prescribing a different color pill and consequently, changing the dosage.

Few cases of the urological emergency priapism (painful erection) have been seen. Immediate treatment is necessary, because the untreated patient may totally lose his ability to have erections.

Interactions

Quite a great number of drugs show clinically significant interactions with bupropion. This may be due to interactions with drugs that are metabolized by CYP2D6 as bupropion inhibits CYP2D6 activity. However, bupropion is not metabolized by CYP2D6.

Manufacturer studies have also indicated that bupropion is primarily metabolized to hydroxybupropion by the CYP2B6 isoenzyme. Theoretically, drug interactions could occur between bupropion and substrates or inhibitors of CYP2B6 (e.g. orphenadrine, thiotepa, or cyclophosphamide).

Bupropion is known to lower the seizure threshold. Bupropion, in combination with other medications, has been suspected to induce seizures in some patients with no prior record of seizure activity.[1] While this is not a common side-effect, a growing number of cases world wide validate the need for consideration. It is not uncommon for patients to receive treatment with other antidepressant and/or atypical antipsychotic medications in combination with bupropion. For this reason, care should be taken when prescribing bupropion with other medications prone to lower the seizure threshold. Bupropion has also been known to produce seizures in combination with non-prescription (recreational) drugs such as cocaine, and alcohol. Study the packing insert carefully and ask your prescribing physician about possible interactions.

Abuse liability

In animal studies and small studies with persons having experience with the use of Amphetamine or cocaine, bupropion caused drug-seeking behaviour (animal experiments) and was recognized as an amphetamine-like drug by humans. In a scale ranging from placebo on the lower side to benzedrine, it was given an intermediate score indicating moderate likelihood of abuse. In clinical practice, bupropion has been shown that the dose required for significant abuse would cause seizures in most patients. Abuse has not become a significant problem in clinical usage, but the drug should be given with caution to patients with a history of drug or alcohol abuse or dependence.

Dosage

- Depression: the target dosage is 300 mg daily, starting with 150 mg in the first few days. If indicated and directed by physician, the dosage may be increased to a maximum of 450 mg daily.
- Tobacco withdrawal: 150 mg initially, may be increased to 300 mg if indicated and directed by physician. In patients also receiving insulin, sympathomimetic anorectical drugs, or antimalaria agents, the daily dose of bupropion should not exceed 150 mg.

Dose forms

Brand and generic pills are available in three forms: immediate release, sustained release (SR), and extended release (XL, ER).

Brand Name	Dosage	Color
Wellbutrin	75 mg	yellow-gold
Wellbutrin	100 mg	red
Wellbutrin SR	100 mg	blue
Wellbutrin SR	150 mg	purple
Wellbutrin SR	200 mg	pink
Wellbutrin XL	150 mg	white
Wellbutrin XL	300 mg	white
Zyban SR	150 mg	purple

Overdosage

GlaxoSmithKline has reported that overdoses of up to 30 g or more of Wellbutrin (bupropion) had resulted in seizure in about one third of all cases. Hallucinations, loss of consciousness, sinus tachycardia, and ECG changes such as conduction disturbances or arrhythmias were reported as other serious reactions of overdoses of bupropion alone. Multiple overdoses including bupropion had resulted in fever, rhabdomyolysis, stupor, hypotension, coma, muscle rigidity, and respiratory failure.[2]

Additional warnings

May cause false-positive for amphetamine

Bupropion contains a similar pharmacological structure to that of amphetamines. In most cases prescription medications that contain bupropion (Wellbutrin, Zyban) will produce a positive result for amphetamine abuse.

Use in pediatric patients

Bupropion has been shown to increase the incidence of suicidal thoughts and attempts in children and adolescents with depression. When treating major depressive disorder in this group of patients, clinical benefits should be weighed carefully against therapeutic hazards. Usually, bupropion is not indicated for pediatric patients under age 18.[3]

Potential indications of bipolar and schizoaffective disorder

The effects of bupropion in treating eleven patients with bipolar or schizoaffective disorder were examined in an open trial.[4] Most patients had been intolerant of or showed minimal to moderate improvement on lithium, neuroleptics, antidepressants, or a combination of these drugs. All patients were maintained on bupropion alone or bupropion in combination with low-dose neuroleptics or anxiolytics for one year or more, with little or no relapse and few side effects. Although these results are encouraging, additional larger studies need to be conducted to confirm this indication.

Alleged risks with certain treatments

In the UK, more than 7,000 reports of potential hazardous side effects have been collected. There have been 44 reports of suspected adverse reactions where there was a fatal outcome while taking Zyban. In reviewing these cases the MHRA state that in the majority of cases the individual's underlying condition may provide an alternative explanation.[5] More than two thirds of reported deaths were from cardio-vascular or cerebro-vascular causes. A case-series analysis showed increased risk of seizure in the population taking bupropion, but no increase in the risk of sudden death.[6] At least 107 cases of serious side effects have been reported in Germany. Wellbutrin is also banned or restricted from use in several countries.

In the UK, bupropion should only be prescribed as an aid in quitting smoking to smokers who have committed to a definite quit date and a prescription will not last more than 4 weeks after this target date. NICE has issued guidance to the effect that if the attempt to quit is unsuccessful the NHS will not provide funding for a further course, for at least 6 months.

In some countries bupropion is approved only as a smoking cessation aid and not for treatment of depression.

Studies of juveniles with depression

A large study gathered the results of twenty-four studies of juveniles with depression. Patients were to take either a placebo (sugar pill) or an antidepressant (SSRIs and others, including bupropion) for one to four months. According to the results, nobody committed suicide in these studies, although two out of every hundred patients became suicidal on a placebo and four out of every hundred become suicidal on antidepressants. Results indicated that the risks of suicidal actions become high for some juveniles. These kinds of juveniles may include patients with:[2]

- Bipolar illness, previously known as manic-depressive illness
- A family history of bipolar illness
- A personal or family history of attempting or committing suicide

Ephedrine (EPH) is a sympathomimetic amine similar in structure to the synthetic derivatives Amphetamine and methamphetamine. Ephedrine is commonly used as a stimulant, appetite suppressant, concentration aid, decongestant and to treat hypotension associated with regional anaesthesia. Chemically, it is an alkaloid derived from various plants in the genus Ephedra (family Ephedraceae). It is most usually marketed in the *hydrochloride* and *sulfate* forms.

In traditional Chinese medicine, the herb ma huang (Ephedra sinica) contains ephedrine as its principal active constituent. The same is true of other herbal products containing extracts from Ephedra species. Nagayoshi Nagai was the first one to isolate ephedrine from Ephedra vulgaris in 1885. The substance called soma mentioned in old Hindu books such as the Rig Veda, may have been ephedra extract.

Chemistry

Ephedrine exhibits optical isomerism and has two chiral centres. By convention the enantiomers with opposite stereochemistry around the chiral centres are designated ephedrine, while pseudoephedrine has same stereochemistry around the chiral carbons. That is, (1R,2R)- and (1S,2S)-enantiomers are designated pseudoephedrine; while (1R,2S)- and (1S,2R)-enantiomers are designated ephedrine.

The isomer which is marketed is (-)-(1R,2S)-ephedrine. [1]

As with other phenylethylamines, it is also somewhat chemically similar to methamphetamine, although the amphetamines are more potent and have additional biological effects.

Ephedrine may also be referred to as: (±R)-±-[(1S)-1-(methylamino)ethyl]benzenemethanol, ±-[1-(methylamino)ethyl]benzyl alcohol, or L-erythro-2-(methylamino)-1-phenylpropan-1-ol. Ephedrine hydrochloride has a melting point of 187-188°C. [2]

Mode of action

Ephedrine is a sympathomimetic amine - that is, its principal mechanism of action relies on its indirect action on the adrenergic receptor system, which is part of the sympathetic nervous system or SNS. Whilst it may have weak agonist activity at ±- and ^{2}-adrenergic receptors, the principal mechanism is to displace noradrenaline from storage vesicles in presynaptic neurons. The displaced noradrenaline is released into the neuronal synapse where it is free to activate the postsynaptic adrenergic receptors.

Ephedrine's mechanism of action on neurotransmission in the brain is wide. Its action as an agonist at most major norepinephrine receptors and its ability to induce moderate stimulation of the release of both dopamine and to a lesser extent, serotonin, is presumed to have a major role in its mechanism of action.

Because of ephedrine's ability to potentiate dopamine neurotransmission it is thought to have addictive properties by some researchers.

While ephedrine's role in the serotonin system is less understood there is preliminary documentation of clinically significant agonism at excitory serotonin receptors, perhaps as a downstream response to the large release of norepinephrine in the nucleus accumbens (commonly referred to as the "pleasure center" of the brain). In mice, stereotypical behaviour was both easily induced by administration of ephedrine and it's primary alkaloids and reversed when serotonin antagonists were administered.

Clinical use

Ephedrine was once widely used as a topical decongestant and as a bronchodilator in the treatment for asthma. It continues to be used for these indications, although its popularity is waning due to the availability of more effective agents for these indications which exhibit fewer adverse effects [3]. The role in nasal congestion has largely been replaced by more potent ±-adrenergic receptor agonists (e.g. oxymetazoline). Similarly the role of ephedrine in asthma has been almost entirely replaced by ^{2}***2***-adrenergic receptor agonists (e.g. salbutamol). Ephedrine continues to be used intravenously in the reversal of hypotension from spinal/epidural anaesthesia [3]. It is also used in other hypotensive states, including overdose with ganglionic blocking agents, antiadrenergic agents, or other medications that lower blood pressure [4]. It can be used in narcolepsy and nocturnal enuresis.

In traditional Chinese medicine, ephedrine has been used in the treatment of asthma and bronchitis for centuries [5].

An ECA stack is a component found in thermogenic weight loss pills, composed of ephedrine, caffeine and aspirin working to speed up the metabolism and thus cause food energy to burn faster. The ECA stack is a popular supplement taken by body builders before workouts due to the increased amount of energy and alertness.

For many years, the US Coast Guard recommended ephedrine together with an equal 25 mg dose of promethazine to its sailors to combat seasickness. Promethazine manages nausea and ephedrine fights the ensuing drowsiness. Commonly referred to as the Coast Guard cocktail, ephedrine may still be available for prescription for this purpose.

Adverse effects

Adverse drug reactions (ADRs) are more common with systemic administration (e.g. injection or oral administration) compared to topical administration (e.g. nasal instillations). ADRs associated with ephedrine therapy include [3]:

- Cardiovascular: tachycardia, cardiac arrhythmias, angina pain, vasoconstriction with hypertension

Dermatological: flushing,acne vulgaris
Gastrointestinal: nausea, appetite loss, anorexia
Genitourinary: increased urine output due to increased blood flow
Nervous system:restlessness, confusion, insomnia, mild euphoria, mania/hallucinations (rare except in previously existing psychiatric conditions), delusions, formication (may be possible, but lacks documented evidence) paranoia, hostility, confusion, panic, stereotypical behaviour ('obsessive compulsive' or repetitive tasks such as cleaning, grooming, organizing items arbitrarily) agitation
Respiratory: dyspnea, pulmonary edema
Miscellaneous: dizziness, headache, tremor, hyperglycemic reactions

The approved maximum daily dosage of ephedrine for use as a bronchodilator is 150mg, as specified on the packaging of the bronchodilator and expectorant combination, Bronkaid, made by Bayer pharmaceuticals.

Overdose can lead to death, although the approved dose is not likely to cause severe reactions when used as directed.

Ephedrine can also lead to damage of the brain receptors over a period of large usage this is because of its constant action on the nuerochemicals. It also leads to high increase in blood pressure which over time can lead to damage in the blood vesasals.

Contraindications

Ephedrine should not be used in conjunction with certain antidepressants, namely SNRIs (Selective norepinephrine re-uptake inhibitors), as this increases the risk of the above symptoms due to excessive serum levels of norepinephrine.

Wellbutrin is an example of an antidepressant with an amphetamine-like structure similar to ephedrine. It has a similar action but also releases serotonin from presynaptic clefts. It should not be used with ephedrine as it may increase the liklihood of the above side effects.

Ephedrine should be used in caution in patients with inadequate fluid replacement, impaired adrenal function, hypoxia, hypercapnia, acidosis, hypertension, hyperthyroidism, prostatic hypertrophy, diabetes mellitus, cardiovascular disease, during delivery if maternal BP > 130/80 mmHg, and lactation.[6]

Contraindications for the use of ephedrine include: closed angle glaucoma, phaeochromocytoma, asymmetric septal hypertrophy (idiopathic hypertrophic subaortic stenosis), concomitant or recent (previous 14 days) monoamine oxidase inhibitor (MAOI) therapy, general anaesthesia with halogenated hydrocarbons (particularly cyclopropane or halothane), tachyarrhythmias or ventricular fibrillation, hypersensitivity to ephedrine or

other stimulants, and psychoneurosis (bipolar disorder, severe depression, obsessive compulsive disorder, etc.)

Ephedrine should NOT be used at any time during pregnancy unless specifically indicated by a qualified physician and ONLY when other options are unavailable.[6.

Recreational and illicit use

Anecdotal reports have suggested that ephedrine helps studying, thinking, or concentrating to a greater extent than caffeine. Some students and some white-collar workers have used ephedrine (or Ephedra-containing herbal supplements) for this purpose, as well as some professional athletes and weightlifters. It is common for many athletes to use stimulants while exercising. Such misuse of ephedrine has been associated with stimulant dependence, as well as deaths from heatstroke in athletes and circulatory problems such as aortic aneurysm in weightlifters.

As a phenylethylamine, ephedrine has a similar chemical structure to Amphetamine. Ephedrine can be used in the synthesis of methamphetamine by chemical reduction; this has made ephedrine a highly sought-after chemical precursor in the illicit manufacture of methamphetamine. The most popular method for reducing ephedrine to methamphetamine is similar to the Birch reduction, in that it uses anhydrous ammonia and lithium metal in the reaction. The second most popular method uses red phosphorus, iodine, and ephedrine in the reaction.

Through oxidation, ephedrine can be easily synthesized into methcathinone. Ephedrine is listed as a Table I precursor under the United Nations Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances [7].

Ephedrine has been reported to cause both physical and psychological dependence after excessive long-term use. This is particularly true with oral forms of ephedrine, since parenteral administration is unlikely to occur over long periods [6].

Neurotoxicity of Ephedrine

As a sympathomimetic agent similar in structure and activity to amphetamines, there has been a dispute over whether ephedrine produces some of the same neurodegenerative effects. It has been shown clinically that certain amphetamines (namely (d)-amphetamine and (d)-methamphetamine) can cause varying levels of long-term dopamine depletion in dopamine-rich brain and nervous centers such as the putamen and the basal ganglia.

Several studies have recently compared the quantities of such neurotransmitters as serotonin, dopamine, glutamate, and adrenaline after concurrent administration of ephedrine and various amphetamine-like agents. The results showed that ephedrine has a reduced neurotoxic effect on dopamine than its amphetamine counterparts.

Ephedrine increases serum dopamine levels minimally in comparison with an equivalent dose of dextroamphetamine (Adderall®). Dextromethamphetamine (Desoxyn®) raises dopamine levels dramatically (more than two times that of an equivalent dose of dextroamphetamine). This supports the general consensus that ephedrine has more of a peripheral action on the sympathetic nervous system, whereas amphetamines appear to

cross the blood brain barrier more freely and tend to have a stronger central action. The fact that dopamine is believed to play a major role in the addiction response has been used in recent years as justification for controlling the distribution of dextroamphetamine and dextromethamphetamine, along with various other amphetamines.[8]

Legality in USA

Ephedrine itself has never been illegal. In 1996, the FDA proposed a regulation on ephedra (the herb from which ephedrine is obtained), which limited an ephedra dose to 8mg with no more than 24mg per day. This proposed rule was then withdrawn in 2000 because "concerns regarding the agency's basis for proposing a certain dietary ingredient level and a duration of use limit for these products." In 2004, the FDA created a ban on ephedrine alkaloids that are marketed for reasons other than asthma, colds, allergies, other disease, or traditional Asian use. Products such as VasoPro's ephedrine HCL contains Guaifenesin, which thins the mucus in the air passages and makes it easier to clear the airway, and thus is sold as a bronchodilator. On April 14th, 2005, the US Federal District Court ruled that the FDA did not have proper evidence that low dosages of ephedrine alkaloids are actually unsafe, but on August 17, 2006, the U.S. Court of Appeals for the Tenth Circuit in Denver upheld the FDA's final rule declaring all dietary supplements containing ephedrine alkaloids adulterated, and therefore illegal for marketing in the United States. Ephedrine is, however, still legal in many applications outside of as dietary supplements. However, currently purchasing is limited and records are kept of how much ephedrine is purchased, with the specifics varying from state to state. Although the FDA claims that their ruling is a result from several deaths from people taking large doses, some people believe that it is only because ephedrine is one of the key ingredients for creating crystal meth, and that is the reason the FDA limits the total quantity one can purchase.

Systematic (IUPAC) name

(S)-N-methyl-1-phenyl-propan-2-amine

Identifiers

CAS number 537-46-2

ATC code N06**BA03**

PubChem 1206

Chemical data

Formula $C_{10}H_{15}N$

Mol. weight 149.2 g/mol

Pharmacokinetic data

Bioavailability Depends on route of administration

Metabolism Hepatic

Half life 9-15 hours[1]

Excretion Renal

Therapeutic considerations

Pregnancy cat. $C_{(US)}$

Legal status Schedule I(CA) Schedule II(US) Class A(NZ), Schedule 5(SA), Injectable:Class A, Oral: B(UK)

Routes Medical: Oral
Recreational: Oral, I.V., I.M., Insufflation, Inhalation, Suppository

Methamphetamine (sometimes referred to as methylAmphetamine or desoxyephedrine) is a psychostimulant drug used primarily for recreational purposes, but is sometimes prescribed for ADHD and narcolepsy under the brand name Desoxyn. It causes euphoria and excitement by acting directly on the brain's reward mechanisms, thus making it highly addictive. Methamphetamine rapidly enters the brain and causes a cascading release of norepinephrine and dopamine (and to a lesser extent, serotonin). Users may become obsessed or perform repetitive tasks such as cleaning, hand-washing or assembling and disassembling objects.[2] Withdrawal is characterized by increased sleeping and eating, and depression-like symptoms, often accompanied by anxiety and drug-craving.[3]

Availability and names

In the U.S., illicit methamphetamine comes in a variety of forms, with an average price of $150 per gram of pure substance.[4] Most commonly it is found as a colorless crystalline solid, sold on the street under the name *crystal meth* and a variety of other names. It is also sold as a less pure crystalline powder called crank, or in crystalline rock form. Colourful flavored pills containing methamphetamine and caffeine are known as yaba (Thai for "crazy medicine"). At its most impure, it is sold as a crumbly brown or off-white rock commonly referred to as "peanut butter crank"[5]. Methamphetamine found on the street is rarely pure, but adulterated with chemicals that were used to synthesize it. It may be diluted or "cut" with non-psychoactive substances like inositol. It may also be cut with other psychoactive substances, but the reverse is presumably more common due to its low price relative to other common drugs.

History

Methamphetamine was first synthesized from Ephedrine in Japan in 1893 by chemist Nagayoshi Nagai. In 1919, crystallized methamphetamine was synthesized by Akira Ogata via reduction of Ephedrine using red phosphorus and iodine. The related compound amphetamine was first synthesized in Germany in 1887 by Lazar Edeleanu.

One of the earliest uses of amphetamine occurred during World War II when the German military dispensed the stimulant under the trade name *Pervitin* to troops.[6] The drug was widely distributed across rank and division, from elite forces to tank crews and aircraft personnel. Chocolates dosed with methamphetamine were known as Fliegerschokolade ("flyer's chocolate") when given to pilots, or Panzerschokolade ("tanker's chocolate") when distributed to tank crews.

Adolf Hitler is rumored to have received three daily IV injections of amphetamines and steroids from his personal physician, Theodore Morell. After World War II, a massive supply of amphetamine, formerly stockpiled by the Japanese military, became available in Japan

under the street name shabu (also Philopon (pronounced ÒíÝó, or Hiropon), its tradename there.[7]) The Japanese Ministry of Health banned it in 1951, which is thought to have added to the growing yakuza activities related to illicit drug production.[8] Today, the Japanese underworld is still associated with the drug, although its use is discouraged by strong social taboos.

With the 1950s came a rise in the legal prescription of methamphetamine to the American public. According to the 1951 edition of Pharmacology and Therapeutics (by Arthur Grollman), it was to be prescribed for "narcolepsy, post-encephalitic parkinsonism, alcoholism, ... in certain depressive states... and in the treatment of obesity."

The 1960s saw the start of the significant use of clandestine manufacture to supply methamphetamine. Prior to 1983, U.S. laws prohibiting the possession of precursors and equipment for methamphetamine production were not yet in place. The recreational use of Levoamphetamine sky-rocketed in the 1980s. The December 2, 1989 edition of The Economist described San Diego, California as the "methamphetamine capital of North America."

In 1986, the U.S. government passed the Federal Controlled Substance Analogue Enforcement Act in an attempt to combat the growing use of designer drugs. In spite of this, its use expanded throughout the rural United States, especially in the Midwest and South. Growth of methamphetamine use continues into the 21st century, and many states are considering tougher legislation.

On August 8, 2005, an issue of Newsweek devoted a cover story to methamphetamine and its abuse,[9] including criticism of the Bush administration's policies regarding meth. Newsweek blamed the administration for not devoting enough resources to education about and prevention of the drug's use. The Bush administration has countered with the position that cannabis is a dangerous 'gateway drug', so prevention of cannabis use should prevent potential abusers from trying and becoming hooked on "hard" drugs such as methamphetamine.

Meanwhile, the online magazine Slate posted an article in reaction to the Newsweek article,[10] attacking Newsweek for failing to appropriately cite sources and data to back up the claim that this is a "new" problem. The topic remains controversial. The most recent figures released by the Federal government indicate that contrary to public perception, methamphetamine use has actually declined nationally in recent years.[11]

Production

Methamphetamine is most structurally similar to methcathinone and Amphetamine. In illicit production, it is commonly made by the reduction of Ephedrine or pseudoephedrine. Most of the necessary chemicals are readily available in household products or over-the-counter medicines. Synthesis is relatively simple, but most methods involve flammable and corrosive chemicals. As a result, clandestine production is often discovered due to fires caused by amateur chemists working with makeshift laboratory equipment.

Most production methods involve hydrogenation of the hydroxyl group on the ephedrine/pseudoephedrine molecule. The most common method in the United States involves red phosphorus and iodine which forms hydroiodic acid. This is a fairly dangerous process; in fact, on the Darwin Awards site, there is a story of a man who burned himself

trying to conceal these chemicals.[12] The red phosphorus production method can create phosphine gas, which is extremely toxic when inhaled. An increasingly common method utilizes a Birch reduction process, where metallic lithium is substituted for metallic sodium (due to the difficulty in obtaining metallic sodium). The Birch reduction is dangerous since the alkali metal and liquid anhydrous ammonia are both extremely reactive, and because the temperature of liquid ammonia makes it susceptible to explosive boiling when reactants are added.

Other less-common methods use other means of hydrogenation, such as hydrogen gas in the presence of a catalyst.

A completely different synthesis procedure involves creating methamphetamine by the reductive amination of phenylacetone with methylamine, both of which are currently DEA list I chemicals (as are pseudoephedrine and ephedrine). This was once the preferred method of production by motorcycle gangs in California, but DEA restrictions on the chemicals have made this an uncommon way to produce the drug today.

One of the more obvious signs of a production lab of metamphetamine in operation is the smell of a cat-urine-like odor.

When performed by individuals who are not trained chemists, methamphetamine manufacture can lead to extremely dangerous situations. For example, if the red phosphorus reaction is allowed to overheat, phosphine gas can be produced. When produced in large quantities, it usually explodes, due to autoignition from diphosphine formation caused by overheating phosphorus.

Until the early 1990s, methamphetamine for the US market was made mostly in clandestine labs run by drug traffickers in Mexico and California. These areas are still the largest producers for the U.S. market. Since then, however, authorities have discovered increasing numbers of small-scale methamphetamine labs all over the United States, mostly located in rural, suburban, or low-income areas. The Indiana state police found 1,260 labs in 2003, compared to just 6 in 1995, although this may only be a result of increased police activity.[13]

Recently, mobile and motel-based methamphetamine labs have caught the attention of both the US news media and law enforcement agencies. The labs can cause explosions and fires, as well as expose the public to hazardous chemicals. In addition to these issues, individuals who manufacture methamphetamine are often harmed by toxic gases. Many police forces have responded by creating a specialized task force educated in responding to persons involved in methamphetamine production.

The amount of methamphetamine actually contributed to the US market by small-scale labs is disputed. Large-scale labs maintained by criminal organizations continue to exist. In the United States, Drug policy critics suggest that restriction of over-the-counter medication is more politically than socially motivated, and may in fact shift the balance of supply more in favor of large criminal organizations.

Distribution

A wide variety of groups are involved in the distribution of methamphetamine, from the aforementioned prison gangs and motorcycle gangs to street gangs, traditional organized crime operations, and impromptu small networks made up of users. The government of

North Korea has been linked to the manufacture and distribution of crystal meth, and allegedly plays a role in distribution networks throughout Asia as well as those in Australia and even in North America [14]. Regardless, meth trafficking is not exclusively dominated by cartels along the lines of Colombian cocaine cartels or Pakistani heroin cartels.

Medical use

- Attention deficit hyperactivity disorder
  Narcolepsy
  Extreme obesity
  Severe depression

- Decongestant

Pharmacology

Methamphetamine is a potent central nervous system stimulant which affects neurochemical mechanisms responsible for regulating heart rate, body temperature, blood pressure, appetite, attention, mood and responses associated with alertness or alarm conditions. Methamphetamine causes the norepinephrine transporter, dopamine transporter to reverse their direction of flow. This inversion leads to a release of these transmitters from the vesicles to the cytoplasm and from the cytoplasm to the synapse, causing increased stimulation of post-synaptic receptors. Methamphetamine also indirectly prevents the reuptake of these neurotransmitters, causing them to remain in the synaptic cleft for a prolonged period. Serotonin levels are only weakly affected (ratio NE: DA = 2:1, NE:5HT = 60:1).[15] It is neurotoxic in overdose.[16]

The acute effects of the drug closely resemble the physiological and psychological effects of an

L-methamphetamine (also called levmetamfetamine and desoxyephedrine) has nasal decongestant activity and no abuse potential. This is the active ingredient in the US Vicks Inhaler.

Tolerance

As with other amphetamines, tolerance to methamphetamine is not completely understood, but known to be sufficiently complex that it cannot be explained by any single mechanism. The extent of tolerance and the rate at which it develops varies widely between individuals, and even within one individual it is highly dependant on dosage, duration of use and frequency of administration. Many cases of narcolepsy are treated with methamphetamine for years without escalating doses or any apparent loss of effect.

Short term tolerance can be caused by depleted levels of neurotransmitters within the vesicles available for release into the synaptic cleft following subsequent reuse (tachyphylaxis). Short term tolerance typically lasts 2-3 days, until neurotransmitter levels are fully replenished. Prolonged overstimulation of dopamine receptors caused by

methamphetamine may eventually cause the receptors to downregulate in order to compensate for increased levels of dopamine within the synaptic cleft.[17] To compensate, larger quantities of the drug are needed in order to achieve the same level of effects.

Side effects

The most common side effects include twitching, "jitteriness", repetitive behavior (known as "tweaking"), and jaw clenching or teeth grinding.

Methamphetamine addicts may lose their teeth abnormally fast, a condition known as "meth mouth". Similar, though far less severe symptoms have been reported in clinical use of other amphetamines, where effects are not exacerbated by a lack of oral hygiene for extended periods.[18] Like other substances which stimulate the sympathetic nervous system, methamphetamine causes decreased production of acid-fighting saliva and increased thirst, resulting in increased risk for tooth decay, especially when thirst is quenched by high-sugar drinks.[19]

Users may exhibit sexually compulsive behavior and may engage in sexual acts with one or more individuals. This sexual behavior is believed to have created a link between meth use and sexually transmitted disease (STD) transmission, especially HIV and syphilis. This caused great concern among larger gay communities, particularly those in Atlanta, Miami, Chicago, New York City, and San Francisco, leading to outreach programs and rapid growth in 12-step organizations such as Crystal Meth Anonymous.

Common side effects:[20]

- Diarrhea, nausea
- Loss of appetite, insomnia, tremor, jaw-clenching
- Agitation, compulsive fascination with repetitive tasks (Punding)
- Talkativeness, irritability, panic attacks
- Increased libido
- Dilated pupils

Side effects associated with chronic use:

- Drug craving
- Weight loss
- Withdrawal-related depression and anhedonia
- Erectile dysfunction ("Crystal cock")
- Rapid tooth decay ("meth mouth")
- Amphetamine psychosis

Side effects associated with overdose:

- Formication (sensation of flesh crawling with bugs, with possible associated compulsive picking and infecting sores "Meth Mites")
- Brain damage (Neurotoxicity)

- Paranoia, delusions, hallucinations
- Kidney damage (from Hyperkalemia)

Overdose fatalities are usually due to stroke or heart failure, but can also be caused by hyperthermia or kidney failure.

Addiction

Methamphetamine is highly addictive, particularly when injected or smoked.[21] While not life-threatening, withdrawal is often intense and, as with all addictions, relapse is common. To combat relapse, many recovering addicts attend 12 Step meetings, such as Crystal Meth Anonymous.

In an article about his son's addiction to methamphetamine, a California writer who has also experimented with the drug put it this way:

[T]his drug has a unique, horrific quality. In an interview, Stephan Jenkins, the singer in the band Third Eye Blind, said that methamphetamine makes you feel 'bright and shiny.' It also makes you paranoid, incoherent and both destructive and pathetically and relentlessly self-destructive. Then you will do unconscionable things in order to feel bright and shiny again.[22]

Former users have noted that they feel stupid or dull when they quit using methamphetamine. This is because the brain is adapting a need for methamphetamine to think faster, or at what seems to be a higher level. Individuals with ADHD may be at higher risk for addiction to methamphetamine, because the drug increases the user's ability to focus and reduces impulsivity. Because of its abuse potential, meth is not generally prescribed for ADHD unless other stimulants, such as methylphenidate (Ritalin®), dextroamphetamine (Dexedrine®) or mixed amphetamines (Adderall®) have failed.

With long-term use, abstinence often leads to slow thinking and depression, which in turn requires that the addict use more meth to 'fix' it. A chronic pattern of such behavior is known colloquially as "The Vampire Life."

Serious drug addiction correlates with poor hygiene and general self-care, and even minor health problems can lead to serious complications when left untreated. Striking health problems popularly associated with methamphetamine addiction, such as severe tooth decay or massive skin infections, are caused by unsterilized needles and a lack of hygiene. Even long-term use does not generally result in outward symptoms, but may lead to hypertension, damage to heart valves, and increased risk of strokes.

Routes of administration

The usual route for medical use is oral administration. In recreational use it can be swallowed, snorted, smoked, dissolved in water and injected (or even without water, in what is called a dry shot), inserted anally (with or without dissolution in water), or into the urethra. [23] As with all addictive drugs, the potential for addiction is greater when it is delivered by methods that cause the concentration in the blood to rise quickly, principally because the effects desired by the user are felt more quickly and with a higher intensity than through a moderated delivery mechanism. In fact, studies have shown that the subjective pleasure of drug use (the reinforcing component of addiction) is proportional to the rate that

the blood level of the drug increases. In general, smoking is the fastest mechanism (i.e., it causes the blood concentration to rise the most quickly in the shortest period of time as it allows the substance to travel to the brain through a more direct route than intravenous injection), followed by injecting, snorting, anal insertion, and swallowing.

"Smoking" methamphetamine actually refers to vaporizing it to produce fumes, rather than burning and inhaling the resulting smoke, as with tobacco. It is commonly smoked in glass pipes, or in aluminum foil heated by a flame underneath. This method is also known as "chasing the white dragon" (as derived from the method of smoking opium known as "chasing the dragon"). There is little evidence that methamphetamine inhalation results in greater toxicity than any other route of administration. Lung damage has been reported with long-term use, but manifests in forms independent of route (pulmonary hypertension and associated complications), or limited to injection users (pulmonary emboli).

Injection is a popular method for use, but potentially carries quite serious risks. The hydrochloride salt of methamphetamine is soluble in water; injection users may use any dose from 125 mg to over a gram in one I.V. dose using a small needle. This dosage range may be fatal to non-addicts; addicts rapidly develop tolerance to the drug. Injection users often experience skin rashes (sometimes called "speed bumps") and infections at the site of injection. As with any injected drug, if a group of users shares a common needle or any type of injecting equipment without sterilization procedures, blood-borne diseases such as HIV or hepatitis can be transmitted as well.

Very little research has focused on anal insertion as a method, and anecdotal evidence of its effects is infrequently discussed, possibly due to social taboos in many cultures regarding the anus. This is often known within communities that use meth for sexual stimulation as a "booty bump" or "Keistering," and is anecdotally reported to increase sexual pleasure while the effects of the drug last.[24] The rectum is where the majority of the drug would likely be taken up, through the mucous membranes lining its walls.

Legality

See pseudoephedrine, for legal restrictions placed on that drug as a result of its use as a precursor in the clandestine manufacture of methamphetamine.

Australia

The medical use of methamphetamine is not recognised in Australia and as such it is outlawed.

Canada

Methamphetamine is not approved for medical use in Canada. As of 2005, it falls under Schedule I of the Controlled Drugs and Substances Act. The maximum penalty for the production and distribution is imprisonment for life.

New Zealand

Methamphetamine is a Class A controlled drug under the New Zealand Misuse of Drugs Act 1975. The maximum penalty for production and distribution is imprisonment for life. The maximum penalty for possession is imprisonment for six months. The NZ Misuse of Drugs Act 1975 also covers a "presumption amount". This refers to the quantity of drug that is in a person's possession. If a person is caught with more than a certain amount, it is assumed that the person is in possession of that drug for the purpose of supplying it.

South Africa

In South Africa, methamphetamine is classified as a Schedule 5 drug, and is listed as Undesirable Dependence-Producing Substances in Part III of Schedule 2 of the Drugs and Drug Trafficking Act, 1992 (Act No 140 of 1992).[25] Commonly called "tik", it is mostly abused by youths under the age of 20 in the Cape Flats areas.

United Kingdom

In the UK, methamphetamine was classified as a Class B drug under the Misuse of Drugs Act 1971. The maximum penalty for possession is five years imprisonment, and the maximum penalty for supplying is 14 years. If methamphetamine (or any other Class B drug) is prepared for injection, then it is re-classified as a Class A drug. The maximum penalty for such possession is seven years imprisonment, and the maximum penalty for supplying is life imprisonment.

In 2006, it was announced that methamphetamine is to be reclassified as a Class A drug and has been reclassed as such, following a recommendation made by the Advisory Council on the Misuse of Drugs.[26]

United States

Methamphetamine is classified as a Schedule II substance by the Drug Enforcement Administration under the Convention on Psychotropic Substances.[27] While there is technically no difference between the laws regarding methamphetamine and other controlled stimulants, most medical professionals are averse to prescribing it due to its notoriety.

Methamphetamine is legally marketed in the United States under the trade name Desoxyn, manufactured by Ovation Pharma. Generic formulations of the drug are also available.

Methamphetamine has become a major focus of the 'war on drugs' in the US in recent years. In some areas of the United States, manufacturing methamphetamine is punishable by a mandatory ten-year prison sentence. In certain instances, however, judges have ruled for life in prison without the possibility of parole, especially in cases where victims were killed

by overdoses or impure substances. Crackdowns on the theft of anhydrous ammonia, a substance used in the manufacture of the drug, have resulted in additional prison time.

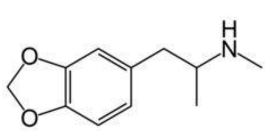
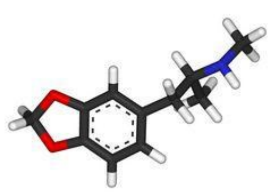
Methylenedioxymethamphetamine





MDMA

1-(benzo[d][1,3]dioxol-5-yl)-N-methylpropan-2-amine

CAS number

42542-10-9
66142-89-0
69610-10-2
81262-70-6

Chemical formula

$C_{11}H_{15}NO_2$

Molecular weight

193.25 g/mol

SMILES

CC(NC)CC1=CC=C(OCO2)C2=C1

Elimination half life

The half-life of MDMA is dose dependent, increasing with higher doses, but is around 6-10 hours at doses of 40-125 mg

Legal status

Schedule I (USA)
Class A (UK)
Schedule III (Canada)

Delivery

75-120 mg tablets
100 mg sublingual

Recreational uses:

euphoria *Other putative uses:* Marriage counseling
Anxiety
PTSD
End of Life Care *Contraindications:* Not for use in combination with stimulants (amphetamines, large doses of caffeine, etc).

Not for use in combination with diuretics (alcohol).

Not for use in individuals with high blood pressure, hypertension, or blood clotting disorders.

Not for use in individuals who have displayed allergies to amphetamine drugs.

Must never be used in combination with MAOI (Monoamine Oxidase Inhibitor) drugs.

Side effects:

Endocrine: hyponatremia *Eye:* dilated pupils

nystagmus *Psychological:* euphoria
strong sense of empathy
serotonin deficiency *Skin:*

- sweaty palms
- heavy sweating
- increased heart rate
- Increased body temperature

Miscellaneous:

- restlessness
- chattering teeth
- muscle spasms

MDMA (*3,4-methylenedioxy-N-methylamphetamine*), most commonly known by the street names *Ecstasy*, *E* or *X*, is a semisynthetic entactogen of the phenethylamine family, whose primary effect is believed to be the stimulation of secretion as well as inhibition of re-uptake of large amounts of serotonin as well as dopamine and norepinephrine in the brain, inducing a general sense of openness, empathy, energy, euphoria, and well-being. Tactile sensations are enhanced for some users, making general physical contact with others more pleasurable; but, contrary to popular belief it generally does not have aphrodisiac effects. Its reported ability to facilitate self-examination with reduced fear may prove useful in some therapeutic settings, leading in 2001 to permission from the United States FDA for testing in patients with post-traumatic stress disorder in conjunction with psychotherapy.

Acute dehydration is a risk among users who are highly physically active and forget to drink water, as the drug may mask one's normal sense of exhaustion and thirst. Also the opposite, "water intoxication," resulting in acute hyponatremia, has been reported as a consequence of use. Sometimes dangerous chemicals such as PMA or methamphetamine alone or in combination with MDMA are added to ecstasy tablets. Long-term effects in humans are largely unknown and the subject of much controversy - particularly with regard to the risks of severe long-term depression as a result of a reduction in the natural production of serotonin.

History

A patent for MDMA was originally filed on Christmas Eve 1912 by the German pharmaceutical company Merck, after being first synthesised for them by German chemist

Anton Köllisch at Darmstadt earlier that year [1][2]. The patent was granted two years later, though in 1916, after two more additional years Köllisch died with no idea of the impact his synthesis would have. At the time, MDMA was not known to be a drug in its own right; rather, it was patented as an intermediate chemical used in the synthesis of a styptic (a drug intended to control bleeding from wounds.) Over half a century would pass before the first recorded ingestion of MDMA by humans.

The U.S. Army did, however, carry out lethal dose studies on MDMA and several other compounds in the mid-1950s. It was given the name *EA-1475*, with the EA standing for Edgewood Arsenal. The results of these studies were not declassified until 1969.

MDMA was legal in the United States until May 31, 1985. Before then, it was used both as an adjunct to psychotherapy and as a recreational drug. MDMA began to be used therapeutically in the mid-1970s after the chemist Alexander Shulgin introduced it to psychotherapist Leo Zeff. As Zeff and others spread word about MDMA, it developed a reputation for enhancing communication, reducing psychological defenses, and increasing capacity for introspection. However, no formal measures of these putative effects were made and blinded or placebo-controlled trials were not conducted. A small number of therapists–including George Greer, Joseph Downing, and Philip Wolfson–used it in their practices until it was made illegal.

MDMA appeared sporadically as a street drug in the early 1970s, but it came into prominence in the early 1980s in certain trendy yuppie bars in the Dallas area, then in gay dance clubs. From there use spread to rave clubs, and then to mainstream society. During the 1990s, along with the growing popularity of the rave subculture, MDMA use became increasingly widespread among young adults in universities and later in high schools. It rapidly became one of the four most widely used illegal drugs in the U.S., along with cocaine, heroin and marijuana.

In the late 1980s and early 1990s, ecstasy was widely used in the United Kingdom and other parts of Europe, becoming an integral element of rave culture. It has also been associated with other psychedelic/dancefloor-influenced music scenes, such as Madchester and Acid House.

Recreational use

The primary effects of MDMA include feelings of openness, euphoria, empathy, love, and heightened self-awareness. Its initial adoption by the dance club sub-culture is possibly due to the enhancement of the overall social and musical experience. Taking MDMA or ecstasy is commonly referred to as popping, rolling, pilling, boshing or dropping in the United Kingdom, "pinging" or "peaking" in Australia, "flipping", "getting chewed" and/or "murfing" in Canada. Some term the rushing feeling of the drug as blowing up, coming up, flying, rolling face,or zooming.

MDMA use has increased markedly since the late 1980s, and spread beyond its original sub-cultures to mainstream use. Prices have also fallen since the 1980s. In countries where distribution is more extensive, such as in the Netherlands and other places in Europe, prices can sometimes be as low as €1 per tablet. In countries where distribution is more difficult, such as the US and Australia, prices are accordingly higher at up to US$10-20 and AUD$35-50 respectively per tablet. In the United Kingdom it is common to pay around £2 to £3 for a

tablet on average. Prices are also usually higher when the drug is purchased in a club or at a rave.

Supply and administration

MDMA is usually ingested in pill form, although use of powder or crystal is increasing in popularity (sometimes known as "Mud," "Molly," "Mandy," "M.D." or "Madman"). Pills come in a variety of "brands", usually identified by the icons stamped on the pills. However the brands do not consistently designate the actual active compound within the pill, as it is possible for "copycat" manufacturers to make their own pills which replicate the features of a well-known brand.

Although full and proper characterization of ecstasy pills requires advanced lab techniques such as gas chromatography-mass spectrometry and gas chromatography-infrared spectroscopy, it is also possible to use a less accurate presumptive alkaloid test known as the Marquis reagent. Many organizations sell testing kits containing this reagent. DanceSafe is one such company, and it includes an extensive database of photographs of different pills, along with the results of a laboratory analysis of their contents. EcstasyData.org [3] is a non-profit site that tests the purity of street pills and compiles results. PillReports.com allows users to post reports of pills they've purchased and share the experience, pictures, and testing results. Other users can then post what they think about the pill in question or even rate the report on the pill.

Effects

Pharmacokinetics

MDMA reaches maximal concentrations in the blood between 1.5 and 3 hours after ingestion. It is then slowly metabolized and excreted, with levels decreasing to half their peak concentration over approximately 8 hrs. Metabolites of MDMA that have been identified in humans include 3,4-methylenedioxyamphetamine (MDA), 4-hydroxy-3-methoxy-methamphetamine (HMMA), 4-hydroxy-3-methoxyamphetamine (HMA), 3,4-dihydroxyamphetamine (DHA, also called alpha-methyldopamine), 3,4-methylenedioxyphenylacetone (MDP2P), and N-hydroxy-3,4-methylenedioxyamphetamine (MDOH). The contributions of these metabolites to the psychoactive and toxic effects of MDMA are an area of active research.

MDMA is known to be metabolized via three pathways. One such pathway proceeds via N-demethylation; byproducts of which include several active metabolites, including MDA. The metabolism may be primarily by the cytochrome P450 enzymes CYP2D6 (in humans, but CYP2D1 in mice), and CYP3A4. Complex, nonlinear pharmacokinetics arise via autoinhibition of CYP2D6 and CYP2D8, resulting in zeroth order kinetics at higher doses. It is thought that this can result in sustained and higher drug concentrations if the user takes consecutive doses of the drug. 65% of MDMA is excreted unchanged in the urine (additionally 7% is metabolised into MDA) during 24 hours after usage

MDMA is a chiral compound and has been almost exclusively administered as a racemate. However, an early uncontrolled report suggests that the S-enantiomer is significantly more potent in humans than the R-enantiomer (Anderson et al. 1978). Studies in humans indicate that the disposition of MDMA is stereoselective, with the S-enantiomer having a shorter elimination half-life and greater excretion than the R-enantiomer. For example, Fallon et al. (1999) reported that the area under the plasma concentration versus time curve (AUC) was two to four times higher for the R-enantiomer than the S-enantiomer after a 40 mg oral dose in human volunteers. Similarly, the plasma half-life of (R)-MDMA was significantly longer than that of the S-enantiomer ((5.8 ± 2.2 hours) vs 3.6 ± 0.9 hours). However, because MDMA has dose dependent kinetics, it is likely that these half lives would be higher at more typical doses (100 mg is sometimes considered a typical dose). Given as the racemate, MDMA has a half-life of around 8 hours.

Short-term neurochemical effects

Serotonin is a neurotransmitter believed to play a role in the regulation of mood and pleasure. MDMA causes serotonin vesicles in the neurons to release quantities of serotonin into the synapses. Although popular press accounts focus on the role of serotonin release, the mechanism by which MDMA causes its unusual psychoactivity is largely unknown. In vitro and nonhuman animal studies have established that MDMA also induces dopamine, norepinephrine, and acetylcholine release and can act directly on a number of receptors, including a2-adrenergic (adrenaline) and 5HT2A (serotonin) receptors. MDMA promotes the release of several hormones including prolactin and the antidiuretic hormone vasopressin, which may be important in its occasional production of water intoxication or hyponatremia.

Subjective effects

Effects desired by users include:

- increased positive emotion and decreased negative emotion
- increased sense of well-being
- increased sociability and feelings of closeness or connection with other people
- reduced defensiveness and fear of emotional injury
- a sense of increased insightfulness and introspective ability

MDMA, particularly with larger doses, is sometimes reported to cause visual distortions. In a review of studies in which 1.5 to 1.7 mg/kg oral MDMA was administered in their laboratory to 74 people, Vollenweider et al. reported that scenic hallucinations were reported only once, while simple patterns, distorted objects, and flashes of light were commonly reported

Other short-term effects

Acute physiological effects include:

- Pupil dilation with attendant photosensitivity and color perception
- Nystagmus
- General restlessness
- Loss of appetite
- Increased heart rate and blood pressure
- Loss of sleep
- Dehydration

Acute toxic/dangerous effects

Apart from the dangers from impurities, the primary acute risks of taking MDMA resemble those of other stimulant amphetamines. The majority of fatalities and cases

requiring emergency care involve hyperthermic syndromes. MDMA appears to decrease heat loss in the body by causing constriction of blood vessels near the skin. In addition, it may sometimes increase heat production by muscles and the brain. These effects may be amplified in people who become dehydrated and are unable to cool by sweating. MDMA can mask the body's normal thirst and exhaustion responses, particularly if a user is dancing or is otherwise physically active for long periods of time without hydration. Because of these effects, MDMA can temporarily reduce the body's ability to regulate its core temperature, and in high-temperature surroundings (e.g. clubs) combined with physical exertion this may lead to hyperpyrexia if precautions are not taken to remain cool. Sustained hyperpyrexia may lead to rhabdomyolysis (muscle breakdown), which in turn can cause renal failure and death.

It has been argued that "the seriousness of the effects can be dependent on environmental factors other than the drug concentration," as blood concentrations of the drug spanned a large range in cases of death in MDMA users. This notwithstanding, "most of the cases of serious toxicity or fatality have involved blood levels... up to 40 times higher than the usual recreational range." (Kalant H., 2001)

While dehydration is undesirable, there also have been a number of users suffering from water intoxication and associated hyponatremia (dilution of the blood that can cause swelling of the brain). Although many cases of this clearly involved individuals drinking large amounts of water, there are cases where there is no evidence of excessive water consumption. Their cases may be caused by MDMA inducing release of the antiduretic hormone vasopressin by the pituitary gland. This causes one to retain water to a greater extent. The death of British teen Leah Betts may be the most widely publicised MDMA-related fatality, and resulted from her consuming too much water due to concerns over dehydration. Signs of hyponatremia include confusion, nausea, headache and loss of consciousness. Hyponatremia in MDMA users is a medical emergency and requires prompt treatment. In general, females are at greater risk of developing symptoms and dying from hyponatremia than males.

MDMA users have also been recorded to demonstrate bruxism (teeth grinding) and trisma (jaw clenching) as a short-term effect from the drug [13] Many users of MDMA alleviate this by using chewing gum [14], however this can result in temporary mouth ulcers through inadvertent biting of the mouth lining. Temporary jaw ache often results from jaw clenching or excessive chewing. Some users consume supplemental magnesium tablets to relax the jaw muscles and relieve clenching.

While users sometimes report increased sexual desire, there are many reports of difficulty achieving orgasm and erection while on the drug. "[MDMA] is a love drug but not a sex drug for most people." (Beck & Rosenbaum, 1994). This is the rationale behind the use of sextasy (combining MDMA with Viagra).

There are reported allergic reactions, which are extremely rare. Liver damage, which may have an immunological cause, has been seen in a small number of users. Animal studies suggest risk and extent of liver damage is increased by high body temperature.

A UK parliamentary committee commissioned report found the use of "Ecstasy" to be less dangerous than tobacco and alcohol in social harms, physical harm and addiction [4]

While most MDMA is taken orally, some users resort to drug injection to achieve a faster, more intense effect. This entails the risks associated with injection of many illicit drugs,

including the transmission of blood-borne viruses, bacterial infections, vein damage and increased chance of overdose.

Addiction and Tolerance

The potential of MDMA to produce addiction (dependence) is controversial. Some studies indicate that many users may be addicted. For example, Cottler et al (2001) interviewed 52 users and found that 43% met standard criteria for dependence. However, some of these people may have been inappropriately diagnosed with dependence because they reported tolerance or after effects from MDMA. Tolerance and after effects ('withdrawal' effects) are symptoms of dependence for many drugs, but seem to occur in some MDMA users who are actually not dependent. For example, studies in Switzerland in which MDMA was given to people who had never used it before documented after effects. When people are classified as addicted to MDMA, it is not clear if that indicates a difficulty in quitting the drug. In a prospective study in Germany, many who were initially categorized as addicted, spontaneously 'improved' without any treatment for the alleged addiction. Given the complexities in classifying MDMA users as addicted, conclusions about the addictive potential of MDMA are less reliable than nicotine addiction.

Long-term adverse effects

Long-term effects are still unknown and heavily debated among scientists. There are several reports of Hallucinogen Persisting Perception Disorder being induced by MDMA. In some cases, the disorder appears to be permanent. The disorder seems to occur in only a small fraction of a percentage of users, and its mechanism of causation is unknown.

Some experiments indicate that use at very high doses may lead to the Synaptic Terminals of serotonin neurons being damaged. The precise mechanism of this action is unknown, but recent evidence (Jones 2004; Miller 1997; Monks et al. 2004) suggests that the metabolic breakdown of MDMA includes the formation of reactive oxygen species (ROS), chemicals known to cause oxidative cell damage when taken up into the releasing synapse.

This effect has been demonstrated experimentally in the brains of rats, where the serotonin terminals of animals who are given extremely high doses of MDMA over a prolonged period of time (usually ten to one hundred times greater than a typical human dose) become withered and useless, although this isn't certain[5][6]. This hypothesis is supported by the fact that the administration of selective serotonin reuptake inhibitors ("SSRIs", which bind to the serotonin cell's reuptake transporters and thus block ROS from entering the serotonin cells) along with or immediately following MDMA seems to block neuron damage in rats given MDMA.

The mechanism proposed as a large part of this neurotoxicity and its functional consequences appear to involve the induction of oxidative stress. This stress results from an increase in free radicals and a decrease in antioxidants in the brain. (Shankaran, 2001) Oxidation is part of the normal metabolic processes of the body. As the cell goes about its life, by-products called oxidative radicals are formed, also called free radicals. These molecules have an unpaired electron that makes them highly reactive. They pull strongly on the

electrons of neighboring molecules and destabilize the electrical balance of those molecules, sometimes causing those molecules to fall apart. This can become a chain reaction.

In normal functioning, there are antioxidants in the system that act as free radical scavengers. These are molecules with an extra electron that they are willing to give up to the free radicals, making both the free radical and the antioxidant more stable. MDMA rapidly increases the levels of free-radicals in the system and overwhelms the reserves of scavengers. The radicals then damage cell walls, reduce the flexibility of blood vessels, destroy enzymes, and cause other molecular damage in the neurological pathways. (Erowid, 2001) It has been shown that MDMA-neurotoxic effects are increased by a hyperthermic environment and decreased by a hypothermic one. (Yeh, 1997)

Studies have suggested that the neurotoxic molecules are not hydroxyl free radicals, but superoxide free radicals. When rats are injected with salicylate, a molecule that scavenges hydroxyl free radicals, the neurotoxic effects of MDMA are not attenuated, but actually potentiated. Further evidence of this superoxide theory comes from the observation that CuZn-superoxide dismutase transgenic mice (mice with excess human antioxidant enzyme) demonstrate neuroprotective mechanisms that protect the mice from MDMA-induced depletion of 5-HT (serotonin) and 5-HIAA and lethal effects. (Baggott, 2001 and Yeh, 1997)

Studies giving animal species injections have shown that ascorbic acid, alpha lipoic acid, l-cysteine, and some other radical scavengers are effective in reducing oxidative stress caused by MDMA. (Erowid, 2001) A combination of antioxidants, including Vitamin A, C, and E are recommended; taking multivitamins including selenium, riboflavin, zinc, cartenoids, etc. should help reduce oxidative damage. Many of these vitamins, though, are water soluble, and are quickly excreted from the body. The typical MDMA user is psychoactive for 4-6 hours and may not have an appetite from the time of taking until the following sleep cycle or many hours later. These vitamins flush through the system in 3-4 hours. Damage occurs in the absence of these antioxidants.

There are some fallacies in applying these animal studies to human use. Firstly, it is difficult to equate rat doses to human doses, rats metabolise MDMA twice as fast as humans and often larger doses or multiple doses are administered to simulate human plasma levels. The doses given in experiments are far greater than typical human use of 100-300 mg in order to notice the problems caused so that we may say that if this happens at large doses, then a lesser form should happen at low doses. There could be a threshold of nothing happening or a threshold of the worst problems at low doses.

Secondly, the effective doses of antioxidants given to these animals are much higher than humans would ever take both in its method of administration (injected vs. oral) and in its dosage. Essentially both the neurotoxic and neuroprotective effects are exaggerated, but it is not possible to say if this scales down the same way.

Some MDMA users administer an SSRI while, or shortly after taking MDMA, in an attempt to prevent possible neurotoxicity. These SSRIs are typically antidepressants such as fluoxetine or

However, MDMA use in conjunction with a different class of antidepressants, namely Monoamine oxidase inhibitors, is strongly contra-indicated due to danger of serotonin syndrome and the possibility of life-threatening hypertension. The safety of this practice has not been systematically evaluated.

Many users also attempt to replenish the deficit of serotonin which follows the use of MDMA [7] by administering 5-HTP, in an attempt to alleviate to a degree the depression and overall mental unsettlement in the days following MDMA usage [8] (including the immediate "come-down" and what is known as "suicide Tuesday"). The serotonin precursor 5-HTP, which is commercially available as a dietary supplement, reportedly supplies the user with more of the raw materials to synthesize the neurotransmitter, reducing the negative psychological effects of depleted serotonin. Pre-loading with 5-HTP has not been shown to increase the subjective effects of MDMA. Anecdotal reports seem to indicate this is largely placebo with some users reporting a moderate muting of the MDMA effect when 5-HTP is consumed within 24 hours prior to MDMA use.[9]

Because the neurotoxicity of MDMA is believed by some to be highly dependent on its metabolic disposition (Jones 2004; de la Torre & Farré 2004), it is unclear how to generalize to humans from experiments in rats and monkeys.

Considerable research has been done into possible cognitive-behavioral deficits among ecstasy users but data have been largely inconclusive. At least two meta-analyses of these studies have been completed (Morgan 2000; Sumnall & Cole 2005). Morgan's analysis of 17 studies showed that ecstasy users had a slight tendency to be more impulsive and depressed than controls. Sumnall and Cole's analysis showed a slight increase in the prevalence of depressive symptoms in ecstasy users over controls. Of course, in retrospective studies like these we are always faced with a chicken-or-egg question: did these impulsive and depressed people use ecstasy to self-medicate or did otherwise normal people become depressed and impulsive after using ecstasy? This question has not been answered.

Although some experimental evidence exists indicating that long-term ecstasy users experience memory difficulties, a large study in 2002 (Strote et al.) showed that ecstasy users in 4-year colleges have GPAs which do not differ significantly from those of non-users.

MDMA and Parkinson's

Research at the University of Manchester indicates that MDMA dramatically reduces tremors in patients receiving L-DOPA treatment for Parkinson's disease.

In a now-retracted study, a research team led by Dr. George A. Ricaurte at Johns Hopkins University implicated MDMA as a cause of Parkinson's-like brain abnormalities in monkeys, suggesting that a single use of MDMA caused permanent and serious brain damage. These claims were hotly disputed by physicians, therapists, and other experts in the field, including a team of scientists at New York University. Criticisms of the study included its use of injection rather than oral administration; that this type and scale of damage (>20% mortality) would translate to hundreds of thousands or millions of deaths which had not materialized in the real world amidst extremely broad global MDMA usage; and, perhaps most important, that other research teams could not duplicate the study's findings.

On September 6, 2003, Dr. George A. Ricaurte and his team announced that they were retracting all results of their commonly cited and controversial study. The researchers said that the labels on the drugs had been somehow switched, and they had inadvertently injected their experimental monkeys and baboons with extremely high doses of methamphetamine instead of MDMA. The chemical supplier, Research Triangle Institute, has publicly claimed

that the proper drug was supplied, and Ricaurte has yet to pursue them for their alleged error.

Ricaurte had also come under fire for supplying PET scans to the U.S. Office of National Drug Control Policy that were used in anti-drug literature (Plain Brain/Brain After Ecstasy) that seemed to suggest MDMA created holes in human brains, an implication that critics called misleading. Ricaurte later asked the Agency to change the literature, citing the "poor quality" of the images. These images are still circulating in educational systems across the U.S., however, and the myth that ecstasy users develop "holes in their brains" remains quite popular and government funded.

Legal issues

Use, supply and trafficking of ecstasy are currently illegal in most countries. In the United States, MDMA was legal and unregulated until May 31st 1985, at which time it was added to DEA Schedule I, for drugs deemed to have no medical uses and a high potential for abuse. During DEA hearings to criminalize MDMA, most experts recommended DEA Schedule III prescription status for the drug, due to its beneficial usage in psychotherapy. The judge overseeing the hearings, Francis Young, also made this recommendation. Nonetheless, the DEA classified it as Schedule I[10].

That same year, the World Health Organization's Expert Committee on Drug Dependence recommended that MDMA be placed in Schedule I of the Convention on Psychotropic Substances. Unlike the Controlled Substances Act, the Convention has a provision (in Article 7(a)) that allows use of Schedule I drugs for "scientific and very limited medical purposes". The Committee's report stated

> The Expert Committee held extensive discussions concerning therapeutic usefulness of 3,4 Methylenedioxymethamphetamine. While the Expert Committee found the reports intriguing, it felt that the studies lacked the appropriate methodological design necessary to ascertain the reliability of the observations. There was, however, sufficient interest expressed to recommend that investigations be encouraged to follow up these preliminary findings. To that end, the Expert Committee urged countries to use the provisions of article 7 of the Convention on Psychotropic Substances to facilitate research on this interesting substance.

In the United Kingdom, MDMA is a Class A drug under the Misuse of Drugs Act 1971, making it illegal to sell, buy, or possess without a license. Penalties include a maximum of seven years and/or unlimited fine for possession; life and/or unlimited fine for production or trafficking. A mandatory seven year sentence is now the penalty for a third conviction for trafficking.

Medical use and clinical studies

In 2001, the FDA granted permission for experimental administration of MDMA to patients suffering from post-traumatic stress disorder. This research is being sponsored by the Multidisciplinary Association for Psychedelic Studies (MAPS). For further information on this, see MAPS's MDMA Research Information and the recent article from MSNBC/Newsweek. This research in patients builds on studies in which MDMA was given to

healthy volunteers. The first of these healthy volunteer studies was conducted by Dr. Charles Grob, with other studies done by Dr. Franz Vollenweider in Switzerland, Drs. John Mendelson and Reese Jones at the University of California San Francisco, and Drs. Magi Faree and Rafael de la Torre in Spain.

Safety and contraindications

The illegality of this drug in many countries makes exact study of its effects difficult. Some safety considerations to consider with the use of ecstasy, which may or may not be conclusive, are the following:

- Because of its illegality, the dose and purity of an ecstasy pill varies dramatically. The dose may be stronger than is advertised, may be adulterated, or might not even contain MDMA.
- Ecstasy affects the regulation of the body's internal systems. Continuous dancing without sufficient breaks or drinks can lead to dangerous overheating and dehydration. Drinking too much water without consuming a corresponding amount of salt can lead to hyponatremia or Water intoxication.
- The use of ecstasy can exacerbate depression and may produce temporary depression as an after-effect for some users. Some individuals also might experience wild or unexpected mood swings the first couple of days following the use of MDMA.
- The use of ecstasy can be very dangerous when combined with other drugs (particularly monoamine oxidase inhibitors (MAOIs) and antiretroviral drugs, in particular Ritonavir). Combining MDMA with MAOIs can precipitate a hypertensive crisis and can result in a near-fatal repercussion.
- In some cases, pills marketed as ecstasy do not contain only MDMA, but instead are substituted with various substances like ketamine, methamphetamine and caffeine. Some users purchase testing kits to verify that pills are actually MDMA. Organizations such as DanceSafe provide testing kits. One effect of this in Europe, and particularly the UK, has been to make pure MDMA powder (known as "Dabs") and crystals (known as "Crystal", not to be confused with Methamphetamine, which is known as Crystal in the US) increasingly popular. In some areas of the UK, pure forms of MDMA are easier to get hold of than Ecstacy pills.
- Long-term after-effects are greatly exacerbated by high doses and frequent use.
- A small percentage of users may be highly sensitive to MDMA; this may make first-time use especially hazardous. This includes but is not limited to people with congenital heart defects. Some scientists have suggested that a small percentage of people lack the proper enzymes to break down the drug. One enzyme involved in MDMA's breakdown is CYP2D6, which is deficient or totally absent in 5-10% of the caucasian population and those of African descent and 1-2% of Asians. However, there is no clear evidence linking lack of this enzyme to problems in users and the connection remains theoretical.

Selective serotonin reuptake inhibitor

Selective serotonin reuptake inhibitors (*SSRIs*) are a class of antidepressants used in the treatment of depression, anxiety disorders and some personality disorders. Studies have also found that SSRIs, as a side effect of their action, may cause in many people either a delay of sexual climax or anorgasmia, so they can be used to develop drugs specifically targeted to treat premature ejaculation.

SSRI drugs are designed to allow the available neurotransmitter serotonin to be utilized more efficiently. A low level of utilization of serotonin is currently seen as one among several neurochemical symptoms of depression. Low levels of serotonin in turn can be caused by an anxiety disorder, because serotonin is needed to metabolize stress hormones .

These medications evolve their effects at the serotonin transporter. They increase the extracellular level of the neurotransmitter serotonin by inhibiting its reuptake into the presynaptic cell. They have no or only weak effects on other monoamine transporters, thus having little direct influence on the level of other neurotransmitters. That distinguishes them from the older tricyclic antidepressants (TCAs), thus they are named selective. SSRIs are considered to be considerably safer than TCAs, since the toxic dose is much higher and they are said to have fewer and weaker side effects and drug interactions.

List of SSRIs

Many drugs in this class are familiar in the USA through advertising, including the following:
(Trade names in parentheses)

- citalopram (Celexa, Cipramil, Emocal, Sepram, Seropram)
escitalopram oxalate (Lexapro, Cipralex, Esertia)
fluoxetine (Prozac, Fontex, Seromex, Seronil, Sarafem, Fluctin (EUR))
fluvoxamine maleate (Luvox, Faverin)
- Paroxetine (Paxil, Seroxat, Aropax, Deroxat, Paroxat)
- Zoloft, Lustral, Serlain)
- dapoxetine (no known trade name)

Escitalopram is simply the left-handed s-enantiomer of the racemic citalopram. It had been introduced to the market just before the patent protection for citalopram had expired.

It is commonly thought that that the primary action of St. John's wort is as an SSRI.

Note that trazodone is not a typical member of the SSRIs - while it is a serotonin reuptake inhibitor, it is believed that its anti-depressant properties may be due to some of its other pharmacokinetic properties rather than its effect on serotonin reuptake inhibition. That said, it does still share many properties of the typical SSRIs, especially the possibility of the so-called 'discontinuation syndrome' (see the section on this below).

Medical indications

The main indication for SSRIs is major depression. Apart from this, SSRIs are frequently prescribed for anxiety disorders, panic disorders, obsessive-compulsive disorder (OCD), social phobia and eating disorders. Though not specifically indicated by the manufacturers, they are also sometimes prescribed to treat irritable bowel syndrome (IBS). Additionally, SSRIs have been found to be effective in treating premature ejaculation in up to 60% of men.

Contraindications / drug interaction

SSRIs are contraindicated with concomitant use of MAOIs (monoamine oxidase inhibitors). This can lead to increase serotonin levels which could cause a serotonin

syndrome. People taking SSRIs should also avoid taking pimozide (a diphenylbutylpiperidine derivative). The non-opioid analgesic tramadol hydrochloride (or Ultram, Ultracet) can, in rare cases, produce seizures when taken in conjunction with an SSRI or tricyclic antidepressant.

Mode of action

Basic understanding

In the brain, messages are passed between two nerve cells via a synapse, a small gap between the cells. The cell that sends the information releases neurotransmitters (of which serotonin is one) into that gap. The neurotransmitters are then recognized by receptors on the surface of the recipient (postsynaptic) cell, which upon this stimulation, in turn, relays the signal. About 10% of the neurotransmitters are lost in this process, the other 90% are released from the receptors and taken up again by monoamine transporters into the sending (presynaptic) cell (a process called reuptake).

Some theories link depression to a lack of stimulation of the recipient neuron at a synapse. To stimulate the recipient cell, SSRIs inhibit the reuptake of serotonin. As a result, the serotonin stays in the synaptic gap longer than it normally would, and has the chance to be recognized again (and again) by the receptors of the recipient cell, which can finally be stimulated fully.

Pharmacodynamics

SSRIs inhibit the reuptake of the neurotransmitter serotonin (5-hydroxytryptamine or 5-HT) into the presynaptic cell, increasing levels of 5-HT within the synaptic cleft.

But there is one counteracting effect: high serotonin levels will not only activate the postsynaptic receptors, but also flood presynaptic autoreceptors, that serve as a feedback sensor for the cell. Activation of the autoreceptors (by agonists like serotonin) triggers a throttling of serotonin production. The resulting serotonin deficiency persists for some time, as the transporter inhibition occurs downstream to the cause of the deficiency, and is therefore not able to counterbalance it. The body adapts gradually to this situation by lowering (downregulating) the sensitivity of the autoreceptors.

Of greater importance is another adaptive process: the downregulation of postsynaptic serotonin 5-HT$_{2A}$ receptors.

These (slowly proceeding) neurophysiological adaptions of the brain tissue are the reason why usually several weeks of continuous SSRI use are necessary for the antidepressant effect to become fully manifested.

Interaction with carbohydrate metabolism

Serotonin is also involved in regulation of carbohydrate metabolism. Few analyses of the role of SSRI's in treating depression cover the effects on carbohydrate metabolism from intervening in serotonin handling by the body.

Neuroprotection

Studies have suggested that SSRIs may promote the growth of new neural pathways.[1] Also, SSRIs may protect against neurotoxicity caused by other compounds (for instance MDMA and Fenfluramine) as well as from depression itself.

SSRIs versus TCAs

SSRIs are described as 'selective' because they affect only the reuptake pumps responsible for serotonin, as opposed to earlier antidepressants, which affect other monoamine neurotransmitters as well. Because of this, SSRIs lack some of the side effects of the more general drugs.

There appears to be no significant difference in effectiveness between SSRIs and tricyclic antidepressants, which were the most commonly used class of antidepressants before the development of SSRIs.[2] However, SSRIs have the important advantage that their toxic dose is high, and, therefore, they are much more difficult to use as a means to commit suicide. Further, they were initially claimed to have fewer and milder side effects.

SSRIs versus 5-HT-Prodrugs

Serotonin cannot be administered directly because when ingested orally, it will not cross the blood-brain barrier, and therefore won't have an effect on brain functions. Also, serotonin would activate every synapse it reaches, whereas SSRIs only enhance a signal that is already present, but too weak to come through.

Biosynthetically serotonin is made from tryptophan, an amino acid. If depression is caused by lack of serotonin, rather than insensitivity to it, SSRIs alone will not work well, whereas supplementing with tryptophan will. In 1989, the Food and Drug Administration made tryptophan available by prescription only, in response to an outbreak of eosinophilia-myalgia syndrome caused by impure L-tryptophan supplements sold over-the-counter. With current standards, L-tryptophan is again available over the counter in the US as well as supplement 5-HTP which is a direct precursor to serotonin.

Adverse effects

General side effects

General side effects are mostly present during the first 1-4 weeks while the body adapts to the drug. Almost all SSRIs are known to cause either one or more of these symptoms:

- nausea
- drowsiness
- headache
- changes in weight and appetite
- changes in sexual behaviour (see the next section)

- increased feelings of depression and anxiety
- tremors
- increased sweating

It is not recommended to quit the medication because of the side effects, as they usually disappear after the adaptation phase and at the same time the antidepressive effects begin to show. However, despite being called general, the side effects and their duration is highly individual and drug-specific, so usually the treatment is begun with a small dose to see how the patient's body reacts to the drug. After that either the dose can be increased or the drug can be changed to some other if the side effects won't disappear or the patient feels they are too uncomfortable.

Suicidality

Over the years there have been many accusations by patients and their families of SSRIs causing suicidal ideation and behavior, but as there is little scientific support for this claim, judicial evidence is piling up that patients committed suicide after using SSRIs.[3] Manufactures of SSRIs historically have vehemently denied any such link and have always blamed the disease rather than the treatment. In 2003 the UKs Committee on Safety of Medicines banned [4] the use of paroxetine (known in that country as Seroxat) in the use of children due to evidence of increased harm and potentially suicidal behaviour. In early 2006 GlaxoSmithKline issued a press release[5] stating that new meta-analysis of their clinical trial data has revealed a statistically significant higher frequency of suicidality in patients treated with their SSRI, paroxetine (Paxil) than with placebo.

In the United States there is a required box warning for suicide risk in children but not for adults.

Sexual side effects

It is well known that the selective serotonin reuptake inhibitors (SSRIs) can cause various types of sexual dysfunction such as anorgasmia, erectile dysfunction, and diminished libido. Initial studies found that such side effects occur in less than 10% of patients, but those studies relied on unprompted reporting, so the frequency of such problems was underestimated. In more recent studies, doctors have specifically asked about sexual difficulties, and found that they are present in between 41%[6] and 83% of patients.[7] This dysfunction occasionally disappears spontaneously without stopping the SSRI, and in most cases resolves after discontinuance. In some cases, however, it does not; this is known as PSSD.

It is believed that sexual dysfunction is caused by an SSRI induced reduction in dopamine. Stimulation of postsynaptic 5-ht2 and 5-ht3 receptors decreases dopamine release from the Substantia Nigra. Sexual dysfunction caused by SSRI's can sometimes be mitigated by several different drugs. These include bupropion, buspirone, methylphenidate, mirtazapine, Amphetamine, pramipexole and ropinirole.

Because of these sexual side effects, the SSRI fluoxetine (Prozac) was recently classified as a reproductive and developmental toxin by the Center for the Evaluation of Risks to Human Reproduction (CERHR), an expert panel at the National Institute of Environmental Health Sciences at the National Institutes of Health.

PANES

Persistent Adverse Neurological Effects following SSRI discontinuation (PANES) are serious side-effects induced by an SSRI that remain or worsen after both the medicine has been completely eliminated from the body, and after SSRI discontinuation syndrome (if it occurs) ends.

Overdose

SSRIs appear to be safer in overdose when compared with traditional antidepressants such as the tricyclic antidepressants. This relative safety is supported both by case series and studies of deaths per numbers of prescriptions.[8] However, case reports of SSRI poisoning have indicated that severe toxicity can occur[9] and deaths have been reported following massive single ingestions,[10] although this is exceedingly uncommon when compared to the tricyclic antidepressants.[8]

Because of the wide therapeutic index of the SSRIs, most patients will have mild or no symptoms following moderate overdoses. The most commonly reported severe effect following SSRI overdose is serotonin syndrome; serotonin toxicity is usually associated with very high overdoses or multiple drug ingestion.[11] Other reported significant effects include coma, seizures, and cardiac toxicity.[8]

Treatment for SSRI overdose is mainly based on symptomatic and supportive care. Medical care may be required for agitation, maintenance of the airways, and treatment for serotonin syndrome. ECG monitoring is usually indicated to detect any cardiac abnormalities.

Criticism of SSRIs

SSRIs have been the focus of controversy. Some feel that SSRIs are prescribed by overzealous doctors or psychiatrists in cases where their use is only marginally indicated. In late 2004 much media attention was given to a proposed link between SSRI use and juvenile suicide. For this reason, the use of SSRIs in pediatric cases of depression is now recognized by the FDA as warranting a cautionary statement to the parents of children who may be prescribed SSRIs by a family doctor. The FDA's currently required packaging insert for SSRIs includes a warning (known as a "black box warning") that a pooled analysis of placebo controlled trials of 9 antidepressant drugs (including multiple SSRIs) resulted in a risk of suicidality that was twice that of placebo. Other studies have shown no increase in rates of suicide but a small increase of non-fatal self-harm[12] and even of reduced incidence of suicide.[13] [14][15]

Critics have also alleged that the widely disseminated television and print advertising of SSRI drugs promotes an inaccurate message, oversimplifying what these medications actually do and perhaps misinforming the public, contributing to the problems listed above.[16] Much of the criticism stems from questions about the validity of claims that such drugs work by correcting chemical imbalances.

Other medications to treat depression

The majority of medications most recently approved to treat depression work on multiple neurotransmitters. Venlafaxine and duloxetine (Cymbalta) are both members of the SNRI class of antidepressant medication. SNRIs (serotonin-norepinephrine reuptake inhibitors) work on the norepinephrine and serotonin neurotransmitters. Mirtazapine also increases levels of norepinephrine and serotonin, but it is a tetracyclic antidepressant, not a

SSRI or SNRI. The arrival of these new drugs suggest that future antidepressants will not work on serotonin exclusively. Since the expiration of Eli Lilly's Prozac patent, Lilly has been promoting their new SNRI, duloxetine. Natural healing professionals often recommend 5-HTP supplements instead of standard SSRI/MAOI prescriptions as 5-HTP allegedly accomplishes the same goal without resorting to disturbing the brain's natural metabolic procedures, although this has not been scientifically proven.

Legal status P*rescription only*

Routes Oral

Paroxetine or *paroxetine hydrochloride* is a selective serotonin reuptake inhibitor (SSRI) antidepressant. It was released in 1992 by the pharmaceutical company GlaxoSmithKline and has since become one of the most prescribed antidepressants on the market due to its efficacy in treating depression as well as a spectrum of anxiety disorders ranging from panic attacks to phobias.

Trade names

Paroxetine is marketed under several tradenames:

- *Aropax* or *Oxetine* in Australia, New Zealand, South Africa, Argentina and Brazil
- Aroxat *or* Aroxat CR *in Chile*
- *Cebrilin* in Latin America
- *Deroxat* in Switzerland and France
- *Optipar* in Finland
- *Paroxat* in Germany and Hungary
- *Paxil or Paxil CR* in the United States, Canada, Argentina and Brazil
- *Pondera* in Brazil
- *Seroxat* in Austria, Belgium, Finland, Greece, Israel, The Netherlands, Poland, Portugal, Singapore, Spain, Turkey, the UK and China.

Indications

Approved

Paroxetine is primarily used to treat the symptoms of depression, obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), panic disorder, generalized anxiety disorder (GAD), [1] social phobia/social anxiety disorder, [2] and premenstrual dysphoric disorder (PMDD).[3]

It was the first (and as of 2002, the only) antidepressant formally approved in the United States for the treatment of social anxiety disorder, causing it to be sometimes referred to (although inaccurately) as an anti-shyness drug.

Clinical Trials

Trials for Paxil CR have not lasted more than twelve months. The effectiveness of Paxil in major depressive disorders has been proven by two twelve week clinical trials in which the patients either had flexible doses or a placebo. Both of the studies concluded that Paxil is significantly more effective than the placebo control group. For another disorder, three 10-week studies were conducted to prove the effectiveness of Paxil CR on panic disorders. In the first and second studies, Paxil proved consistently better than the placebo. But the third

trial Paxil CR failed to have any significant difference to the placebo. For social anxiety disorder, a 12-week trial for adult outpatients was conducted to show Paxil's effectiveness against the disease and prior information of Paxil's nature in the immediate release formulation. The study did not include adolescents with the disorder.

Unapproved/Off-label/Investigational

Paroxetine can also be used in the treatment of premature ejaculation,[4] chronic headache,[5] and bipolar disorder.[6]

Paroxetine has been found to significantly reduce the symptoms of diabetic neuropathy.[7]

There is also evidence that paroxetine may be effective in the treatment of compulsive gambling[8] and hot flashes.[9]

Pharmacology

Paroxetine is the most potent selective serotonin (5-hydroxytryptamine, 5-HT) reuptake inhibitor (SSRI). This activity of the drug on brain neurons is thought to be responsible for its antidepressant effects.

Paroxetine is a phenylpiperidine derivative which is chemically unrelated to the tricyclic or tetracyclic antidepressants. In receptor binding studies, paroxetine did not exhibit significant affinity for the adrenergic (±1, ±2, ^{2}), dopaminergic, serotonergic (5HT1, 5HT2), or histamine receptors of rat brain membrane. A weak affinity for the muscarinic acetylcholine and noradrenaline receptors was evident. The predominant metabolites of paroxetine are essentially inactive as 5-HT reuptake inhibitors.

Paroxetine controlled release (CR)

Paroxetine controlled release contains a Geomatrix™ tablet that controls the absorption of the drug. Clinical studies show that controlled release tablet provides effective symptom relief with a lower number of patients stopping their treatment due to side effects.[10]

However, the need for an extended release form of paroxetine has not been established, as the FDA indicated that the half-life for the original Paxil was ideal for once-daily dosing, and that a CR version was not needed.

Chemistry

Paroxetine hydrochloride is an odorless, off-white powder, having a melting point range of 120° to 138°C and a solubility of 5.4 mg/mL in water.

Formulations

Paxil / Seroxat (paroxetine) is available in 10, 20, 30, and 40 mg tablets.

Paxil CR (paroxetine extended release) is available in 12.5, 25, and 37.5 mg tablets.

Paxil, Seroxat and Paxil CR are manufactured by GlaxoSmithKline, however a generic is now available under the chemical name paroxetine.

Side effects

General side effects are mostly present during the first 1-4 weeks while the body adapts to the drug. Almost all SSRIs are known to cause either one or more of these symptoms. A person receiving paroxetine treatment may experience a few, all, or none of the following side-effects, and most side-effects will disappear or lessen with continued treatment, though some may last throughout the duration.

- Nausea
Drowsiness
Headache
Changes in weight and appetite
Changes in sexual behaviour
Increased feelings of depression and anxiety (initially)
Dry mouth
Constipation
Diarrhea
Aggressive behavior (esp. in children)
Possible suicidal behavior
Possible congenital malformations
Rash
Restlessness or Akathisia
Itch
Sodium depletion
Changes in urination
Sweating
Muscle weakness
Uncharacteristic levels of aggression
Inability to reach orgasm and other sexual side effects

Individuals experiencing any of the following symptoms should contact their doctor immediately:

- Jaw, neck, and back muscle spasms
Fever, chills, sore throat, or flu-like symptoms
Yellowing of the skin or eyes
Black, tarry stools (this can indicate upper GI bleeding)

Paroxetine and other SSRIs have been shown to cause sexual side effects in some patients, both males and females. Although usually reversible, these sexual side effects can sometimes last for months, years or possibly indefinitely even after the drug has been completely withdrawn. This disorder is known as Post SSRI Sexual Dysfunction.

Discontinuation syndrome

While any psychoactive medication (from caffeine to anti-psychotics) can cause withdrawal symptoms upon discontinuation from acute administration, anecdotal evidence suggests that paroxetine has a higher incidence rate and severity of SSRI discontinuation syndrome than other SSRIs and psychoactive medications. For those experiencing extreme and unusual difficulty discontinuing paroxetine, it is recommended that an SSRI with a

longer half-life, such as fluoxetine, be administered for approximately two weeks, then discontinued, to lessen symptoms.[11][12]

Suicidal ideation is a frequently reported experience in those withdrawing from SSRIs.[13] Withdrawal from paroxetine or any other SSRI should be medically supervised.

Routes Oral

Sertraline hydrochloride (also labeled under numerous brand names: *Zoloft*, *Sertralin*, *Lustral*, *Apo-Sertral*, *Asentra*, *Gladem*, *Serlift*, *Stimuloton*, *Xydep*, *Serlain*, *Concorz*) is an orally administered antidepressant of the selective serotonin reuptake inhibitor (SSRI) type. It was first approved by the Food and Drug Administration (FDA) in 1991.

Invention

The invention of Sertraline has been attributed to two scientists at Pfizer: Steve Werner and Billy Dzomba. At the time, the notion that the neurotransmitter serotonin and depression might be linked was a fairly new concept. Together, Werner and Dzomba explored a variety of potential anti-depressant compounds and, within the space of one year, developed Sertraline.[1]

Indications

Approved

Sertraline is used medically mainly to treat the symptoms of depression and anxiety. It is also prescribed for the treatment of obsessive-compulsive disorder (OCD),[2] post-traumatic stress disorder (PTSD),[3] premenstrual dysphoric disorder (PMDD),[4] panic disorder (PD)[5] and social phobia/social anxiety disorder.[6]

Unapproved, off-label, and investigational

Sertraline can also be used in the treatment of general anxiety disorder,[7] binge eating disorder,[8] and premature ejaculation.[9]

There is also evidence that sertraline may be effective in the treatment of refractory neurocardiogenic syncope in children and adolescents.[10]

A study has shown that sertraline is an effective treatment for impulsive aggressive behavior in personality disordered patients.[11]

Side effects

Sertraline can have adverse effects, including: Sleep disorder (both insomnia and increased sleep time), asthenia, gastrointestinal complaints, tremors, confusion, dizziness, anorgasmia, nauseua/vomiting, and decreased libido; it can induce mania or hypomania in around 0.5% of patients. It has also been known to cause minor weight loss. It is contraindicated in individuals taking monoamine oxidase inhibitors (MAOIs) or undergoing electroconvulsive therapy. It is advised you are off MAOI for at least 14 days before beginning to consume Zoloft. (http://drugs.com/zoloft.html)

Until 2003, Zoloft was only approved for use in adults ages 18 and over; that year it was approved by the FDA for use in treating children ages 6 to 17 with extreme obsessive compulsive disorder. In June 2004, Britain banned Zoloft's use by minors and in February 2005, Pfizer was forced to change Zoloft's labeling to include information regarding increased incidences of suicidal behavior and depression in adolescent users of the drug. According to mentalhealth.com, Zoloft is not currently recommended or advised for use in individuals under the age of 18. After these changes, multiple incidences and at least one medical study showed an increased suicide risk in seniors who were taking Zoloft. In response to these findings, the FDA released a public health warning. This warning indicates that anyone currently using Zoloft for any reason has a greater chance of exhibiting suicidal thoughts or behaviors regardless of age. This warning is questionable, however, due to the types of illnesses Zoloft is used to treat, it is impossible to determine if these tendencies are a side effect of the drug or the illness the drug is meant to treat. Zoloft should still truly be only recommended in rather persistent cases as drugs such as these are still in the arena of the unknown.

Zoloft has long been seen as the best option for breastfeeding mothers who wish to continue breastfeeding and be able to take their antidepressants. Despite its apparent safety and effectiveness during the breastfeeding period, recent studies and consumer complaints have seen a need to alter Zoloft's labeling regarding use during the third trimester of pregnancy. Though there are no teratogenic effects associated with Zoloft, there is reason to be concerned about its effects on infants who were exposed to sertraline during the third trimester in utero. It seems that Zoloft use in late pregnancy significantly increases the potential need for hospitalization and breathing assistance in the newborn period and has also been shown to cause an increased risk of neonatal death. In light of this increased risk it is still being used due to the greater potential risk of a seriously depressed mother to herself and her fetus. Like all other medications Zoloft's use must be decided only after carefully weighing out all potential risks and benefits.

Although SSRI anti-depressants may cause problems in newborn babies whose mothers took Zoloft during pregnancy, the ceasing of Zoloft consumption during pregnancy may cause a relapse of depression. If you are planning on becoming pregnant, or are currently pregnant and are taking Zoloft, do not stop taking this medication. Consult your physician first. (http://www.drugs.com/zoloft.html)

According to the manufacturer's website, "if depression is left untreated, the risk of childhood suicide increases about 12 times, according to federal figures". (http://www.zoloft.com)

Sertraline and other SSRIs have been shown to cause sexual side effects in 40-75% of both males and females taking them. This disorder is known as Post SSRI Sexual Dysfunction.

Distribution

This drug has been heavily prescribed in the United States. According to one source, more than 115 million prescriptions for Sertraline had been written in the U.S. by February of 2000.[12] The world over, $3.5 billion worth of Zoloft was sold in 2005.[13]

Formulations

Sertraline is manufactured by Pfizer and sold as Zoloft in the United States as small green 25 mg tablets, blue 50 mg tablets, and yellow 100 mg tablets (Generic 100 mg sertraline tablets are also yellow), each of which is scored to allow easy halving.

In the UK, the brand name is Lustral and is available in white 50 mg or 100 mg scored tablets, according to the British National Formulary (BNF). Elsewhere in the EU the brand name is Zoloft, available in white 50 mg or 100 mg scored tablets. In Australia, only the 50 mg and 100 mg strengths are available, both as white tablets.

Sertraline is an odorless, white, sparingly soluble crystalline solid. The minimum effective dose is usually 50 mg per day (it can be still effective at 25 mg or 37.5 mg), but lower doses may be used in the initial weeks of treatment to acclimate the patient's body, especially the liver, to the drug and to minimize the severity of any side effects. Patients who do not experience relief of symptoms at 50 mg a day may have their dose increased, up to 200 mg a day.

The patent for this brand-name drug expired in June 2006.[14] The drug is now available in generic form in the United States. The generic version of the drug is being produced by Israeli drug maker Teva Pharmaceutical Industries Ltd.[15] In Scandinavia a generic drug called Sertralin, manufactured by HEXAL, is available. The price differences between Zoloft and Sertralin are as much as 1.50 dollars per pill. In India, this drug is sold under the name Zosert.

Green Technology?

In 2002, Pfizer, inc. received an award from the U.S. Environmental Protection Agency, specifically in relation to the manufacture of Sertraline. According to the EPA, Pfizer introduced methods of production that reduced necessary inputs of raw materials and allowed for a reduction of toxic waste. These new methods have been described as more energy-efficient, permitting the company to multiply Sertraline production two-fold. Further, the application of this new process is purportedly safer for workers.[16]

Precautions

- Liver impairment can affect the elimination of this drug from the body. If someone with liver impairment is treated with sertraline, lower or less frequent dosage should be used.
- Patients should limit their alcohol intake while on sertraline (or any antidepressant). Because the liver is doubly taxed with processing both substances (in addition to any other drugs the patient may be taking), alcohol remains in the bloodstream longer, so the effects of alcohol may be more strongly and quickly felt by people taking sertraline or other antidepressants.
- According to some studies grapefruit juice might interfere with the metabolisation of sertraline, increasing its concentration in the blood.
- People 80 years or older should be started on 25 mg initial dose.

Dopamine

Sertraline appears to also be a minor dopamine reuptake inhibitor. At higher dosages (300 mg/day), sertraline inhibits the reuptake of dopamine as well as serotonin.

Controversy

In June 2003, Britain banned sertraline's use for patients under 18 years of age after studies showed a link to increasing suicidal rates. Similar concern has prevailed in the United States, where only the anti-depressant fluoxetine (another SSRI) was officially banned by the FDA for the treatment of depression in minors. However, because the antidepressant-suicide link is correlational, scientists do not know whether the increased suicide risk for people taking antidepressants occurs because the drugs make people suicidal, whether suicide occurs because the drugs un-depress the people enough to motivate the energy required to commit suicide (a popular theory), whether people statistically more likely to commit suicide are over-represented among takers of Zoloft, or because of a fourth, unknown factor.

The brand-name form of setraline, Zoloft, was widely advertised to consumers as "correcting a chemical imbalance", a claim not found in the FDA-approved product labeling. Hundreds of millions of dollars were spent promoting Zoloft this way while it was still on-patent. Some have argued that this advertising may lead consumers to believe that they must take Zoloft to recover when in fact they may benefit from other non-medical treatments such as psychotherapy or exercise.[17]

In the case of Hawkins v The Commonwealth (an Australian court case from the state of New South Wales), Zoloft was described as an important factor in Hawkins murder (through strangling) of his wife. Hawkins had been depressed, was prescribed 50 mg of Zoloft a day and on his first day of treatment took 250 mgs. He claimed on the night of the murder that he couldn't sleep, was agitated and claimed he had hallucinations during the attack on his wife. As a result of this case Zoloft received a large amount of negative publicity, with questions being raised about its impact on behaviour. [1]

Discontinuation Syndrome

Zoloft, along with other SSRIs, has been associated with a "cessation syndrome." This syndrome has both somatic and psychological elements, although SSRIs fall short of being classified as addictive. This non-addictive classification stems from the fact persons given the drug will not seek it out in ever-increasing quantities. Although Zoloft is defined as non-habit forming, the existence of SSRI discontinuation syndrome often necessitates a gradual tapering of one's prescribed dose when seeking to stop SSRI therapy. The prescription insert for Zoloft describes the potential side effects SSRI discontinuation as follows:

"During marketing of Zoloft and other SSRIs and SNRIs (Serotonin and Norepinephrine Reuptake Inhibitors), there have been spontaneous reports of adverse events occurring upon discontinuation of these drugs, particularly when abrupt, including the following: dysphoric mood, irritability, agitation, dizziness, sensory disturbances (e.g. paresthesias such as electric shock sensations), anxiety, confusion, headache, lethargy, emotional lability,

insomnia, and hypomania. While these events are generally self-limiting, there have been reports of serious discontinuation symptoms."[18]

Serotonin-norepinephrine reuptake inhibitor

Serotonin-norepinephrine reuptake inhibitors (SNRIs) are a class of antidepressant used in the treatment of clinical depression and other affective disorders. They are also sometimes used to treat anxiety disorders, obsessive-compulsive disorder, attention deficit hyperactivity disorder (ADHD) and chronic neuropathic pain. They act upon two neurotransmitters in the brain that are known to play an important part in mood, namely, serotonin and norepinephrine. This can be contrasted with the more widely-used selective serotonin reuptake inhibitors (SSRIs), which act only on serotonin.

The abbreviation "SNRI" should not be used for "'selective' norepinephrine reuptake inhibitors".

Mode of action

Activity on norepinephrine reuptake is thought necessary for an antidepressant to be effective on neuropathic pain, a property shared with the older tricyclic antidepressants but not with the SSRIs.

Depression is thought to be caused by a lack of information flow between neurons in certain parts of the brain. Neurons pass information to each other by means of chemicals known as neurotransmitters, which shoot across the tiny synapses between the cells. After firing, most of the neurotransmitter is reabsorbed by the presynaptic cell in a process called reuptake.

Antidepressants work by increasing the amount of neurotransmitters active in the synapse, thereby enhancing neuronal activity and increasing the responsiveness of mood. Modern antidepressants usually achieve this effect by blocking the transporter proteins that reabsorb certain neurotransmitters, hence the name "reuptake inhibitors".

SNRIs were developed more recently than SSRIs, and there are relatively few of them. Their efficacy as well as their tolerability appears to be somewhat better than the SSRIs, owing to their compound effect. Norepinephrine, epinephrine, dopamine and serotonin are

monoamine neurotransmitters subdivided into two groups catecholamines and indolamines. Serotonin is the only indolamine as its synthesised from amino acid tryptophan

Adverse effects

As with the SSRIs, abrupt discontinuation of SNRI-medication usually leads to a discontinuation syndrome which could include states of anxiety and further symptoms. It is therefore recommended to slowly taper down the dose under the supervision of a psychopharmacologist when discontinuing SNRIs.

SNRIs currently available

- *venlafaxine* (tradenames *Effexor XR*®, *Efexor*®) is the first and most commonly used SNRI. Although it also works on dopamine somewhat at high dosages, the majority of its effect is on serotonin and norepinephrine.
- *nefazodone* (tradename *Serzone*®) is an antidepressant with efficacy similar to SSRIs, but without the sexual side effects. In fact, Serzone at times may act similarly to Wellbutrin in its neutral or at times positive effect on function. It has been discontinued in several countries due to rare cases of liver failure. The tradename "Serzone®" has been discontinued, however generic nefazodone is currently available (May 06). However, the liver failure is rare, and a simple blood test every 6 months to assess liver enzyme levels is sufficient. Nefazodone has an active metabolite which at higher doses (> 250mg/day) can increase anxiety. One of the benefits nefazodone has over *Effexor*® and *Cymbalta*® is its enhanced sedation when taken at bedtime.
- *milnacipran* (tradename *Dalcipran*®*/ Portugal*; *Ixel*®*/ France*) has shown to be significantly effective in the treatment of depression and Fibromyalgia syndrome (FMS). Although it has not yet been approved by the Food and Drug Administration (FDA) for use in the United States, it has been commercially available in Europe and Asia for several years.
- *desipramine* (tradenames *Norpramine*®, *Pertofraneis*®) is technically a tricyclic antidepressant, and is usually categorized as such. It works, however, on both serotonin and norepinephrine, so it can also be considered an SNRI.
- *duloxetine* (tradename *Cymbalta*®) by Eli Lilly and Company, also inhibits serotonin and has been approved for the treatment of depression and neuropathic pain in August of 2004.

Please note that some of the above medications may not be considered "true" SNRIs; refer to specific peer-reviewed scientific journals for more in-depth coverage on classifications and pharmaco-kinetics.

Selective serotonin reuptake enhancers

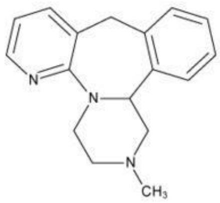
Selective serotonin reuptake enhancers (SSREs) are antidepressants that enhance the reuptake of serotonin instead of blocking it.

Examples of selective serotonin reuptake enhancers include:

- Tianeptine (INN) (Stablon®, Coaxil®, Tatinol®)

Tetracyclic antidepressants

There are also several chemically unrelated tetracyclic antibiotics based on Tetracycline.



The structure of the tetracyclic antidepressant mirtazapine

A *tetracyclic antidepressant* is an antidepressant drug from the tetracyclic drug group.

The name tetracyclic is derived from the drug's molecular structure which consists of four ring-like structures in a T-shape (compare tricyclic antidepressant).

Maprotiline, trade named *Ludiomil*®, and Mirtazapine, trade named *Remeron*® in the USA, *Zispin*® in Europe and *Avanza*® in Australia, are the only two drugs from this group widely used for the treatment of clinical depression. The tetracyclic antidepressant Mianserin was previously available internationally, however in most markets it has been phased out in favor of Mirtazapine.

Research on other tetracyclic antidepressant compounds (for example setiptiline) have been reported in the scientific literature. These other tetracyclic antidepressants are not publicly available.

List of tetracyclic antidepressants

- Amoxapine
Maprotiline
Mianserin
Mirtazapine
Nefazodone
Setiptiline
Trazodone

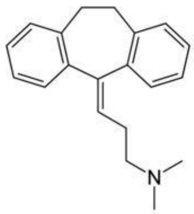
Tricyclic antidepressants



Chemical structure of the tricyclic antidepressant amitriptyline.

Tricyclic antidepressants are a class of antidepressant drugs first used in the 1950s. They are named after the drugs' molecular structure, which contains three rings of atoms (compare tetracyclic antidepressant). The term 'tricyclic antidepressant' is sometimes abbreviated to *TCA*.

Mechanism of action

The exact mechanism of action is not well understood, however it is generally thought that tricylic antidepressants work by inhibiting the re-uptake of the neurotransmitters norepinephrine, dopamine, or serotonin by nerve cells. Tricyclics may also posses an affinity for muscarinic and histamine H1 receptors to varying degrees. Although the pharmacologic effect occurs immediately, often the patient's symptoms do not respond for 2 to 4 weeks.[1]

Clinical use

Tricyclic antidepressants are used in numerous applications; mainly indicated for the treatment of clinical depression, pain, nocturnal enuresis, and ADHD, but they have also been used successfully for headache, bulimia nervosa, interstitial cystitis, irritable bowel syndrome, narcolepsy, persistent hiccups, pathological crying or laughing, smoking cessation, as an adjunct in schizophrenia, and in ciguatera poisoning.[1]

Depression

For many years they were the first choice for pharmacological treatment of depression. Although still considered effective, they have been increasingly replaced by SSRIs and other newer drugs. These newer antidepressants are thought to have fewer side effects and are also thought to be less effective if used in a suicide attempt, as the treatment and lethal doses (see therapeutic index) are farther apart than with the tricyclic antidepressants. Tricyclic antidepressants are sometimes still used to treat refractory depression that has failed to respond to standard SSRI therapy.[2] They are not considered addictive and are preferable to the MAOIs. Side effects usually occur before depression is effectively suppressed; for this reason and via other mechanisms they can be dangerous, as volition may be increased, giving the patient greater ability to attempt suicide.[3]

ADHD

Tricyclic antidepressants have been shown to be effective in treating attention-deficit hyperactivity disorder.[4] ADHD is thought to be caused by dopamine and norepinephrine shortages in the brain's prefrontal cortex. Tricyclic antidepressants block the reuptake of these neurotransmitters, thus acting as dopamine and norepinephrine agonists.[5] They are commonly used in patients for whom psychostimulants (the primary medication for ADHD) are ineffective. TCAs are more effective in treating the behavioral aspects of ADHD than the cognitive deficits; they help limit hyperactivity and impulsivity but have little effect on attention.[6]

Analgesia

Tricyclics are also known as effective analgesics for different types of pain, especially neuropathic or neuralgic pain (like back pain in radiculitis).[7][8] A precise mechanism for their analgesic action is unknown, but it is thought that they modulate opioid systems in the CNS via an indirect serotonergic route.[9] Typically pain modification requires lower dosages than for treating depression (e.g. Amitriptyline at 10 to 30 mg rather than 75 to 150 mg). They are also effective in migraine prophylaxis, but not in relief of an acute migraine attack. This is also believed to be related to serotonergic effects. There is, however, little evidence for an analgesic effect in acute pain.[1]

Nocturnal enuresis

Tricyclics with greater anti-muscarinic action (i.e., amitriptyline, imipramine and nortriptyline) may prove useful in helping to treat nocturnal enuresis (bedwetting) in children over the age of 7 years. The drug needs to be gradually withdrawn and the total treatment period is advised to be no greater than 3 months at a time. It is thought that the anticholinergic effects of tricyclics may inhibit urination, and/or the CNS stimulant effect may lead to easier arousal when the stimulus of a full bladder occurs.[10] However, one robust review of tricyclics for the treatment of enuresis found the benefits of tricyclics were relatively small and transient and due to potentially serious adverse effects suggested more research into other methods (bedwetting alarms, behavioural methods, desmopressin) which may be better suited for treatment of this condition.[11]

Side effects

Many side effects are related to tricyclics antimuscarinic actions. The antimuscarinic side effects are relatively common and include:

- Dry mouth (salivary secretion is affected)
- Blurred vision (accommodation in the eye is affected)
- Decreased gastro-intestinal motility and secretion. This may lead to constipation
- Urinary retention or difficulty with urination

- Hyperthermia

Tolerance to the these adverse effects often develops if treatment is continued, side effects may also be less troublesome if treatment is initiated with low dose and then gradually increased, although this may delay the clinical effect.

Other side effects may include drowsiness, anxiety, restlessness, cognitive and memory difficulties, confusion, dizziness, akathisia, hypersensitivity reactions, increased appetite with weight gain, sweating, decrease in sexual ability and desire, muscle twitches, weakness, nausea and vomiting, hypotension, tachycardia, and rarely, irregular heart rhythms.[1]

Interactions

TCAs are highly metabolized by the cytochrome P450 hepatic enzymes. Drugs that inhibit cytochrome P450 (for example cimetidine, methylphenidate, antipsychotics, and calcium channel blockers) may produce decreases in the tricyclics metabolism leading to increases in tricyclic blood concentrations and accompanying toxicity. Drugs which prolong the QT interval including antiarrythmics such as quinidine, the antihistamines astemizole and terfenadine, and some antipsychotics may increase the chance of ventricular dysrhythmias. TCAs may enhance the response to alcohol and the effects of barbiturates and other CNS depressants. Side effects may also be enhanced by other drugs which have antimuscarinic properties.[1]

Overdose

Tricyclic antidepressant overdose is a significant cause of fatal drug poisoning. The severe morbidity and mortality associated with these drugs is due to their well documented cardiovascular and neurological toxicity. Additionally, they are a serious problem in the pediatric population due to their inherent toxicity[12] and the availability of these in the home when prescribed for bed wetting and depression.

Symptoms

The central nervous system and heart are the two main systems that are affected. Initial or mild symptoms include drowsiness, a dry mouth, nausea, and vomiting. More severe complications, include hypotension, cardiac rhythm disturbances, hallucinations, and seizures. Electrocardiogram (ECG) abnormalities are frequent and a wide variety of cardiac dysrhythmias can occur, the most common being sinus tachycardia and intraventricular conduction delay (QRS prolongation).[13] Seizures and cardiac dysrhythmias are the most important life threatening complications.

Toxicity

Tricyclics have a narrow therapeutic index, i.e. the therapeutic dose is close to the toxic dose. In the medical literature the lowest reported toxic dose is 6.7 mg per kg body weight, ingestions of 10 to 20 mg per kilogram of body weight are a risk for moderate to severe

poisoning, although doses ranging from 1.5 to 5 mg/kg may even present a risk. Most poison control centers refer any case of TCA poisoning (especially in children) to a hospital for monitoring.[14] Factors that increase the risk of toxicity include advancing age, cardiac status, and concomitant use of other drugs.[15] Serum drug levels are not useful in tricyclic overdose.[16]

Toxic mechanism

Most of the toxic effects of TCAs are caused by four major pharmacological effects. TCAs have anticholinergic effects, cause excessive blockade of norepinephrine reuptake at the postganglionic synapse, direct alpha adrenergic blockade, and importantly they block sodium membrane channels with slowing of membrane depolarization, thus having quinidine like effects on the myocardium.[17]

Treatment

Initial treatment of an acute overdose includes gastric decontamination of the patient. This is achieved by administering activated charcoal which adsorbs the drug in the gastrointestinal tract either orally or via a nasogastric tube. Other decontamination methods such as stomach pumps, ipecac induced emesis, or whole bowel irrigation are not recommended in TCA poisoning.[18][19]

Symptomatic patients are usually monitored in an intensive care unit for a minimum of 12 hours, with close attention paid to maintenance of the airways, along with monitoring of blood pressure, arterial pH, and continuous ECG monitoring.[17] Supportive therapy is given if necessary, including respiratory assistance, maintenance of body temperature, and administration of sodium bicarbonate as an antidote. Sodium bicarbonate is given intravenously and it has been shown to be an effective treatment for resolving the metabolic acidosis and cardiovascular complications of TCA poisoning. If sodium bicarbonate therapy fails to improve cardiac symptoms, conventional antidyshythmic drugs such as phenytoin and magnesium can be used to reverse any cardiac abnormalities. However, no benefit has been shown from lidocaine or other class 1a and 1c antiarrhythmic drugs; it appears they worsen the sodium channel blockade, slow conduction velocity, and depress contractility and should be avoided in TCA poisoning.[20] Hypotension is initially treated with fluids along with bicarbonate to reverse metabolic acidosis (if present), if the patient remains hypotensive despite fluids then further measures such as the administration of epinephrine, norepinephrine, or dopamine can be used to increase blood pressure.[20] Another potentially severe symptom is seizures; often seizures resolve without treatment but administration of a benzodiazepine or other anticonvulsive may be required for persistent muscular overactivity. There is no role for physostigmine in the treatment of tricyclic toxicity as it may increase cardiac toxicity and cause seizures.[17]

Tricyclic antidepressants are highly protein bound and have a large volume of distribution; therefore removal of these compounds from the blood with hemodialysis, hemoperfusion or other techniques are unlikely to be of any significant benefit.[19]

Epidemiology

Studies in the 1990s in Australia and the United Kingdom showed that between 8 and 12% of drug overdoses were following TCA ingestion. TCAs may be involved in up to 33% of all fatal poisonings, second only to analgesics.[21][22]

Example compounds

The first tricyclic antidepressant discovered was imipramine, which was discovered accidentally in a search for a new antipsychotic in the late 1950s.

Antidepressant drugs in the tricyclic drug group include:

- amitriptyline (Elavil®, Endep®, Tryptanol®, Trepiline®)

clomipramine (Anafranil®)
desipramine (Norpramin®, Pertofrane®)
dothiepin hydrochloride (Prothiaden®, Thaden®)
doxepin (Adapin®, Sinequan®)
imipramine (Tofranil®)
lofepramine (Gamanil®, Lomont®)
nortriptyline (Pamelor®)
protriptyline (Vivactil®)
trimipramine (Surmontil®)

- Tetracyclic antidepressant

Anxiolytics

An *anxiolytic* is a drug prescribed for the treatment of symptoms of anxiety. Some anxiolytics have been shown to be useful in the treatment of anxiety disorders as have antidepressants such as the class of selective serotonin reuptake inhibitors (SSRIs).

Though not anxiolytics, beta-receptor blockers such as propranolol and oxprenolol can be used to combat the somatic symptoms of anxiety.

Types of anxiolytics

Anxiolytics are generally divided into two groups of medication, benzodiazepines and non-benzodiazepines. There are also herbal treatments used, though research into their efficacy and safety is limited.

Benzodiazepines

- Main article: Benzodiazepine

Benzodiazepines are prescribed for short-term relief of severe and disabling anxiety. Common medications are lorazepam (Ativan®), alprazolam (Xanax®), and diazepam (Valium®). Benzodiazepines may also be indicated to cover the latent periods associated with the medications prescribed to treat an underlying anxiety disorder. They are used to treat a wide variety of conditions and symptoms and are usually a first choice when short-term CNS sedation is needed. Longer term uses include severe anxiety and psychosis. There is a risk of withdrawal symptoms and rebound syndrome after continuous usage past two weeks. There is also the added problem of the accumulation of drug metabolites and adverse effects.

Non-benzodiazepines

Buspirone (Buspar®) is a serotonin 1A agonist. It lacks the sedation and the dependence associated with benzodiazepines and causes much less cognitive impairment. It may be less effective than benzodiazepines in patients who have been previously treated with benzodiazepines as the medication does not provide the euphoria and sedation that these patients may expect or equate with anxiety relief.

Barbiturates and meprobamate exert an anxiolytic effect linked to the sedation they cause. The risk of abuse and addiction is high. Many experts consider these drugs as obsolete for treating anxiety, although they may be valuable for the short term treatment of severe insomnia.

Herbal treatments

Certain herbs, such as St. John's wort and kava (kava kava), have been used as anxiolytics, but limited reliable evidence is available for their efficacy. In Europe, the root of the valerian is also popular as an anxiolytic.

Alternatives to medication

Psychotherapy (e.g. cognitive or behavior therapy) is often useful as an adjunct to pharmacotherapy or as an alternative to medication.

Cannabis

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Rosales
Family: Cannabaceae
Genus: *Cannabis* L.

Species Cannabis sativa L

Cannabis is a genus of flowering plant that includes one or more species. The plant is believed to have originated in the mountainous regions just north-west of the Himalayas. It is also known as hemp, although this term usually refers to varieties of Cannabis cultivated for non-drug use. Cannabis plants produce a group of chemicals called cannabinoids which produce mental and physical effects when consumed. As a drug it usually comes in the form of dried flowers and leaves (marijuana), resin (hashish), or various extracts collectively known as hash oil [1]. In the early 20th century, it became illegal in most of the world to cultivate or possess Cannabis for drug purposes.

Species

Cannabis sativa L

Putative species or subspecies:

    - C. indica Lam. = C. sativa L subsp. indica (Lam.) E. Small & Cronquist
- C. ruderalis Janisch. = C. sativa subsp. sativa var. spontanea Vav. = C. sativa L subsp. sativa

Description

Cannabis is a dioecious annual flowering herb. Cannabis usually has imperfect, unisexual flowers; the male (staminate) reproductive structures are completely separate from the female (carpellate, sometimes called pistillate) structures, [2] [3] although sometimes perfect hermaphrodite flowers also occur.[4] Cannabis is dioecious [2], which means that entire plants usually bear only male or only female flowers, with male flowers borne on loose panicles, and female flowers borne on racemes.[5] However it is not unusual for individual plants to bear both male and female flowers, a condition called monoecy. [6] Flowers of both sexes sometimes occur on separate inflorescences, or sometimes within the same inflorescence. [4] Dense clusters of female flowers produced by drug varieties of Cannabis are commonly called "buds" although in this usage the term refers to clusters of mature flowers, rather than the undeveloped shoots that the word ordinarily describes.

All varieties of Cannabis are wind-pollinated [2] [7] and produce seeds that are called nuts [2] or achenes. [8]. Most varieties of Cannabis are short day plants [7], with the exception of C. sativa subsp. sativa var. spontanea (syn. C. ruderalis), which is commonly described as "auto-flowering" and may be either day-neutral or require long days.

Cannabis is used as a food plant by the larvae of some Lepidoptera species including Ghost Moth and The Nutmeg.

Taxonomy

The genus Cannabis was formerly placed with nettles in the family Urticaceae or with mulberries in the family Moraceae, but is now considered along with hops (Humulus sp.) to belong to the family Cannabaceae.

All strains of Cannabis can interbreed, and produce fertile offspring, which means that all known Cannabis plants satisfy one criterion for a single species type called Cannabis sativa L.[9]. But whether the different strains of Cannabis actually do constitute a single species or multiple species has been a contentious issue for more than two centuries.[10][11][12][13][14]

Early classifications

Cannabis was first classified by Carolus Linnaeus in 1753 as a genus comprising a single species, called Cannabis sativa, describing hemp, which was widely cultivated at the time. In 1785, famous French biologist Jean-Baptiste Lamarck described C. indica, a type of Cannabis from India having morphological distinctiveness from the C. sativa previously described, and in particular not suitable for use as hemp because of poor fiber quality, but having greater potential as an inebriant. Numerous additional species were proposed in the 19th century, but by the beginning of the 20th century, the single-species concept was widely

accepted.[5][10], except within the Soviet Union, where Cannabis continued to be the subject of active taxonomic study.

20th Century

In 1924, Janischevsky described the low-intoxicant type of wild (ruderal) Cannabis found in central Russia as either a species or a variety, proposing C. ruderalis or C. sativa var. ruderalis as alternative names.[10] In 1929, Vavilov described wild populations of drug-type Cannabis as the variiety C. indica var kafiristanica, and recognized the wild populations previously described by Janischevsky as the variety C. sativa L subsp sativa var. spontanea Vav. [14][15][11] In 1940, Serebriakova and Sizov proposed a classification of Cannabis recognizing C. sativa L and C. indica Lam. as distinct species, describing "common hemp" and "Indian hemp" respectively. Within common hemp, they recognized cultivated and wild populatins as distinct subspecies, C. sativa var. culta and C. sativa var spontanea. They additionally recognized a total of 17 varieties within C. sativa, including 4 distinct groups within the cultivated subspecies, but did not describe variation within C. indica.[10]

In the late 1960's and 1970's, the question of scientific classification of Cannabis took on legal importance in North America. Laws prohibiting Cannabis in the United States and Canada specifically named products of Cannabis sativa L. as the prohibited substances. Several persons charged with violating these laws claimed that the material was in fact derived from C. indica or C. ruderalis, and was therefore not prohibited by the laws. Legal defenses on this basis were not often successful. [14]

In the early 1970's, botanists Richard E. Schultes and Loran Anderson conducted taxonomic studies of Cannabis, and concluded that sufficient evidence exists to support recognition of three species, C. sativa L, C. indica Lam., and C. ruderalis Janisch. [16][17] For Schultes, this was a reversal of his previous opinion that Cannabis is a monotypic genus. [10] According to their species descriptions, C. sativa is tall and laxly branched with relatively narrow leaflets, C. indica is shorter, conical in shape, and has relatively wide leaflets, and C. ruderalis is short, branchless, and grows wild in central Asia. This concept was embraced by Cannabis aficionados who commonly distinguish narrow-leafleted "sativa" drug strains from wide-leafleted "indica" drug strains.

In 1976, Ernest Small and Arthur Cronquist proposed a classification comprising a single species Cannabis sativa L, with two subspecies: C. sativa L subsp. sativa and C. sativa L subsp. indica (Lam). According to this concept, C. sativa subsp. sativa was selected for traits that enhance fiber or seed production and has low levels of the psychoactive delta-9-tetrahydrocannabinol (THC), whereas C. sativa subsp. indica was primarily selected for drug production and has relatively high levels of THC. Within these subspecies they described C. sativa L subsp. sativa var. spontanea (Vav.) as a wild or escaped type of low-intoxicant Cannabis, and described C. sativa L subsp. indica var. kafiristanica (Vav.) as a wild or escaped variety of the high-intoxicant type. [11]. This classification was based on several factors, including interfertility, chromosome uniformity, systematic chemotype analysis, and numerical analysis of diagnostic characters. [11][18]. [19] Ernest Small was awarded the G. M. Cooley Prize by the American Association of Plant Taxonomists for his work involving Cannabis. [20]

Ongoing research

Molecular analytical techniques developed in the late twentieth century are being brought to bear on questions of scientific classification. This has resulted in many reclassifications based on evolutionary systematics. Scientific classification of Cannabis has been investigated using molecular biology and genetic techniques.

Several groups conducted genetic analyses of RAPD markers among drug and fiber cultivars. These analyses showed an extremely high degree of genetic polymorphism between and within populations, suggesting a very high degree of potential variation, even in heavily selected cultivars. [21] [22][23] Long-time Cannabis researcher EPM de Meijer described these analyses as confirming the continuity of the gene pool throughout the studied accessions, and as further confirmation that the genus comprises a single species. [24]

In 2004, Karl W. Hillig, then a postgraduate student at Indiana University teamed with Cannabis expert[25] Paul Mahlberg to conduct a chemotaxomic analysis of Cannabis, using analytical chemistry of cannabinoid content to determine allele frequencies within studied populations. They concluded that observed chemotypes support recognition of C. sativa and C. indica as distinct species, but concluded that recognition of C. ruderalis was not supported but rather was consistent with classification of C. ruderalis as C. sativa var spontanea Vav. The authors categorized fiber/seed landraces and feral populations from Europe, central Asia, and Asia Minor in C. sativa., and categorized narrow-leaflet drug (NLD), wide-leaflet drug (WLD) cultivars, southern and eastern Asian hemp cultivars, and feral Himalayan populations as C. indica. [15] In 2005, Hillig published another paper based on the same research, with additional statistical analyses, and this time proposed a 3-species classification, recognizing C. sativa, C. indica, and C. ruderalis.[26] In his doctoral dissertation, published the same year, Hillig stated that principal components analysis failed to differentiate the putative species, but that canonical variates analysis resulted in a high degree of discrimination of the putative species and infraspecific taxa. Hillig stated that the patterns of variation support a two-species concept, but not recognition of C. ruderalis as a separate species from C. sativa. His conclusion was that taxonomic revision of Cannabis is warranted, but further research is needed to substantiate his proposed taxonomic treatment. [27]

As of 2006, the single-species concept of Cannabis continues to be widely accepted. [28][29][30][31][24][32][33]

Popular usage

Breeders, seed companies, and cultivators of drug type Cannabis often describe the ancestry or gross phenotypic characteristics of cultivars by categorizing them as pure indica, mostly indica, indica/sativa, mostly sativa, or pure sativa.[34]

In September of 2005, New Scientist reported that researchers at the Canberra Insitute of Technology had identified a new subspecies of Cannabis, based on analysis of mitochondrial and chloroplast DNA. [35]. The New Scientist story, which was picked up by many news agencies and web sites, indicated that the research was to be published in the

journal Forensic Science International. As of November 2006, the work has not appeared in that journal.

Geographical distribution

Wild cannabis

Wild C. sativa subsp. indica is mainly confined to hash producing areas such as Afghanistan, and parts of Morocco. Wild C. sativa subsp. sativa shows great local variation; for example, in warm places, it can reach heights up to 20 feet (6 m) tall, but in colder climates it can be as short as 1 foot (30 cm) in height. Almost every single flower branch bears a seed. The wild C. sativa subsp. sativa has long, thin and airy buds and a Christmas tree shape structure. Wild C. sativa subsp. indica remains compact and bushy with thick buds for the most part, and is sometimes used by the locals for hashish production. Generally, there are far fewer seeds in wild C. sativa subsp. indica.

In many areas, wild or naturalized populations of Cannabis are considered invasive species, and are often targeted by government-sponsored eradication programs.

Reproduction

Breeding systems

Cannabis has been described as predominantly dioecious [2][7][36], although some monoecious varieties have also been described [37] Subdioecy (the occurrence of monoecious individuals and dioecious individuals within the same population) is widespread. [6][38][39] Many populations have been described as sexually labile. [40][41][23]

As a result of intensive selection in cultivation, Cannabis exhibits many sexual phenotypes, which can be described in terms of the ratio of female to male flowers occurring in the individual or typical in the cultivar[42]. Dioecious varieties are preferred for drug production, where the female plants are preferred. Dioecious varieties are also preferred for textile fiber production, whereas monecious varieties are preferred for pulp and paper production. It has been suggested that the presence of monoecy can be used to differentiate between licit crops of monoecious hemp and illicit dioecious drug crops. [6]

Mechanisms of sex determination

Cannabis has been described as having one of the most complicated mechanisms of sex determination among the dioecious plants.[42] Many models have been proposed to explain sex determination in Cannabis.

Based on studies of sex reversal in hemp, it was first reported in 1924 by K. Hirata that an XY sex-determination system is present.[40] At the time, the XY system was the only known system of sex determination. The X:A system was first described in Drosophila spp in 1925.[43] Soon thereafter, Schaffner disputed Hirata's interpretation,[44] and published

results from his own studies of sex reversal in hemp, concluding that an X:A system was in use and that futhermore sex was strongly influenced by environmental conditions.[41]

Since then, many different types of sex determination system have been discovered, particularly in plants[36]. Dioecy is relatively uncommon in the plant kingdom, and a very low percentage of dioecious plant species have been determined to use the XY system. In most cases where the XY system is found it is believed to have evolved recently and independently.[45]

Since the 1920's, a number of sex determination models have been proposed for Cannabis. Ainsworth[36] describes sex determination in the genus as using "an X/autosome dosage-type."

The question of whether heteromorphic sex chromosomes are indeed present is most conveniently answered if such chromosomes were clearly visible in a karyotype. Cannabis was one of the first plant species to be karyotyped, however, this was in a period when karyotype preparation was primitive by modern standards. Heteromorphic sex chromosomes were reported to occur in staminate individuals of dioecious 'Kentucky' hemp, but were not found in pistillate individuals of the same variety. Dioecious 'Kentucky' hemp was assumed to use an XY mechanism. Heterosomes were not observed in analyzed individuals of monoecious 'Kentucky' hemp, nor in an unidentified German cultivar. These varieties were assumed to have sex chromosome composition XX. [37] But according to other researchers no modern karyotype of Cannabis had been published as of 1996.[46] Proponents of the XY system state that Y chromosome is slightly larger than the X, but difficult to differentiate cytologically. [47]

More recently, Sakamoto and various co-authors[48][49] have used RAPD to isolate several genetic marker sequences that they name Male-Associated DNA in Cannabis (MADC), and which they interpret as indirect evidence of a male chromosome. Several other research groups have reported identification of male-associated markers using RAPD and AFLP[50][23][24]. Ainsworth commented on these findings, stating that "It is not surprising that male-associated markers are relatively abundant. In dioecious plants where sex chromosomes have not been identified, markers for maleness indicate either the presence of sex chromosomes which have not been distinguished by cytological methods or that the marker is tightly linked to a gene involved in sex determination." [36]

Environmental sex determination is known to occur in a variety of species.[51] Many researchers have suggested that sex in Cannabis is determined or strongly influenced by environmental factors [41]. Ainsworth reviews that treatment with auxin and ethylene have feminizing effects, and that treatment with cytokinins and gibberellins have masculinizing effects.[36] It has been reported that sex can be reversed in Cannabis using chemical treatment.[52]

Aspects of cannabis production and use

- Medical cannabis discusses its use as a medication.

Cannabis (drug) discusses its use as a recreational drug.

Spiritual use of cannabis discusses sacramental and religious use.

Hemp discusses its uses as a source of housing, oil, food, fibers, and industrial materials.

Cannabis (drug) cultivation discusses aspects of cultivation for medicinal and recreational drug purposes

Legal issues of cannabis focuses on the law and enforcement aspects of growing, transporting, selling and using cannabis as a drug.

Health issues and the effects of cannabis discusses the pharmacology, physical, and mental effects of Cannabis when used as drug.

Etymology

The plant name *cannabis* is probably of Semitic origin, possibly Hebrew.

Hebrew ç°àµÔ Ñ¹¼é¶ÂÝ *qnh bo[em* > ç·à·¼Ñ¼Õ¹á *qannabbôs* > Greek º±½½±²¹Â *kannabis* > Latin *cannabis* > English

However, the earlier Sumerian language used the word "kanubi", which means 'cane of two (sexes?)'. This is possibly the source for the Semitic usage.

The Biblical Hebrew term qnh bo[em, literally "reed of balm", probably [53] refers to cannabis according to some etymologists [54], but is more commonly thought to be lemon grass, calamus , or even sweet cane, due to widespread translation issues. [55] The Hebrew Bible mentions it in Exodus 30:23 where God commands Moses to make a holy oil of myrrh, cinnamon, qnh bo[em and cassia to anoint the Ark of the Covenant and the Tabernacle (and thus God's Temple in Jerusalem). Notably, this anointing oil is a special herbal formula that functions as a kind of polish and fragrance for the Ark and Tabernacle, and the Bible forbids its manufacture and use to anoint people (Exodus 30:31-33) with the exception of the Aaronic priesthood (Exodus 30:30)

Elsewhere, the Hebrew Bible simply uses "reed" qnh as the name of a plant in four places whose context seems to mean "reed of balm" as a fragrant resin, Isaiah 43:24, Jeremiah 6:20, Ezekiel 27:19 and Song of Songs 4:14. The Hebrew name "reed of balm" comes from qnh (the noun construct form of qneh) means a "reed" or "cane" and bo[em means "balm" or "aromatic" resin. Hebrew may have adapted the name qannabbôs from "reed of balm" qnh bo[em as a substitute for the ambiguous name "reed".

This Biblical Hebrew term is often mistranslated as "calamus", also called "lemon grass" (Cymbopogon citratus) or "sweet flag" (Acorus calamus), following an ancient misunderstanding in the Greek Septuagint translation. The Hebrew Bible was written across centuries well up to the 5th Century BCE. However, centuries later, by the time the Septuagint was written around the 2nd Century BCE, the archaic Hebrew word qnh bo[em appears to have already abbreviated into the later Hebrew form qannabbôs, which is attested in Post Biblical Hebrew literature. Thus, the Septuagint did not recognize the Hebrew expression "reed of balm" and mistook it to refer to some unidentified plant. As a dynamic equivalent, the Septuagint rendered it as "calamus" (Greek kalamos), which indeed is a "balmy" (scented) reed. The calamus plant was known in Greek mythology and processed into an aphrodisiac.

Unambiguous Hebrew or Aramaic references to cannabis are rare and obscure. Syriac has qanpa (a loan from kannabis) and tanuma (see the Comprehensive Aramaic Lexicon.) but neither is found in the Peshitta, the Syriac Bible. Late Syriac Ahiqar texts include qanpa as "ropes of hemp" (tunbei de-qanpa). The Hebrew word qanbes, a loan word from kannabis,

is used in the Mishnah as hemp [Kilaim 2:5; 5:8; 9:1,7; Negaim 11:2] in the sense of a constituent of clothing or other items.

The Scythian term cannabis probably derives from a Semitic origin as well. Sara Benetowa of the Institute of Anthropological Sciences in Warsaw is quoted in the Book of Grass as saying:

> The astonishing resemblance between the Semitic *kanbos* and the Scythian *cannabis* lead me to suppose that the Scythian word was of Semitic origin. These etymological discussions run parallel to arguments drawn from history. The Iranian Scythians were probably related to the Medes, who were neighbors of the Semites and could easily have assimilated the word for hemp. The Semites could also have spread the word during their migrations through Asia Minor.

Likely, the name 'cannabis' was known from the Semitic merchants who sold this commodity throughout the ancient trade routes of Southeast Asia.

Comparing the English word hemp and the Greek word kannabis shows that the word came down from the presumed Proto-Indo-European language. Words like kanapish for "hemp" occur in some Finno-Ugrian languages. It is likely that, soon after agriculture started, hemp as a cultivated plant spread widely, carrying its name with it. Source of Rus. konoplja, Pers. kanab, Lith. kanapes "hemp," and Eng. canvas and hemp.

Cannabis drug

The psychoactive drug *cannabis* is known by many nicknames (some pertaining to certain preparations.) It is produced from parts of the Cannabis sativa plant, primarily the cured flowers and gathered trichomes of the female plant (as well as the less psychoactive remains of the plant, and its highly psychoactive resin.) The major active chemical compound ”9-tetrahydrocannabinol, commonly referred to as THC, has psychoactive and medicinal effects when consumed, usually by smoking or ingestion. Humans have been consuming cannabis since prehistory, though in the 20th century there was a rise in the use of cannabis for recreational and religious purposes. At the beginning of the 21st century, it is estimated that cannabis is used by four per cent of the world's adult population each year, making cannabis more popular than all other illicit drugs combined. [1] The possession, use, or sale of psychoactive cannabis products became illegal in many parts of the world in the early 20th century. Since then, while some countries have intensified the enforcement of cannabis prohibition, others have reduced the priority of enforcement to the point of tolerating consumption. The supplying of cannabis remains illegal almost everywhere in the world through the 1961 Single Convention on Narcotic Drugs, the 1971 Convention on Psychotropic Substances, and the 1988 United Nations Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances, while simple possession of small quantities is tolerated in a few countries.

Ancient history

Biologists generally agree that the natural cannabis plant first grew somewhere in the Himalayas. Evidence of the smoking of cannabis can be found as far back as the Neolithic age, where charred hemp seeds were found in a ritual brazier at a burial site in present day Romania[2] . The most famous users of cannabis were the ancient Hindus. It was called ganjika in Sanskrit (ganja in modern Indian languages).[3] According to legend, Shiva, the

destroyer of evil in the Hindu trinity, told his disciples to revere the plant. The ancient drug soma, mentioned in the Vedas as a sacred intoxicating hallucinogen, was sometimes associated with cannabis. It has also been identified with a number of other plants and a mushroom, Amanita muscaria, so the involvement of cannabis cannot be definitively quantified.

The citizens of the Persian Empire would partake in the ceremonial burning of massive cannabis bonfires, directly exposing themselves and neighboring tribes to the billowing fumes, oftentimes for over 24 hours. [4][5]

Cannabis was also well known to the Assyrians, who discovered it from the Aryans. Using it in some religious ceremonies, they called it qunubu, or the drug for sadness. Also introduced by the Aryans, the Scythians as well as the Thracians/Dacians used it, whose shamans (the kapnobatai - "those who walk on smoke/clouds") burned cannabis flowers in order to induce trances. The cult of Dionysus, which is believed to have originated in Thrace, is also believed to have inhaled cannabis smoke.

Religious and spiritual use

Cannabis has a long history of religious use, especially in India, where it has been used by wandering spiritual sadhus for centuries. The religious group that (in the west) is most well-known for their use of cannabis in a spiritual context is the Rastafari movement, though it is by no means the only group (others include the Church of the Universe). Some historians and etymologists have claimed that cannabis was used by ancient Jews, early Christians, and of early Muslims of the Sufi order.[6] Hashish was said to have been used by the Hashshashin, a warrior sect, but there is no significant evidence for this, as the name was only used as a derogatory term for them by others. [6]

Many individuals also consider their use of cannabis to be spiritual regardless of organized religion.

Medicinal use

Medically, cannabis is most often used as an appetite stimulant and pain reliever for certain illnesses, including cancer, AIDS and other diseases. It is used to relieve glaucoma and certain neurological illnesses such as epilepsy, migraine and bipolar disorder. It has also been found to relieve nausea for chemotherapy patients. A recent study has also indicated that cannabis can be used to prevent Alzheimer's disease[1]. The medical use of cannabis is politically controversial, but physicians sometimes recommend it informally. A synthetic version of the major active chemical in cannabis, THC, is available in many countries in the form of a pill as the prescription drug dronabinol (Marinol). THC has also been found to reduce arterial blockages[7]. A sublingual spray derived from an extract of cannabis has also been approved for treatment of multiple sclerosis in Canada as the prescription drug Sativex [8] - this drug may now be legally imported into the United Kingdom and Spain on prescription.[9]

United States

Eleven states[10] in the United States passed laws allowing cannabis possession and consumption for medical purposes; however, the Supreme Court of the United States in Gonzales v. Raich ruled that the listing of cannabis as a Schedule I controlled substance was constitutional, and that possession for any reason other than approved medical research was therefore illegal under federal law. This remained consistent with their ruling in United States v. Oakland Cannabis Buyers' Cooperative, an 8-0 decision stating that there is no exception as a Schedule I drug for people to use cannabis for medical purposes.[11] This creates an interesting tension between state and federal laws.[12]

Some local and state governments have either partially decriminalized the possession of small amounts of cannabis, or simply advised local authorities to limit enforcement of controlled substance laws to more serious offenses. A 2005 initiative ordinance in Denver, Colorado, for instance, repealed municipal penalties for possession of less than one ounce of cannabis by adults twenty-one and older, though Colorado state and federal penalties remain in effect.[13] A 2006 advisory policy adopted by the city of West Hollywood, California holds that the city's contracted law enforcement agency, the Los Angeles County Sheriff, should not target simple possession or private consumption of cannabis by adults within the city.[14][15] With the 1975 Ravin v. State decision, the Alaska Supreme Court declared the state's anti-drug law unconstitutional with respect to possession of small amounts of cannabis, holding that the right to privacy guaranteed by the Alaska state constitution outweighed the state's interest in banning the drug.[16] Despite a 1990 initiative statute and a 2006 legislative statute contradicting the Ravin decision, Alaska courts continue to follow Ravin, voiding laws which criminalize possession of small amounts of cannabis.[17][18][19]

In the November 7, 2006 election, voters in Colorado, Nevada and South Dakota rejected propositions that would have legalized possession of up to one ounce of marijuana.[20]

A 1998 study by pro-legalization lobby NORML estimated cannabis to be the largest cash crop in several non-Midwestern states, and the fourth largest cash crop nationwide.[21]

New breeding and cultivation techniques

Advances in breeding and cultivation techniques have increased the diversity and potency of cannabis strains since 1970, and these strains are now widely smoked all over the world. These advances are known as the sinsemilla techniques of production; sinsemilla, Spanish for without seed, are the dried, seedless female flowers of cannabis plants which have been grown in the absence of males to ensure no pollination takes place. Because THC potency and production drops off once pollination takes place, various techniques such as seed banks, hydroponics, cloning, lighting techniques, and the sea of green method have been utilized, in part as a response to prohibition enforcement efforts which have made outdoor cultivation more risky; thus, efficient indoor cultivation has become more common. These same advances have led to fewer seeds being present in cannabis currently than were present 20 years ago.

Many opponents of cannabis use, both in and out of government, have exaggerated the increases in potency and ramifications thereof. In the United States, government advertisements encourage parents to disregard their own experience with cannabis when speaking to their children, on the premise that pot today is significantly stronger and thus more dangerous than that which they themselves might have smoked in the past.[22] In a

general pattern of proposing reverses in cannabis rescheduling, the UK government is considering scheduling stronger cannabis (skunk, in local parlance) as a separate, more restricted substance. Many cannabis proponents disagree vehemently, reasoning that as one must smoke less cannabis to achieve the same effect, it actually is safer and less potentially carcinogenic in the long run than that which was smoked in earlier times.

Preparations for human consumption

Cannabis is prepared for human consumption in several forms:

- Marijuana or buds, the resin gland-rich flowering tops of female plants.
- Hashish, a concentrated resin mostly comprised of trichomes that are extracted physically, as with ice hash, or chemically.
- Sinsemilla or sensemillia, flowering tops which are free of seeds as a result of being grown in a pollen-free environment. Since no plant energy can go into seed formation, this version is higher in psychoactive components.
- Kief or kif, a powder containing the resin glands (glandular trichomes, often incorrectly called "crystals" or "pollen"); it is produced by sifting marijuana and leaves.
- Charas, hand-made hashish produced by hand-rubbing the resin from the resin gland-rich parts of the plant. Often thin dark rectangular pieces.
- Bhang, prepared by the wet grinding of the leaves of the plant and used as a drink.
- Hash oil, resulting from extraction or distillation of THC-rich parts of the plant with isopropyl or butane.
- Budder, processed hash oil. Ordinary hash oil is whipped to incorporate air, making it a foam. It has been marketed as being anywhere between 82% and 100% THC, though no actual lab tests have been done to validate this claim.
- Resin, when smoked through a pipe all of the above will cause black goo to create a film on the sides or collect in certain nooks depending on its shape. This can be collected and resmoked. This method is commonly referred to as scraping.
- Minimally potent leaves and detritus, called shake, brush, bush or leaf.

These forms are certainly not exclusive and combinations of two or more different forms of cannabis are common. Mixing different forms is done mainly to obtain a different or more powerful effect. Between the many different strains of Cannabis and the various ways that it is prepared for consumption, there are innumerable types of blends or mixes, similar to the countless varieties of mixed alcoholic beverages that are available.

There are two recognized subspecies of Cannabis sativa, Cannabis sativa subsp. sativa and C. sativa subsp. indica. [23]

Smoking

There are a wide variety of methods of smoking cannabis. The most popular include the joint, the blunt, the bong, the pipe more commonly called a "bowl" or "piece", the shotgun,

and the one-hitter. These are sometimes smoked inside a small closed area (such as a car) used to trap smoke so that it is inhaled with every breath. This is often referred to as "hotboxing", "fishbowling", "clam-baking", or "green-housing.". Smoking in a small enclosed area such as a car or under a blanket is commonly referred to in Australia as smoking in a "Dutch Oven".

To create a joint, cannabis is rolled up into a cigarette, using rolling paper (where available). Brown paper, newsprint, and other assorted paper products can be used, but these often contain harmful chemicals. Cannabis cigars, or blunts, can also be created by using the wrapper of a standard cigar.

A bong is a water pipe through which cannabis smoke is filtered. Variants include the gravity bong, which consists of a cone atop a perforated or cut water bottle. This method of cannabis smoking is one of the most efficient, as the presence of a chamber and carburetor reduce smoke waste.

Pipes are usually made of blown glass, wood, or non-reactive metals. Metal pipes are often made of interchangeable pieces. Glass pipes often have a carburetor, colloquially referred to as a carb, rush, choke, or shotgun, that is covered for suction then released for inhalation. Some users also prefer vertically held pipes, or improvised pipes ("tinnies") made from aluminium foil (either constructed entirely from the foil or by using it as a gauze), small plumbing fittings, soda cans, crisp fruits or vegetables, or the cardboard from bathroom-tissue or aluminium foil rolls.

A "one-hitter" is a device that allows smaller amounts of cannabis to be smoked with equal suction. Cannabis buds are loaded into a compartment for combustion. The smoker then lights the compartment and the entire amount of cannabis is smoked. This is repeated for each hit. This method is also efficient in titrating the exact dose desired.

Oral consumption

Cannabis may be orally consumed. In order to release its psychoactive properties hashish can be eaten raw or mixed with water but marijuana will only be absorbed into the bloodstream by blending it with ethanol or lipids. The effects of the drug take longer to begin, but last longer and may be perceived as more physical rather than mental, though there are claims to the contrary. A dose of oral cannabis is often considered to give a stronger experience than the equivalent dose of smoked cannabis. A common belief holds that smoking cannabis leads to a large amount of the active compounds being lost in the exhaled smoke or simply decomposing on burning, whereas ingested cannabis results in 100% consumption of the active compounds, an assertion which cannot be confirmed without objective analysis. It is thought that the active component of cannabis, ”9-THC, is converted to the more psychoactive 11-hydroxy-THC in the liver.[24] Titration is much more complex than through inhalation. Common preparations involve blending with butter, to create Cannabutter that is used in preparing Brownies, fudge, cookies, ganja goo balls or space cakes. When blended with melted butter, the drug is finely minced almost into powder form. However there are some preparations that do not contain butter in them and therefore fall into a slightly different category; these include the Leary biscuit, which requires less preparation than more "conventional" recipes. Infusion in drinks containing milk and

flavoring herbs is also possible, and more common in India. Hollowed-out gumballs filled with the drug, wrapped and distributed labeled as Greenades, were identified in 2006 as being used by high school students in the United States.[25]

As with other drugs that are taken orally, it is sometimes customary to fast before taking the drug to increase the effect, possibly because an empty stomach will absorb the drug faster so it 'hits' stronger. However, some people do eat before consuming the drug because eating it on an empty stomach makes them feel sick. Still, time to effect onset is an hour or sometimes more, as opposed to smoking, where effects can be almost immediate.

Cannabis can also be leached in high-percentage ethanol (often grain alcohol) to create Green Dragon. This process is often used to utilize otherwise low-quality stems and leaves.

Cannabis can also be consumed as a tea. THC is lipophilic and only slightly water soluble, with a solubility of only 2.8 grams per litre,[26] but enough to make a tea effective. Water-based infusion is generally considered to be inefficient.

The seeds of the plant, high in protein and fatty acids, are appreciated by many species of birds. Many countries, including the United States, make the possession of viable cannabis seeds illegal[27], although they can be openly bought and sold legally in much of Europe, including the UK.

Vaporization

With a vaporizer, cannabis can be heated to a temperature of about 365 °F (185 °C), at which the active ingredients are released into gaseous form with little or no burning of the plant material. With this method, the user does not inhale as many (or any) toxic chemicals depending on the quality of the vaporizer. Scientific studies by MAPS/NORML have yielded varied results on the effectiveness of vaporizing as a method of cannabis consumption. One particular study by MAPS/NORML found 95% THC and no toxins delivered in the vapor.[28] However, an older study by MAPS/NORML showed minimal reduction of toxins.[29]

Hot-knifing (Blades)

Hot-knifing, spots, blasting or doing blades is a process in which the tips of two knives are heated to a very high temperature, often by inserting them into the heating element of an electric or gas stove. The cannabis is then pressed between the heated knife-tips, rapidly combusting, or vaporising it depending upon the amount of heat used. The vaporized cannabis is funneled into the mouth of the smoker through the use of a glass or plastic bottle, empty pen, or other hollow tube or funnel or free handed.

In New Zealand and Australia, this is known as "spots". "Spots" can refer to both the activity of hot-kniving (aka "spotting") and the small, rolled balls of cannabis consumed in the process. Spots are much more efficient than bongs or joints; as the amount of cannabis required to constitute a hit is less and the dosage is easily controlled. This method is most commonly employed with high quality cannabis or hashish.

Another method of "spotting" uses knife blades heated to a much lower temperature, only hot enough to vaporise the active ingredients, leaving the organic material scorched, rather than burnt to ash, thus decreasing potential harmful consequences of the smoke itself.

Immediate effects of consumption

The nature and intensity of the immediate effects of cannabis consumption vary according to the dose, the species or hybridization of the source plant, the method of consumption, the user's mental and physical characteristics (such as possible tolerance), and the environment of consumption. This is sometimes referred to as set and setting. Smoking the same cannabis either in a different frame of mind (set) or in a different location (setting) can alter the effects or perception of the effects by the individual. Effects of cannabis consumption may be loosely classified as cognitive and physical. Anecdotal evidence suggests that drug varieties of Cannabis sativa subsp. sativa tend to produce more of the cognitive or perceptual effects, while C. sativa subsp. indica tends to produce more of the physical effects.

Active ingredients, metabolism, and method of activity

Of the approximately 315[30] different psychoactive chemicals found in Cannabis, the main active ingredient is tetrahydrocannabinol (delta-9-tetrahydrocannabinol, *THC*). THC can degrade to other cannabinoids, such as cannabidiol or cannabinol, which can make one feel sleepy and disoriented. Different cannabis products have different ratios of these and other cannabinoids. Depending on the ratio, the quality and nature of the "high" will vary.

THC has an effect on the modulation of the immune system, which may have an effect on malignant cells, but there is insufficient scientific study to determine whether this might promote or limit cancer. Cannabinoid receptors are also present in the human reproductive system, but there is insufficient scientific study to conclusively determine the effects of cannabis on reproduction. Mild allergies to cannabis may be possible in some members of the population.

A study has shown that holding cannabis smoke in one's lungs for longer periods of time does not conclusively increase THC's effects on psychological test performance.[31] However, a more recent study by the same authors indicates that a longer breath-holding duration increases the subjective ratings of ones' "high."[32] This latter study also found that a long breath-holding duration decreased subjects' subjective ratings of "calmness" more than a short breath-holding duration. Additionally, subjects who held cannabis smoke in their lungs for a long duration felt slightly less "relaxation" while subjects who held the smoke for a short period gave higher "relaxation" ratings.

List of effects

Cannabis has a broad spectrum of possible cognitive, behavioral, and physiological effects, the occurrence of which vary from user to user. Some of these are the intended effect desired by users, some may be considered desirable depending on the situation, and others are generally considered undesirable. Users of cannabis report that these kinds of effects are more often produced by material derived from Cannabis sativa subsp. sativa.

Cannabis also has effects that are predominantly physical or sensory, widely believed to be more common with material derived from C. sativa subsp. indica.

Cognitive effects

- Short or long-term psychosis/schizophrenic disorders that begin in some young users [33]
- Varying amounts of paranoia and anxiety in some users (usually when overdosed or anxious before use)[34]
- Some studies report the loss of coordination and distorted sense of time in some users[35], while others fail to find effects on time perception and reaction time. [36]
- Impairment of short-term memory in some heavy users (7 cigarettes a week and more) [37]

- Auditory or visual hallucinations at high doses in some users[38]
- Increased mental activity, like metacognition and introspective or meditative states of mind in most users[39]
- Relaxation or stress reduction in some users
- Entheogenesis (e.g. per Rastafarian users, more "Jah-Vibrations") in some users[40]

Additionally, cannabis affects blood flow to the brain by narrowing blood vessels analogous to how heart disease affects blood flow. Although studies have not proven altogether conclusive on the subject, recent work suggests that blood flow of those consuming less than 70 joints a week shows improvement after a month's cessation.[41]

Behavioral effects

- Varying degrees of euphoria (though usually mild) and feelings of well-being[42]

Physiological effects

- Antiemetic properties (in moderate doses) [43]
- Lowered intraocular pressure, beneficial to glaucoma patients and sufferers of certain types of headaches, cramps, and eye pain.
- Dilation of blood vessels (vasodilatation),[44] resulting in:
    - Increased blood flow and heart rate (possibly even tachycardia)
    - Reddening or drying of eyes
- Lower blood pressure while standing. Higher blood pressure while sitting (note that this can lead to instances of orthostatic hypotension, also known as head rush).[45]
- Change in appetite, increase (often referred to as "the munchies") is an effect of stimulation of the endocannabinoid system, which affects body weight, insulin resistance, and dyslipidemia[46] though recent scientific and ongoing anecdotal evidence also points to it as an appetite suppressant.
- Varying degrees of dry (cotton) mouth[47]
- Dilation of alveoli (air sacs) in lungs, resulting in deeper respiration and increased coughing.

Lethal dose

According to the Merck Index, 12th edition, the LD50, the lethal dose for 50% of rats tested by inhalation, is 42 mg/kg of body weight. That is the equivalent of a 165 lb (75 kg) man ingesting all of the THC in 21 one-gram cigarettes of high-potency (15% THC) cannabis buds at once, assuming no THC was lost through burning or exhalation. For oral consumption, the LD***50*** for rats is 1270 mg/kg and 730 mg/kg for males and females,

respectively, equivalent to the THC in about a pound of 15% THC cannabis. Only with intravenous administration may such a level be even theoretically possible. [48] The ratio of cannabis required to saturate cannaboid receptors to the amount of cannabis required to have a fatal over dose is 1:40,000.

There has only ever been one recorded instance of an alleged fatal overdose due to cannabis. In January 2004, Lee Maisey of Pembrokeshire, Wales was found dead. The coroner's report stated "Death due to probable cannabis toxicity". It had been reported that Maisey smoked about six joints a day. Mr. Maisey's blood contained 130 nanograms per milliliter (ng/ml) of the THC metabolite THC-COOH. However, the validity of the finding did not stand up well under review. As reported on 2004-01-28 in the Neue Züricher Zeitung, the Federal Health Ministry of Switzerland asked Dr. Rudolf Brenneisen, a professor at the department for clinical research at the University of Bern, to review the data of this case. Dr. Brenneisen said that the data of the toxicological analysis and collected by autopsy were "scanty and not conclusive" and that the conclusion "death by cannabis intoxication" was "not legitimate."[49]

Health issues and the effects of cannabis

There is some conclusive scientific evidence about the long-term effects of human cannabis consumption.[50]

The most significant confounding factor is the use of other drugs, including alcohol and tobacco, by test subjects in conjunction with cannabis. When subjects using only cannabis were combined in the same sample with subjects using other drugs as well, researchers could not reach a conclusion as to whether their findings were caused by cannabis, other drugs, or the interaction between them. In addition, research using cannabis is heavily restricted in many countries, making it difficult to get new studies funded or approved. Since there are so many different compounds in cannabis, it is difficult to predict or accurately measure its effects. Some conclusions established with some degree of certainty that cannabis is less likely to cause emphysema or cancer than tobacco[51]; that it is unlikely to cause birth defects or developmental delays in the children of users,[52][53] and in a study done by the University of California Los Angeles in 2006, that even heavy cannabis smokers do not increase their risk for lung cancer.[54] According to a United Kingdom government report, using cannabis is less dangerous than both tobacco and alcohol in social harms, physical harm and addiction.[55]

Newer research has also shown that cannabis use is generally higher among sufferers of schizophrenia, but causality has not been established[56][57] and confirmed that sustained early-adolescent cannabis use among certain genetically predisposed individuals has an elevated correlation with certain mental illness outcomes, ranging from psychotic episodes to clinical schizophrenia.[58][59]

Legality

Since the 20th century, most countries have enacted laws against the cultivation, use, possession, or transfer of cannabis for recreational use. Naturally, these laws impact adversely on the cannabis plant's cultivation for non-recreational purposes, but there are

many regions where, under certain circumstances, handling of cannabis is legal or licensed, and others where laws against its use, possession, or sale are not enforced. Many jurisdictions have also decriminalized possession of small quantities of cannabis, so that it is punished by confiscation or a fine, rather than imprisonment. By effectively removing the user from the criminal justice system, decriminalization focuses more on those who traffic and sell the drug on the black market. However, this does not solve the problem of how a user will obtain the "legal amount" of cannabis, since buying or growing cannabis is still illegal. Increasingly, many jurisdictions also permit cannabis use for medicinal purposes. Some countries allow the sale through drug companies. However, simple possession can carry long jail sentences in some countries, particularly in East Asia, where the sale of cannabis may lead to a sentence of life in prison or even execution.

Recent history

Under the name cannabis, 19th century medical practitioners sold the drug, (usually as a tincture) popularizing the word amongst English-speakers. It was rumoured to have been used to treat Queen Victoria's menstrual pains as her personal physician, Sir John Russell Reynolds, was a staunch supporter of the benefits of cannabis.[60] Cannabis was also openly available from shops in the US. By the end of the 19th century, its medicinal use began to fall as other drugs like aspirin took over its use as a pain reliever.

In 1894, the Report of the Indian Hemp Drugs Commission commissioned by the UK Secretary of State and the government of India, was instrumental in the decision not to criminalize the drug in those countries. The Report, which at over 500 pages remains one of the most complete collections of information on cannabis in existence, shows the stark contrast in the way that the American and British governments went about deciding whether to criminalize cannabis.[61]

The name marijuana (Mexican Spanish marihuana, mariguana) is associated almost exclusively with the plant's psychoactive use. The term is now well known in English largely due to the efforts of American drug prohibitionists during the 1920s and 1930s, which deliberately used a Mexican name for cannabis in order to turn the populace against the idea that it should be legal.

Although cannabis has been used for its psychoactive effects since ancient times, it first became well known in the United States during the jazz music scene of the late 1920s and 1930s. Louis Armstrong became a prominent and life-long devotee. It was popular in the blues scene as well, and eventually became a prominent part of 1960s counterculture.

Decriminalization and legalization

In recent decades, a movement to decriminalize cannabis has arisen in several countries . This movement seeks to make simple possession of cannabis punishable by only confiscation or a fine, rather than prison. In the past several years, the movement has started to have some successes. These include Denver, Colorado legalizing possession of up to an ounce of cannabis[62], a broad coalition of political parties in Amsterdam, Netherlands unveiling a pilot program to allow farmers to legally grow it,[63] and Massachusetts voting

in favor of a bill to decriminalize the possession of up to an ounce of cannabis[64]. Also, in Alaska, cannabis was decided legal for in-home, personal use under the Raven vs. State ruling in 1975. This ruling allowed up to four ounces of cannabis for these purposes. In a response to former Governor Frank Murkowski's successive attempt to re-criminalize cannabis, the ACLU filed a lawsuit against the state and on July 17, 2006, Superior Court Judge Patricia Collins awarded the Case Summary judgement to the ACLU. However she said, "No specific argument has been advanced in this case that possession of more than 1 ounce of cannabis, even within the privacy of the home, is constitutionally protected conduct under Ravin or that any plaintiff or ACLU of Alaska member actually possesses more than 1 ounce of cannabis in their homes.", at first glance it appears that possession has been reduced to one ounce when in fact this was a mere case summary review filed by the ACLU, and she even said "A lower court cannot reverse the State Supreme Court's 1975 decision in Ravin v. State" and "Unless and until the Supreme Court directs otherwise, Ravin is the law in this state and this court is duty bound to follow that law". The law regarding possession of cannabis has not changed in Alaska, and the Supreme Court has rejected to review the case, therefore the law still stands at 4 ounces.[citation needed] In 2001 in the United Kingdom, it was announced that cannabis would become a Class C drug, rather than a Class B, this change took effect in 2004. Since then there has recently been some controversy amongst UK politicians about the message this sends out, with some calling for its reclassification to Class B. [65] The Government of Mexico voted to legalize the possession of cannabis under 5 grams on April 28, 2006. [66] However, as of May 3, 2006, Mexican President Vicente Fox has said that he will not sign this proposed law until Congress removes the parts that would decriminalize the possession of small quantities of drugs[67] and vetoed the bill on May 4, 2006,[68] sparking broad controversy over the bill.[69][70][71] In the early summer of 2006 Fox and the Mexican congress came to an agreement and legalized possession of small amounts (and also measured amounts of other drugs). On July 17th, 2006, Italian Social Solidarity Minister Paolo Ferrero, speaking of the urgent need for depenalising the consumption of light drugs, said that "a joint is less harmful than a litre of wine." [72] In The Australian state of South Australia and the Australian Capital Territory, two plants both less than 6 ft tall are allowed for personal use.

Dissociatives

A *dissociative* is a drug which reduces (or blocks) signals to the conscious mind from other parts of the brain, typically, but not necessarily, limited to the physical senses. Such a state of sensory deprivation and dissociation can facilitate self exploration, hallucinations, and dreamlike states of mind which may resemble some psychedelic mindstates. Essentially similar states of mind can be reached via contrasting paths—psychedelic or dissociative. That said, the entire experience, risks and benefits are markedly different.

The primary dissociatives are similar in action to phencyclidine (PCP), and include ketamine and dextromethorphan. Also included are nitrous oxide (laughing gas), salvia divinorum, and muscimol from the amanita muscaria (fly agaric) mushroom.

Many dissociatives also have central nervous system depressant effects, thereby carrying similar risks as opioids to slowing breathing or heart rate to levels resulting in death, when using very high doses.

Their effects are characterized by intense feelings of depersonalization, derealization, and analgesia.

Pharmacological classes of dissociatives, and their general subjective effects

Entries marked with a # are naturally occurring.

NMDA receptor antagonists and sigma1 ligands

- dextromethorphan
- ketamine
    - memantine
- phencyclidine, *PCP*
    - Ibogaine # (is also classed as a psychedelic)
    - dizocilpine

riluzole
Tiletamine
MK-801 (dizocilpine)

Kappa opioid receptor agonists

- Salvinorin-A #, the active constituent of Salvia divinorum (diviner's sage)
Enadoline
ibogaine (Weak / Complex mechanism of action)
Pentazocine

Inhalants

- Nitrous oxide

Amanita muscaria constituents

- Muscimol # GABA-A agonist, primary active constituent
Ibotenic acid # NMDA agonist, metabolizes to muscimol
- Muscarine # muscarinic ACh agonist, trace constituent, deliriant

These four groups of dissociatives have slightly different effects but also share similarities separating them from other classes of hallucinogens. They are markedly different from psychedelics such as LSD, where alert and fully conscious users experience cognitive distortion while simultaneously interacting with the "real world". Hallucinations from these dissociatives are generally only experienced in dark rooms or with eyes closed, unless at very high doses above what is normally consumed recreationally. Nitrous oxide has very different effects however, and even at low doses includes auditory distortions. Unlike with many other psychedelic chemicals, salvia users are generally not ambulatory and the experience is frequently dissociative. Often a very brief trance is entered, where the user experiences an intense and very realistic dream state. On the other hand, the effect of salvia on emotion has been reported to be less marked than that of true psychedelics.

Although muscimol does not usually cause normal hallucinations, it has a tendency to put the user to sleep, during which the user is able to have very vivid dreams with good dream recall.

- Psychoactive drug

Hypnotics

Hypnotic drugs are a class of drugs that induce sleep (which differentiates them from the sedative category), used in the treatment of severe insomnia and in surgical anesthesia. Often the treatment of insomnia will not begin with drugs at all, however, as many (not all) hypnotic drugs are habit forming. A physician will usually recommend alternative sleeping patterns and exercise before prescribing medication for sleep. This is due to a large number of factors known to disturb the human sleep pattern.

These drugs include barbiturates, benzodiazepines, zolpidem, zaleplon, zopiclone, eszopiclone, chloral hydrate, chlormethiazole or the antihistamines doxylamine, promethazine, and diphenhydramine. Alcohol is often tried as a hypnotic drug but it is not particularly effective.

Mood stabilizers

A *mood stabilizer* is a psychiatric medication used to treat mood disorders characterized by rapid and unstable mood shifts. These disorders include bipolar disorder, where mood stablizers suppress swings between mania and depression, and borderline personality disorder. Most mood stabilizers are anticonvulsants, with the important exception of lithium.

Mood stabilizers include:

- Lithium carbonate — the first Food and Drug Administration-approved mood stabilizer, and still popular in treatment. Therapeutic drug monitoring required. Monitor blood lithium levels (therapeutic range: 0.6 or 0.8-1.2 mEq/L) and look for signs and symptoms of toxicity (such as nausea, vomiting, diarrhea, ataxia).
- Valproic acid (Depakene®), divalproex sodium (Depakote®), and sodium valproate (Depacon®) — Available in extended release form. Can be very irritating to the stomach, especially when taken as valproic acid. Liver function and CBC should be monitored. Therapeutic drug monitoring is required. Lamotrigine (Lamictal®) — Particularly effective for bipolar depression. Monitor for signs and symptoms of Stevens-Johnson syndrome, very rare but can be fatal.
- Carbamazepine (Tegretol®) — CBC should be monitored; can lower white blood cell count. Therapeutic drug monitoring is required. Not FDA-approved for bipolar disorder, but widely used for many years.
- Gabapentin (Neurontin®) — Not FDA approved for bipolar disorder. Recent scientific studies suggest it is not an effective treatment, however many psychiatrists continue to use it.
- Oxcarbazepine (Trileptal®) — Not FDA approved for bipolar disorder.
- Topiramate (Topamax®) — Not FDA approved for bipolar disorder.

Sometimes mood stabilizers are used in combination, such as lithium with one of the anticonvulsants.

Many atypical antipsychotics also have mood stabilizing effects and are thus commonly prescribed even when psychotic symptoms are absent. It is also conjectured that Omega-3 fatty acids may have a mood stabilizing effect. However, more research is needed to verify this (a multi-year study of this is now being carried out as of 2001).

Most mood stabilizers are effective at treating mania and mood cycling and shifting, but are not very effective at treating depression (with lamotrigine and lithium carbonate being exceptions). Often, an antidepressant is prescribed in addition to the mood stabilizer during depressive phases. However this brings some risks, as antidepressants can induce mania, psychosis, and other disturbing problems in bipolar patients, particularly when taken alone, but sometimes even when used with a mood stabilizer.

Phenethylamines

Phenethylamine

Chemical name 2-Phenylethylamine

Other names Phenethylamine, ²-Phenylethylamine, 2-Phenyl-1-aminoethane, ²-Aminoethylamine, 2-Phenylethanamine

Chemical formula $C_8H_{11}N$

Molecular mass 121.18 g/mol

CAS number [64-04-0]

Density 0.964 g/cm^3

Melting point -60 °C

Boiling point 194.5-195 °C

SMILES c1ccccc1CCN

Phenethylamine, or ²-Phenylethylamine, is an alkaloid and monoamine. In the human brain, it is believed to function as a neuromodulator or neurotransmitter (trace amine). Phenethylamine is a natural compound biosynthesized from the amino acid phenylalanine

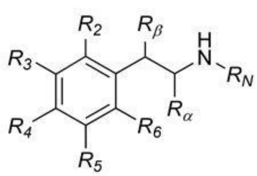
by enzymatic decarboxylation. It is also found in many foods such as chocolate, especially after microbial fermentation. It has been suggested that phenethylamine from food may have psychoactive effects in sufficient quantities. However, it is quickly metabolized by the enzyme MAO-B, preventing significant concentrations from reaching the brain.

Substituted phenethylamines are a broad and diverse class of compounds that include neurotransmitters, hormones, stimulants, hallucinogens, entactogens, anorectics, bronchodilators, and antidepressants. The phenethylamine structure can also be found as part of more complex ring systems such as the ergoline system of LSD or the morphinan system of morphine.

Chemistry

Phenethylamine is an aromatic amine which is a colorless liquid at room temperature. It is soluble in water, ethanol, and ether.[1] Similar to other low molecular weight amines, it has a fishy odor. Upon exposure to air, it forms a solid carbonate salt with carbon dioxide. Phenethylamine is strongly basic and forms a stable crystalline hydrochloride salt with a melting point of 217 °C. Phenethylamine is also a skin irritant and possible sensitizer.

Substituted phenethylamines



General structure of phenethylamines and amphetamines (see the table below).

Substituted phenethylamines carry additional chemical modifications at the phenyl ring, the sidechain, or the amino group:

- Amphetamine are homologues of phenethylamines carrying an alpha-methyl (±-CH3) group at the sidechain carbon atom next to the amino group.
- Catecholamines are phenethylamines carrying two hydroxy groups in positions 3 and 4 of the phenyl ring. Examples are the hormones and neurotransmitters dopamine,
- The aromatic amino acids phenylalanine and tyrosine are phenethylamines carrying a carboxyl group (COOH) in alpha position.

Pharmacology

Many substituted phenethylamines are pharmacologically active drugs due to their similarity to the monoamine neurotransmitters:

- Stimulants like the plant alkaloids Ephedrine and cathinone and the synthetic drugs Amphetamine (speed, benzedrine) and methylphenidate
- Hallucinogens like the plant alkaloid mescaline and the synthetic drug 2C-B

- Empathogen-entactogens **like** MDMA **(*ecstasy*) and MDA**
    - Anorectics like phentermine, fenfluramine, and Amphetamine
- Bronchodilators **like** salbutamol **and Ephedrine**
- Antidepressants **like** bupropion **and the** monoamine oxidase inhibitors **phenelzine and tranylcypromine.**

2C-T-7

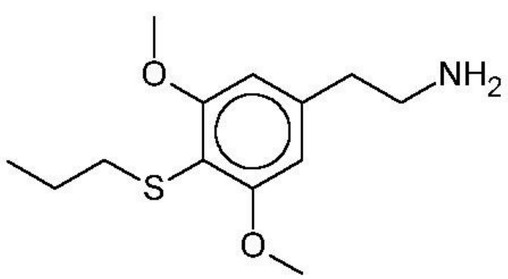
Chemical name 2-[2,5-dimethoxy-4-(propylthio)phenyl]ethanamine

Chemical formula C***13***H***21***NO***2***S

Molecular mass 255.3799

CAS numbers 207740-26-9

SMILES COc1cc(SCCC)c(cc1CCN)OC



THIS IS ACTUALLY 3,5 dimethoxy, NOT 2,5 dimethoxy. SOMEONE PLEASE CORRECT IT.

2C-T-7 is a psychedelic phenethylamine and is sometimes used as an entheogen. It was presumably first synthesized in 1986 by Alexander Shulgin. It has structural and pharmacodynamic properties similar to the drugs Mescaline, MDMA, 2C-T-2 and 4-MTA. An often used slang term for 2C-T-7 is "watusi".

Chemistry

2C-T-7 is 4-(n)-propylthio-2,5-dimethoxyphenethylamine with the formula C12H21O2NS. The full name of the chemical is 2-[2,5-dimethoxy-4-(propylthio)phenyl]ethanamine.

Pharmacology

2C-T-7 is a hallucinogenic phenethylamine. In his book PIHKAL (Phenethylamines I Have Known and Loved), Shulgin lists the dosage range as 10-30mg. 2C-T-7 is generally taken orally, and produces psychedelic and entheogenic effects that last 8 to 12 hours.

The mechanism that produces the hallucinogenic and entheogenic effects of 2C-T-7 is most likely to result from action as a 5-HT2A serotonin receptor agonist in the brain, a mechanism of action shared by all of the hallucinogenic tryptamines and phenethylamines.[1]

2C-T-7 also has a separate action as a selective monoamine oxidase A inhibitor. This makes 2C-T-7 a potentially dangerous drug as at high doses it can slow down the degradation of serotonin in the brain, which can lead to serotonin syndrome and potential death without treatment.[2]

Several of the deaths involving 2C-T-7 followed co-administration of the drug with other stimulants such as MDMA and Ephedrine, and so these kind of combinations should be avoided.

Recreational usage

2C-T-7 has been sold on the street under the names "Blue Mystic," "Tweetybird Mescaline," "7th Heaven," and "Lucky 7." The drug can be taken orally or snorted, and can be lethal even in small doses.[3]

Around the year 2000, 2C-T-7 began to change from an obscure chemical to a drug used at parties and clubs in North America and Europe as it became available through a number of grey-market commercial vendors.

There have been at least three reported deaths related 2C-T-7 use, and in January of 2002, Rolling Stone published an article about 2C-T-7 entitled "The New (legal) Killer Drug". It can cause nausea and may be dangerous when combined with alcohol.

Legality

On September 20, 2002, 2C-T-7 was classified as a Schedule I substance in the United States by an emergency ruling by the DEA.

MDEA

 MDEA

MDEA (also *MDE*), which stands for 3,4-methylenedioxy-N-ethylamphetamine, is a psychedelic hallucinogenic drug and empathogen-entactogen of the phenethylamine family. It is chemically very similar to MDMA, the active chemical in the drug "ecstasy". MDEA differs from MDMA in that it has one more carbon atom, and two more hydrogen atoms in the substituent on the nitrogen atom. The difference is evidenced in its name by the "ethyl" prefix, rather than the "methyl" prefix designating a single-carbon chain (see Alkanes). MDEA is sometimes sold as a substitute for ecstasy on the black market. It can be prepared by reductive amination of MDP2P.

MDEA works by releasing serotonin, a neurotransmitter that affects mood and perception. It requires a slightly larger dose (100 - 200 mg.) than MDMA with major effects lasting typically between 3 and 5 hours [1]. The subjective effects of MDEA are similar to MDMA. The euphoric 'loved up' feelings associated with MDMA use are not as pronounced. The effects are also not as stimulating as MDMA, MDE has somewhat of a stoning effect and may be responsible for rumors of heroin-laced ecstasy pills. However, MDEA does have a mildly hallucinogenic effect. This, coupled with an increase in the user's energy levels (similar to amphetamine use) had led some users to conclude that MDEA is more suitable as a nightclub drug.

Mescaline

Chemical name 3,4,5-Trimethoxy- phenethylamine or 2-(3,4,5-trimethoxyphenyl) ethanamine

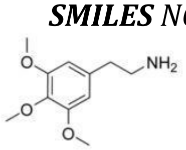
Chemical formula C***11***H***17***NO***3***

Molecular mass 211.26 g/mol

Melting point 128–129 °C

CAS numbers 54-04-6

SMILES *NCCC1=CC(OC)=C(OC)C(OC)=C1*



Mescaline (3,4,5-trimethoxyphenethylamine) is a hallucinogenic alkaloid of the phenethylamine class.

It occurs naturally in the peyote cactus (Lophophora williamsii), the San Pedro cactus (Echinopsis pachanoi), in the Peruvian Torch cactus (Echinopsis peruviana), and it is also found in a number of other members of the Cactaceae. It can be extracted from these sources. Mescaline was first isolated and identified in 1897 by the German Arthur Heffter and first synthesized in 1919 by Ernst Späth.

Usage and history

The use of extract from peyote in Native American religious ceremonies has been noted since the earliest European contact, notably by the Huichols in Mexico.

Dosage and effects

For the drug to take effect, disk-shaped buttons are cut from the roots, on the top of the cactus, and dried. It is chewed to produce its effect or soaked in water for an intoxicating drink. The effective human dosage is 0.3–0.5 grams, with the effects lasting for up to 12 hours. Users typically experience visual hallucinations and radically altered states of consciousness, often experienced as pleasurable and illuminating but occasionally as accompanied by feelings of anxiety or revulsion. It is not physically addictive.

Legal status

In the US it was made illegal in 1970 by the Comprehensive Drug Abuse Prevention and Control Act. It was prohibited internationally by the 1971 Convention on Psychotropic Substances[1] and is categorised as a Schedule I hallucinogen by the CSA.

Chemistry

A common synthetical approach starts from 3,4,5-trimethoxybenzaldehyde (PiHKAL entry).

Side effects

One or more of the following side effects may or may not accompany any individual experience with mescaline.

- Open eye visuals

Closed-eye visuals
New thought processes
Dream-like scenarios
Euphoria
Mystical experience
Pupil dilation

Sensations of warm and cold
Temporary splitting/destruction of ego
Dizziness
Vomiting
Tachycardia
Diarrhea
Headaches
Anxiety
Feeling of dying or genocide
Fear of not being able to return to normal consciousness
Hallucinogen persisting perception disorder (HPPD)
Irrationality of the thought-process

Famous users

Methylphenidate

Systematic (IUPAC) name

methyl 2-phenyl-2-(2-piperidyl)acetate

Identifiers

CAS number 113-45-1

ATC code N06**BA04**

PubChem 4158

DrugBank APRD00657

Chemical data

Formula $C_{14}H_{19}NO_2$

Mol. weight 233.306 g/mol

Pharmacokinetic data

Bioavailability **11–52%**

Metabolism Liver

Half life 2–4 hours

Excretion Urine

Therapeutic considerations

Pregnancy cat. C

Legal status Class B(UK) Schedule II(US)

Indicated for:

ADD
ADHD
narcolepsy
Recreational uses:
Stimulant / "Speed" / "Uppers"
Other uses:
treatment-resistant depression
appetite suppressant

antidepressant augmentation

Contraindications:
Use of tricyclic antidepressants (e.g. desipramine), as MPH may dangerously increase their plasma concentrations, leading to potential toxic reactions (mainly, cardiovascular effects).
Use of MAO Inhibitors, such as phenelzine (Nardil) or tranylcypromine (Parnate), and certain other drugs.
MPH should not be given to patients who suffer from the following conditions: Severe Arrhythmia, Hypertension or Liver damage.
Drug-seeking behaviour
Pronounced agitation or nervousness

Side effects:

Cardiovascular:
Tachycardia
Arterial hypertension
Endocrinal:
Appetite loss
Eye:

Blurred vision
Pupil dilation (If snorted)
Gastrointestinal:
Nausea/vomiting, abdominal pain
Musculoskeletal:
Muscle twitches
Neurological:
Insomnia, drowsiness, dizziness, headache
Psychological:
Nervousness
Euphoria
Respiratory:
Increased respiration rate

Methylphenidate (*MPH*) is an Amphetamine-like prescription stimulant commonly used to treat Attention Deficit Hyperactivity Disorder (ADHD) in children and adults. It is also one of the primary drugs used to treat symptoms of traumatic brain injury and the daytime drowsiness symptoms of narcolepsy and chronic fatigue syndrome. Brand names of drugs that contain methylphenidate include *Ritalin*® (*Ritalina*®, *Rilatine*®), *Attenta*®, *Concerta*® (a timed-release capsule), *Metadate*®, *Methylin*® and *Rubifen*®. *Focalin*® is a preparation containing only dextro-methylphenidate, rather than the usual racemic dextro- and laevo-methylphenidate mixture of other formulations.

History

Methylphenidate was patented in 1954 by the Ciba pharmaceutical company (one of the predecessors of Novartis) and was initially prescribed as a treatment for depression, chronic fatigue, and narcolepsy, among other ailments. Beginning in the 1960s, it was used to treat children with ADHD, known at the time as hyperactivity or minimal brain dysfunction (MBD). Today methylphenidate is the medication most commonly prescribed to treat ADHD around the world. According to most estimates, more than 75 percent of methylphenidate prescriptions are written for children, with boys being about four times as likely to take methylphenidate than girls. Production and prescription of methylphenidate rose significantly in the 1990s, especially in the United States, as the ADHD diagnosis came to be better understood and more generally accepted within the medical and mental health communities. Methylphenidate has been used illegally by students for whom the drug has not been prescribed, to assist with coursework and examinations. [1]

While ADHD medication is directed for children, it has not been studied for children under the age of 6. It is also important to note that while ADHD is a condition that includes hyperactivity, problems holding still, and following directions, this is also typical of a child under the age of 6. This causes difficulty in diagnosing children under this age and should probably not be studied.[1]

Most brand-name Ritalin is produced in the United States, although methylphenidate is also produced in Mexico and Argentina by respective contract pharmaceutical manufacturers and is most commonly marketed under the brand name "Ritalin" for Novartis. In the United States, various generic forms of methylphenidate are also produced by several

pharmaceutical companies (such as Methylin, etc.), and Ritalin is also sold in the United Kingdom, Germany, and other European countries (although in much lower volumes than the United States). These generic versions of methylphenidate tend to outsell brand-name "Ritalin" four-to-one. In Belgium the product is sold under the name "Rilatine" for Novartis.

Another medicine is Concerta, a once-daily extended release form of methylphenidate, which was approved in April 2000. Studies have demonstrated that long-acting methylphenidate preparations such as Concerta are just as effective, if not more effective, than IR (instant release) formulas. [2] [3][4] [5] Time-release medications are also harder to misuse.

In April 2006, the FDA approved a transdermal patch for the treatment of ADHD, called Daytrana. The once-daily patch administers methylphenidate in doses of 10, 15, 20, or 30mg.[6] However, the patch must be applied several hours before the effect is desired, and the drug's effect remains for several hours after removal, making it necessary to remove the patch in the mid-to-late afternoon or else insomnia may result.

Effects

Methylphenidate is a central nervous system (CNS) stimulant. It is claimed to have a 'calming' effect on many children who have ADHD,[7] reducing impulsive behavior and the tendency to "act out", and helps them concentrate on schoolwork and other tasks. Adults who have ADHD often claim that MPH increases their ability to focus on tasks and organize their lives.

Methylphenidate has been found to have a lower incidence of side-effects compared to dextroamphetamine, a less commonly prescribed medication. [8] When prescribed at the correct dosage, methylphenidate is usually well-tolerated by patients.[2]

The means by which methylphenidate helps people with ADHD are not well understood. Some researchers have theorized that ADHD is caused by a dopamine imbalance in the brains of those affected. MPH is a dopamine reuptake inhibitor, which means that it increases the level of the dopamine neurotransmitter in the brain by partially blocking the transporters that remove it from the synapses. [9] An alternate explanation which has been explored is that the MPH affects the action of serotonin in the brain.[10]

In the United States, methylphenidate is classified as a Schedule II controlled substance, the designation used for substances that have a recognized medical value but which have a high potential for abuse because of their addictive potential. Internationally, methylphenidate is a Schedule II drug under the Convention on Psychotropic Substances. [11] Some people abuse MPH by crushing the tablets and snorting them, the "high" resulting from the increased rate of dopamine transporter blockade due to quicker absorption into the bloodstream. In this manner, the effect of Ritalin is similar to that of cocaine or Amphetamine and such abuse can lead to addiction. When taken orally in prescribed doses, MPH has a low addiction liability and rarely produces a "high".

Side effects

Common reported side effects are[12][13]: difficulty sleeping (which can lead in turn to other problems); loss of appetite (thus its use as an appetite suppressant); Depression; irritability; nervousness; stomach aches; headaches; dry mouth; blurry vision; nausea; dizziness; drowsiness; motor tics or tremors. Up to 5% of children experience disturbing hallucinations often involving worms, snakes, or insects (New Scientist, 31 March 2006).

Less common side effects are: hypersensitivity; anorexia; palpitations; blood pressure and pulse changes; cardiac arrhythmia; anemia; scalp hair loss; toxic psychosis.

There have also been reports of: abnormal liver function; cerebral arteritis; leukopenia; death. There have been at least 19 cases of sudden death in children taking methylphenidate, leading to calls by the Drug Safety and Risk Management Advisory Committee to the FDA to require the most serious type of health warning on the label, but this advice was rejected (New Scientist 18 Feb. 2006).

Medline [14] lists a number of side-effects of unquantified frequency.

Formulations

Most products containing methylphenidate contain a racemic mixture of dextro-methylphenidate and levo-methylphenidate, although it is only dextro-methylphenidate, the active enantiomer, which is considered to provide the pharmacologically useful effects of mental focus. However, with the introduction of Focalin, pure dextro-methylphenidate is available. Described as a fast-acting form of the drug, it is absorbed more quickly by the body, with a shorter time to peak concentration (and excretion) than with the racemic compound.

The pharmacological profiles and relative usefulness of dextro- and levo-methylphenidate is analogous to what is found in amphetamine, where dextro-amphetamine is considered to have a more beneficial effect than levo-amphetamine.

Delivery

Ritalin: 5 mg, 10 mg and 20 mg tablets;
Ritalin SR: 20 mg tablets;
Ritalin LA: 20 mg, 30 mg and 40 mg capsules;
Attenta: 10mg tablets;
Methylin: 5 mg, 10 mg, and 20 mg tablets;
Methylin ER: 10 mg and 20 mg tablets;
Metadate ER: 10 mg and 20 mg tablets;
Metadate CD: 10 mg, 20 mg and 30 mg capsules;
Concerta: 18 mg, 27 mg, 36 mg and 54 mg tablets;
Equasym: 5 mg, 10 mg tablets;
Rubifen: 5 mg, 10 mg and 20 mg tablets;
Daytrana: 10 mg, 15 mg, 20 mg, 30 mg and 40 mg patches

Criticism

Similarity to Cocaine

Like cocaine, methylphenidate is a powerful stimulant that increases alertness and productivity. Methylphenidate and cocaine have similar chemical structures. [15] Their effects, too, are similar; both increase the brain-levels of dopamine -- a joy-inducing neurotransmitter -- by blocking the ability of neurons to reabsorb dopamine. When taken as prescribed, however, Methylphenidate is absorbed into the body at a much slower rate than cocaine. In this way, methylphenidate is like low-dosage, slow-acting cocaine. [16] The similarities between methylphenidate and cocaine have prompted concern that the unknown dangers of methylphenidate could be similar to the known dangers of cocaine. [17] There have also been some reports showing a cross-tolerance between cocaine, methylphenidate, and a third common stimulant, amphetamine. [18]

Overprescription

The incidence of ADHD is believed to be between three and five percent of the population, while the number of children in America taking Ritalin is estimated at one to two percent. [19] In a small study of four American communities, the incidence of ADHD varied from 1.6% to 9.4%. The study also found that 12.5% of the children meeting the DSM-III-RADHD criteria for ADHD had been treated with stimulants during the past year.[20]

Addiction

The question of whether or not MPH use in children leads to future addictive tendencies has sparked many inquiries and analyses. One study examined the history of a group of adults who had used cocaine at least once, and found that those who as children had been medically diagnosed with hyperactivity and had received methylphenidate treatment for between one and ten years had a percentage of cocaine abuse twice that of either of two control groups: one group of same-age individuals who had not been diagnosed with hyperactivity, and one group of individuals who had also been diagnosed with hyperactivity but had not been treated with stimulants. This research has been described as indicating that "... methylphenidate was still capable of explaining a small but significant proportion of the variance in cocaine use even after approximately 15 years."[21] On the flip side, a 2003 project suggests that boys with ADHD who are treated with stimulants like MPH are actually less likely to abuse drugs (including alcohol) later in life.[22]

Long-term effects

Ritalin has been used on a long-term basis since the mid-20th century, yet clinical studies of the long-term use effects have not been undertaken. A great deal of controversy has been generated by non-expert groups, many of them basing 'research' on the negative effects of ritalin on children. Many of these reports have been forwarded by Scientology-related groups.

In a 2005 study, no "clinically significant" effects on growth, vital signs, tics, or laboratory tests (including urinalysis, hematology/complete blood counts, electrolytes, and liver function tests) were observed after 2 years of treatment. [23]

Still, some theoretical studies raise theoretical questions. For example, Adriani et al (2005) found plastic changes in reward related behavior in rats after they were in a drug-free state. [24] Whether or not this would have any effect on human cognition is unknown.

Effects on stature

Researchers have also looked into the role of methylphenidate in affecting stature, with some studies finding slight decreases in height acceleration. [25] Other studies indicate height may normalize by adolescence. [26][27]

Risk of death

As mentioned above, methylphenidate has been implicated in cases of sudden death by heart failure. The FDA decided against requiring warning labels, even though its advisory committee voted in favor of this. According to the Merck Index Methylphenidate had an LD***50*** of 150mg/kg body mass.

Potential Carcinogen

In February 2005, a team of researchers from The University of Texas M.D. Anderson Cancer Center led by R.A. El-Zein announced that a small scale study of 12 children indicated that methylphenidate may be carcinogenic. In the study, 12 children were given standard therapeutic doses of methylphenidate. At the conclusion of the 3 month study, all 12 children displayed significant, treatment induced chromosomal aberrations. The researchers indicated that while their study was relatively small, they indicated the results should be reproduced one more time in a bigger population for a definitive conclusion about the genotoxicity of methylphenidate to be drawn. The link between chromosomal aberrations and cancer risk has been established. [28]

The results are controversial, however, since there have been conflicting results regarding the mutagenicity of methylphenidate.

A 2003 study tested the effects of d-methylphenidate (Focalin), l-methylphenidate, and d,l-methylphenidate (Ritalin) on mice to search for any carcinogenic effects. The researchers found that all three compounds were non-genotoxic and non-clastogenic; d-MPH, d,l-MPH, and l-MPH did not cause mutations or chromosome aberrations. They concluded that none of the compounds present a carcinogenic risk to humans. [29]

In 2005, the U.S. Food and Drug Administration issued a series of public health advisories warning that Ritalin and its sister drugs may cause visual hallucinations, suicidal thoughts, psychotic behavior, as well as agression or violent behavior.

Illicit use

Both the United States Drug Enforcement Administration (DEA) and the United Nations International Narcotics Control Board have expressed concern about the ease with which legally prescribed MPH is diverted to the illicit market.[30][31]

According to the DEA, "The increased use of this substance [MPH] for the treatment of ADHD has paralleled an increase in its abuse among adolescents and young adults who crush these tablets and snort the powder to get high. Youngsters have little difficulty obtaining methylphenidate from classmates or friends who have been prescribed it."[32]

Street names for Ritalin include: diet coke, kiddie cocaine, kiddie coke, vitamin R, R-ball, poor man's cocaine, rids, skittles, and smarties.

Psychedelics, dissociatives and deliriants

Certain drugs can affect the subjective qualities of perception, thought or emotion, resulting in altered interpretations of sensory input, alternate states of consciousness, or hallucinations. This general group of pharmacological agents can be divided into three broad categories: *psychedelics*, *dissociatives* and *deliriants*. All of these agents act as neurotransmitter mimics, often as agonists or antagonists at neurotransmitter receptors. Their primary effects are markedly different from those of other psychoactives such as cocaine, Amphetamine, heroin or alcohol.

The term *hallucinogen* is often broadly applied, especially in current scientific literature, to some or all of these substances. The term, though, has long attracted criticism. (See Etymology and alternative terms)

Despite the use of "hallucinogen" as a cover term, true hallucinations, as distinct from illusions, are rare with these substances. The apparent unity of the category is further belied by the quite different effects of psychedelics, dissociatives, and deliriants on consciousness. Broadly speaking, psychedelics reduce the filters in the brain causing sensory overload which is often manifested in visual and audial distortion, dissociatives cause a separation between cognition and sensory awareness (possibly including hallucination or dreamlike experiences), and deliriants are a class of drug that produce a fragmented dissociated state of quasi-consciousness akin to sleepwalking where dreams and reality intertwine to produce potentially dangerous hallucinations indistinguishable from reality.

These substances have a millennial history of traditional use in medicine and religion, where they have been prized as means to access spiritual realities and to promote physical and mental healing. Together with other plant agents, like tobacco, they are important tools of shamans and other hierophants. Native American practitioners using peyote have reported success in treating alcoholism, and Mazatec practitioners routinely use psilocybin mushrooms for healing and divination.

Psychedelics

Main article: psychedelic drug

The psychedelic (mind manifesting) drugs are classified as those whose primary action is that of enhancing or amplifying the thought processes of the brain. One prominent psychological explanation of psychedelics' effects is the "reducing valve" hypothesis, derived from Aldous Huxley's reflections on his experiments with mescaline. In this view, the drugs disable the brain's experiential "filters," which block or suppress unimportant or undesired signals to the conscious mind from other parts of the brain, including but not limited to the senses, emotions, memories and the unconscious (or subconscious) mind. This effect has

been described as mind expanding, or consciousness expanding as the conscious mind becomes aware of (or sometimes assaulted by) things normally inaccessible to it. At high levels this can become overwhelming, and can result in a dissociative state whereby one is so occupied by their racing thoughts that they lose touch with the outside world during the peak of the experience.

Classic psychedelics include LSD (acid), psilocybin (psychedelic mushrooms), mescaline (peyote), LSA (morning glory seeds) and also Ayahuasca (yage). Some of the synthetic "club drugs" such as MDMA ('pure' ecstasy), 2C-B (nexus), DOM (STP) and 5-MeO-DIPT (Foxy Methoxy) which have much more specific action to particular aspects of the psyche are also classed as psychedelics, as well as cannabis (marijuana).

Some psychedelics (namely LSD, psilocybin and cannabis) are extremely non-toxic, making it difficult to overdose unless these compounds are combined with other drugs.

Dissociatives

Main article: dissociative drug

A dissociative is a drug which reduces (or blocks) signals to the conscious mind from other parts of the brain, typically (but not necessarily, or limited to) the physical senses. Such a state of sensory deprivation can *facilitate* self exploration, hallucinations, and dreamlike states of mind which may resemble some psychedelic mindstates. Essentially similar states of mind can be reached via contrasting paths -- psychedelic or dissociative. That said, the entire experience, risks and benefits are markedly different.

The primary dissociatives are similar in action to PCP (angel dust) and include Ketamine (an anaesthetic), and DXM (an active ingredient in many cough syrups, dextromethorphan). Also included are nitrous oxide, salvia divinorum, and muscimol from the amanita muscaria (fly agaric) mushroom.

Many dissociatives also have CNS depressant effects, thereby carrying similar risks as opioids to slowing breathing or heart rate to levels resulting in death (when using very high doses). This does not appear to be true in other cases, toxic effects do not appear to exist in the case of salvia divinorum, and the principal risk of nitrous oxide seems to be due to oxygen deprivation. Injury from falling is also a danger, as nitrous oxide may cause sudden loss of consciousness, an effect of oxygen deprivation. Long term use of dissociative anesthetics such as PCP and Ketamine (and possibly DXM) have been suspected to cause Olney's lesions, though these lesions have never been demonstrated in primates to date.

Deliriants

Main article: Deliriant

The deliriants (or anticholinergics) are a special class of dissociative which are antagonists for the acetylcholine receptors (unlike muscarine and nicotine which are agonists of these receptors). Deliriants are considered to be true hallucinogens as users will have conversations with people who aren't there, or become angry with a 'person' mimicking their actions, not realizing it is their own reflection in a mirror (which could be dangerous if

they became aggressive towards a glass mirror). While the regular dissociatives can produce effects similar to lucid dreaming (where one is consciously aware they are dreaming), the deliriants have effects akin to sleepwalking (where one doesn't remember what transpired during the experience).

Included in this group are such plants as deadly nightshade, mandrake, henbane and datura, as well as a number of pharmaceutical drugs when taken in very high doses such as the antihistamine diphenhydramine (Benadryl) and the antiemetic dimenhydrinate (Dramamine or Gravol).

In addition to the danger of being far more "out of it" than with other drugs, and retaining a truly fragmented dissociation from regular consciousness without being immobilized, the anticholinergics are toxic, can cause death due to overdose, and also include a number of uncomfortable side effects. These side effects include dehydration and mydriasis.

Etymology and alternative terms

A variety of different, imprecise terms have also been used to refer to drugs of this type. One of the first terms used in English to describe these substances was "Phantastica", coined in 1928 by Louis Lewin in his ground-breaking monograph of the same name. The term was applied to plants that "bring about evident cerebral excitation in the form of hallucinations, illusions and visions ... followed by unconsciousness or other symptoms of altered cerebral functioning." Lewin complained that the word "does not cover all that I should wish it to convey", and indeed with the advent of the discovery of LSD and the widespread scientific experimentation with it and similar drugs, numerous supposedly improved terms were constructed, including hallucinogen, psychedelic, psychotomimetic, psycholytic, schizophrenogenic, cataleptogenic, mysticomimetic and psychodysleptic.

Of all the terms created, "hallucinogen", meaning roughly "generating delusions and false notions" (particularly in the form of sensory distortions), probably enjoys the most widespread and accepted usage. "Psychedelic", meaning "mind manifesting" and emphasizing the introspective potential of the drugs, and "entheogen", meaning "becoming divine within", are also widely used, particularly among those with positive attitudes towards their usage. In some cases, authors who otherwise use these terms have felt themselves pressured to use "hallucinogen" or "psychotomimetic" (or sometimes "psychomimetic", in either case meaning "mimicking psychosis") in scientific publications. The terms "empathogen" and "entactogen" (see empathogen-entactogen) are also applied to certain drugs (notably those similar to MDMA) that are also sometimes classed as hallucinogens.

Many different names have been proposed over the years for this drug class. The famous German toxicologist Louis Lewin used the name phantastica earlier in this century, and as we shall see later, such a descriptor is not so farfetched. The most popular names, hallucinogen, psychotomimetic, and psychedelic ("mind manifesting"), have often been used interchangeably. Hallucinogen is now, however, the most common designation in the scientific literature, although it is an inaccurate descriptor of the actual effects of these drugs. In the lay press, the term psychedelic is still the most popular and has held sway for nearly four decades. Most recently, there has been a movement in nonscientific circles to recognize the ability of these substances to provoke mystical experiences and evoke feelings of

spiritual significance. Thus, the term entheogen, derived from the Greek word entheos, which means "god within," was introduced by Ruck et al. and has seen increasing use. This term suggests that these substances reveal or allow a connection to the "divine within." Although it seems unlikely that this name will ever be accepted in formal scientific circles, its use has dramatically increased in the popular media and on internet sites. Indeed, in much of the counterculture that uses these substances, entheogen has replaced psychedelic as the name of choice and we may expect to see this trend continue.

—David E. Nichols: "Hallucinogens", Pharmacol Ther 101(2):131-181[1]

The World Health Organization effectively endorses the "psychotomimetic" point of view, defining a hallucinogen as "a chemical agent that induces alterations in perception, thinking, and feeling which resemble those of the functional psychoses without producing the gross impairment of memory and orientation characteristic of the organic syndromes." [2]

History of use

Hallucinogenic drugs are among the oldest drugs used by humankind, as hallucinogens naturally occur in mushrooms, cacti, and various other plants. Whether the use of hallucinogens is encouraged, unregulated, regulated, or prohibited, and whether hallucinogens are used for recreational, medicinal, or spiritual purposes, varies from culture to culture and nation to nation. In most nations of the world, the possession of many hallucinogens, even those that are common in nature, is a crime punished by fines, imprisonment or in many countries, death. For some religious purposes, however, there are exceptions. For instance, though possession of peyote cactus is illegal for most purposes in the United States, American Courts have upheld the Constitutional right of Native Americans to grow and consume peyote.

Traditional religious and shamanic use (entheogens)

In human culture hallucinogens have historically most commonly been used in the setting of religious or shamanic rituals. In this context they are more precisely referred to as entheogens, and are used to facilitate healing, divination, communication with the spirits, and coming of age ceremonies. Evidence exists for the use of entheogens in prehistoric times, as well as in numerous ancient cultures, including the Ancient Egyptian, Mycenaean, Ancient Greek, Vedic, Maya, Inca the and Aztec cultures, not to mention the Upper Amazon, arguabaly the region of globe where entheogens have assumed--literally over millennia--the greatest symbolic and sacred import, as noted among the Urarina of Peruvian Amazonia, who continue to practice an elaborate system of ayahuasca shamanism, coupled with animistic religious beliefs.

The rise of the Abrahamic religions (Judaism, Christianity and Islam) caused a decline of entheogen use in their area. Witness the destruction of the Eleusinian Mysteries, or the Great Witch Hunt of the Early Modern Age, in which practitioners of entheogenic rites in Western Europe were accused of associating with the Devil. Nevertheless, some (mainly tribal) cultures have survived this (ongoing) assault and still practise entheogen use. In others, non-religious hallucinogen use, while not exactly encouraged, is tolerated and not seen as

uncommon. Present-day, historical and mythological aspects of entheogens are discussed in the entry entheogen.

Early scientific investigations

Although natural hallucinogenic drugs have been known to mankind for millennia, it was not until the early 20th century that they received extensive attention from Western science. Earlier beginnings include scientific studies of nitrous oxide in the late 18th century, and initial studies of the constituents of the peyote cactus in the late 19th century. Starting in 1927 with Kurt Beringer's Der Meskalinrausch (The Mescaline Intoxication), more intensive effort began to be focused on studies of psychoactive plants. Around the same time, Louis Lewin published his extensive survey of psychoactive plants, Phantastica (1928). Important developments in the years that followed included the re-discovery of Mexican magic mushrooms (in 1936 by Robert J. Weitlaner) and ololiuhqui (in 1939 by Richard Evans Schultes). Arguably the most important pre-World War II development was by Albert Hofmann's 1938 invention of the semi-synthetic drug LSD, which was later discovered to produce hallucinogenic effects, in 1943.

Hallucinogens after World War II

After World War II there was an explosion of interest in hallucinogenic drugs in psychiatry, owing mainly to the discovery of LSD. Interest in the drugs tended to focus on either the potential for psychotherapeutic applications of the drugs (see psychedelic psychotherapy), or on the use of hallucinogens to produce a "controlled psychosis", in order to understand psychotic disorders such as schizophrenia. Between the mid 1950s and the mid 1960s over 1000 scholarly articles were published on hallucinogen research. Hallucinogens were also researched in several countries for their potential as agents of chemical warfare. Most famously, several tragic incidents associated with the CIA's MK-ULTRA mind control research project have been the topic of media attention and lawsuits.

At the beginning of the 1950s, the existence of hallucinogenic drugs was virtually unknown among the general public of the West. However this soon changed as several influential figures were introduced to the hallucinogenic experience. Aldous Huxley's 1953 essay The Doors of Perception, describing his experiences with mescaline, and R. Gordon Wasson's 1957 Life magazine article (Seeking the Magic Mushroom) brought the topic into the public limelight. In the early 1960s countercultural icons such as Timothy Leary, Allen Ginsberg and Ken Kesey advocated the drugs for their psychedelic effects, and a large subculture of psychedelic drug users was spawned. Many people argue that psychedelic drugs played a major role in catalyzing the vast social changes initiated in the 1960s. As a result of the growing popularity of LSD, and, some contend, establishment disdain for the hippies with whom it was heavily associated, LSD was banned in the United States in 1967.

Social status of hallucinogens

After the fading from public sight as one of the many elements of the 1960s counterculture, hallucinogen use took a less visible but nevertheless persistent role in Western society in the 1970s and 1980s. In the 1990s and 2000s something of a revival of interest in the drugs has occurred. There are probably several important contributing factors to the resurgence. One is the rise of dance-based rave and trance culture, in which participants frequently employ drugs such as the entactogen MDMA, and to a lesser extent, other hallucinogenic drugs such as LSD, magic mushrooms and ketamine, as an aid to inducing ecstatic or trance states of consciousness. A second major contributing factor to the revival of interest in hallucinogenic drugs has been the advent of the Internet and World Wide Web. This has made information pertaining to drugs much more accessible to the general public, provided a platform for advocacy that was not previously available, and has enabled otherwise isolated interested parties to communicate and exchange information and experiences. Some well-known contemporary authors of topics relating to hallucinogens include Terence McKenna, Stanislav Grof, Alan Watts, Aldous Huxley, Timothy Leary, Alexander Shulgin, Jonathan Ott and Rick Strassman.

Legal status

As of 2004, most well known hallucinogens (aside from DXM) are illegal in most Western countries. One notable exception to the current criminalization trend is in parts of Western Europe, especially in the Netherlands, where hallucinogenic mushrooms are considered to be so-called "soft drugs", along with cannabis. While the possession of soft drugs is technically illegal, the Dutch government has decided that using law enforcement to combat their use is largely a waste of resources. As a result, public "coffeeshops" in the Netherlands openly sell cannabis, and "smart shops" sell drugs like psilocybin mushrooms and ayahuasca for personal use (See Drug policy of the Netherlands).

Since the latter part of the twentieth century, this attitude has spread throughout Europe; many European countries no longer actively pursue anti-drug policies, and rarely enforce extant legal penalties for personal-use quantities of hallucinogenic drugs. This is especially true with mild hallucinogens such as cannabis, which is rapidly gaining acceptance in western Europe as a harmless and socially acceptable intoxicant, much as alcohol is considered throughout the West. Despite being scheduled as a controlled substance in the mid 1980s, ecstasy's popularity has been growing since that time in western Europe and in the United States.

Attitudes towards hallucinogens other than cannabis have been slower to change. Several attempts to change the law on the grounds of freedom of religion have been made. Some of these have been successful, for example the Native American Church in the United States, and Santo Daime in Brazil. Some people argue that a religious setting should not be necessary for the legitimacy of hallucinogenic drug use, and for this reason also criticize the euphemistic use of the term "entheogen". Non-religious reasons for the use of hallucinogens including spiritual, introspective, psychotherapeutic, recreational and even hedonistic motives, each subject to some degree of social disapproval, have all been defended as the legitimate exercising of civil liberties, including freedom of thought and freedom of self-harm.

Many connect the idea of being "high" or going through a psychedelic state, as having brain damage or going crazy. This is due to the effect of the drug which, in some cases, can be overwhelming. Effects of these drugs can mimic psychological conditions such as psychosis, schizophrenia, and thought disorder. However, this is largely a misconception of the psychedelic state. After many studies investigating its possible use as a "psychotomimetic" and decades of personal/spiritual use it has become apparent that the psychedelic state is wholly different from a psychotic state and thus is ill-compared to schizophrenia and other mental disorders.

Several medical and scientific people, including Albert Hofmann, advocate the drugs should not be banned, but should be strongly regulated like opiates and warn they can be dangerous without proper psychological supervision. [3] Taking a hallucinogenic drug without knowledge can result in psychological trauma, and has occurred many times because many psychedelic drugs such as LSD have low dose and can easily be added to food or drink, similar to "date rape drugs" or Mickey Finns, and those who deliberately do that can be charged with assault. (These occurrences have created some urban myths such as the blue star tattoo myth).

Pharmacology

Hallucinogens can be classified by quality of action, mechanisms of action, or by chemical structure. These classifications often correlate to some extent. The classification system below attempts to blend these three approaches in order to create a balanced and simple overview that is as clear and easy to grasp as possible.

Almost all hallucinogens contain nitrogen and are therefore classified as alkaloids. THC and Salvinorin A are exceptions. Many hallucinogens have chemical structures similar to those of human neurotransmitters, such as serotonin, and temporarily modify the action of neurotransmitters and/or receptor sites.

A classical classification is that of Lewin (Phantastica, 1928): Class I Phantastica roughly correspond to the psychedelics, which is a more modern term usually used as synonym to "hallucinogen" by people with positive attitudes towards them. Here the term is used a bit differently to discriminate one particular class of hallucinogens which it seems to describe best. They typically have no sedative effects (sometimes the opposite) and there is usually a clearcut memory to their effects.

Class II Phantastica correspond to the other classes in this scheme. They tend to sedate in addition to their hallucinogenic properties and there often is an impaired memory trace after the effects wear off.

Psychedelics and mental illnesses in long-term users

Most psychedelics are not known to have long-term physical toxicity. However, amphetamine-like psychedelics, such as MDMA, that release neurotransmitters may stimulate increased formation of free radicals possibly formed from neurotransmitters released from the synaptic vesicle. Free radicals are associated with cell damage in other contexts, and have been suggested to be involved in many types of mental conditions including Parkinson's disease, senility, schizophrenia, and Alzheimer's. Research on this question has not reached a firm conclusion. The same concerns do not apply to psychedelics that do not release neurotransmitters, such as LSD, nor to dissociatives and deliriants.

No clear connection has been made between psychedelic drugs and organic brain damage; however, high doses over time of some dissociatives and deliriants have been shown to cause Olney's lesions in animals, and have been suspected to occur in humans. Additionally, Hallucinogen persisting perception disorder (HPPD) is a diagnosed condition where some effects of drugs persist after a long time--although medical technology has yet to determine what causes the condition.

Pharmacological classes of hallucinogens

Psychedelics (serotonin 5-HT2A receptor agonists)

- Tryptamines
    - Lysergamides

- Phenethylamines
    - Substituted phenethylamines
    - Substituted Amphetamine
        - Empathogens and/or Entactogens **(serotonin releasers)**
- Cannabinoids (CB-1 cannabinoid receptor agonists)

Dissociatives

- NMDA receptor antagonists and sigma***1*** ligands
- Kappa opioid receptor agonists
- Inhalants
- Cholinergics

Deliriants (**anticholinergics**)

- Tropanes
- Antihistamines

Hallucinogenic plants, fungi, and animals

Among the best-known hallucinogenic plants and fungi are:

Plants

Psychedelics

- Ayahuasca (contains DMT and an MAOI, commonly Banisteriopsis caapi with Psychotria viridis)
- Epená (Virola sp.) (contains 5-MeO-DMT and DMT)
- Hawaiian baby woodrose (Argyreia nervosa) (contains Ergine)
- Ololiuhqui/Coaxihuitl (Turbina/Rivea corymbosa) (contains Ergine)
- Tlitliltzin/Badoh Negro (Ipomoea violacea) (contains Ergine)
- Iboga (Tabernanthe iboga) (contains ibogaine)

Cacti psychedelics

- Peruvian Torch cactus (Trichocereus peruvianus) (contains mescaline)
- Peyote cactus (Lophophora williamsii) (contains mescaline)
- San Pedro cactus (Trichocereus pachanoi) (contains mescaline)

Quasi-psychedelics

- Cannabis (contains THC)
- Sinicuichi (Heimia salicifolia) (questioned hallucinogenic activity)
- Nutmeg (Myristica fragrans) (hallucinogenic activity results from ingestion of massive doses of this spice)

Dissociatives

- Diviner's sage (Salvia divinorum) (contains salvinorin A)

Deliriants

- Deadly nightshade (Atropa belladonna) (contains tropane alkaloids) Floripondio (Brugmansia sp.) (contains tropane alkaloids) Henbane (Hyoscyamus niger) (contains tropane alkaloids) Mandrake (Mandragora sp.) (contains tropane alkaloids) Thorn Apple/Jimson Weed (Datura sp.) (contains tropane alkaloids)

Fungi

Psychedelics

- Psilocybe mushrooms (Psilocybe sp. and some Conocybe, Panaeolus and Stropharia) (contain psilocybin and psilocin)
- Ergot fungus (Claviceps purpurea) (not hallucinogenic in itself, but contains LSD precursors)

Dissociatives

- Fly Agaric mushroom (Amanita muscaria) (contains muscimol)

Animals

Psychedelics

- Psychoactive toads (Bufo alvarius) (contain 5-MeO-DMT and Bufotenine)

Entactogens and Empathogens

The terms *empathogen* and *entactogen* are different terms used to describe a class of psychoactive drugs that produce distinctive emotional and social effects similar to MDMA ("ecstasy"). Other members of this class are MDA, MDEA, MBDB, and AET . Entactogens are often incorrectly referred to as hallucinogens or stimulants. The chemical structure of most entactogens contains a substituted Amphetamine core.

The term "*empathogen*" was coined in 1983 by Ralph Metzner to denote chemical agents inducing feelings of empathy.

"*Entactogen*" was coined by David E. Nichols as an alternative to "empathogen", attempting to avoid the potential for improper association of the latter with negative concepts related to the Greek root "pathos" (suffering); Nichols also thought the word was limiting, and did not cover other therapeutic uses for the drugs which go beyond instilling feelings of empathy. The word "entactogen" is derived from the roots "en" (Greek: within), "tactus" (Latin: touch) and "gen" (Greek: produce). Neither term is dominant in usage, and despite their difference in connotation are essentially interchangeable as they refer to precisely the same chemicals.

These drugs appear to produce a different spectrum of psychological effects from stimulants such as methamphetamine and Amphetamine or from psychedelic drugs such as LSD or Psilocybin. As implied by the category names, users of entactogens say the drugs often produce feelings of empathy, love, and emotional closeness to others. However, there have been only very preliminary comparisons of these different drugs in humans in properly controlled laboratory studies.

If MDMA is taken as a representative entactogen, the pharmacological mechanisms of this class appear to resemble those of methamphetamine. Extracellular dopamine, serotonin, and norepinephrine are all increased by both MDMA and methamphetamine. However, entactogens other than MDMA have received relatively little scientific attention, making it difficult to draw conclusions about the mechanisms of entactogens in general. It is also unknown why entactogens might produce emotional effects that differ from stimulants.

Entheogens

An *entheogen*, in the strictest sense, is a psychoactive substance (most often some plant matter with hallucinogenic effects) that occasions an enlightening spiritual or mystical experience, within the parameters of a cult, in the original non-pejorative sense of cultus. In a broader sense, the word "entheogen" refers to artificial as well as natural substances that induce alterations of consciousness similar to those documented for ritual ingestion of traditional shamanic inebriants, even if it is used in a secular context.

The word *entheogen* is a modern term derived from two Ancient Greek words, ½¸µ¿Â (entheos) and ³µ½Ã¸±¹ (genesthai). Entheos literally means "god (theos) within", more freely translated "inspired". The Greeks used it as a term of praise for poets and other artists. Genesthai means "to cause to be" or becoming. So an entheogen is "that which causes God (or godly inspiration) to be within a person".

Terminology and uses of the word

The word "entheogen" was coined in 1979 by a group of ethnobotanists and scholars of mythology (Carl A. P. Ruck, Jeremy Bigwood, Danny Staples, Richard Evans Schultes, Jonathan Ott and R. Gordon Wasson). The literal meaning of the word is "that which causes God to be within an individual". The translation "creating the divine within" is sometimes given, but it should be noted that entheogen implies neither that something is created (as opposed to just perceiving something that is already there) nor that that which is experienced is within the user (as opposed to having independent existence).

The term was coined as a replacement for the terms "hallucinogen" (popularized by Aldous Huxley's experiences with mescaline, published as The Doors of Perception in 1953) and "psychedelic" (a Greek neologism for "soul-revealing", coined by psychiatrist Humphry Osmond, who was quite surprised when the well-known author, Aldous Huxley, volunteered to be a subject in experiments Osmond was running on mescaline). Ruck et al. argued that the term "hallucinogen" was inappropriate due to its etymological relationship to words

relating to delirium and insanity. The term "psychedelic" was also seen as problematic, due to the similarity in sound to words pertaining to psychosis and also due to the fact that it had become irreversibly associated with various connotations of 1960s pop culture.

The meanings of the term "entheogen" were formally defined by Ruck et al.:

> In a strict sense, only those vision-producing drugs that can be shown to have figured in shamanic or religious rites would be designated entheogens, but in a looser sense, the term could also be applied to other drugs, both natural and artificial, that induce alterations of consciousness similar to those documented for ritual ingestion of traditional entheogens.

Since 1979, when the term was proposed, its use has become widespread in certain circles. In particular, the word fills a vacuum for those users of entheogens who feel that the term "hallucinogen", which remains common in medical, chemical and anthropological literature, denigrates their experience and the world view in which it is integrated. Use of the strict sense of the word has therefore arisen amongst religious entheogen users, and also amongst others who wish to practice spiritual or religious tolerance.

The use of the word "entheogen" in its broad sense as a synonym for "hallucinogenic drug" has attracted criticism on three grounds:

- On pragmatic grounds, the objection has been raised that the meaning of the strict sense of "entheogen", which is of specific value in discussing traditional, historical and mythological uses of entheogens in religious settings, is likely to be diluted by widespread, casual use of the term in the broader sense.
- Secondly, some people object to the misuse of the root theos (god in ancient Greek) in the description of the use of hallucinogenic drugs in a non-religious context, and coupled with the climate of religious tolerance or pluralism that prevails in many present-day societies, the use of the root theos in a term describing non-religious drug use has also been criticised as a form of taboo deformation.
- Thirdly, there are some substances that at least partially fulfil the definition of an entheogen that is given above, but are not considered hallucinogenic in the usual sense. One important example is the bread and wine of the Christian (especially Roman Catholic and Episcopal) Eucharist. The 'bread' and 'wine' of early Christianity were discussed and treated in a way that fits the description of an entheogenic substance; ingesting the Eucharist induced the Holy Spirit, as a shared unity-experience in the mystic altered state.

Ideological objections to the broad use of the term often relate to the widespread existence of taboos surrounding psychoactive drugs, with both religious and secular justifications. The perception that the broad sense of the term "entheogen" is used as a euphemism by hallucinogenic drug-users bothers both critics and proponents of the secular use of hallucinogenic drugs. Critics frequently see the use of the term as an attempt to obscure what they perceive as illegitimate motivations and contexts of secular drug use. Some proponents also object to the term, arguing that the trend within their own subcultures and in the scientific literature towards the use of term "entheogen" as a synonym for "hallucinogen" devalues the positive uses of drugs in contexts that are secular but nevertheless, in their view, legitimate.

Beyond the use of the term itself, the validity of drug-induced, facilitated, or enhanced religious experience has been questioned. The claim that such experiences are less valid than religious experience without the use of any chemical catalysts faces the problem that the descriptions of religious experiences by those using entheogens are indistinguishable from many reports of religious experiences without drugs. In an attempt to empirically answer the question about whether drugs can actually facilitate religious experience, the Marsh Chapel Experiment was conducted by physician and theology doctoral candidate, Walter Pahnke, under the supervision of Timothy Leary and the Harvard Psilocybin Project. In the double-blind experiment, volunteer graduate school divinity students from the Boston area almost all claimed to have had profound religious experiences under the influence of psilocybin. (A brief video about the Marsh Chapel experiment can be viewed here.)

In 2006, a more rigorously controlled version of this experiment was conducted at John Hopkins University, yielding very similar results.[1]

Use of entheogens

Naturally occurring entheogens such as Psilocybin and Dimethyltryptamine were, for the most part, discovered and used by older cultures, as part of their spiritual and religious life, as plants and agents which were respected, or in some cases revered. By contrast, artificial and modern entheogens, such as MDMA, never had a tradition of religious use.

Currently entheogens are used in three principal ways: as part of established traditions and religions, secularly for personal spiritual development, and secularly in a manner similar to recreational drugs. A lesser use of entheogens for medical and therapeutic use is rarely pursued due to legislative and cultural objections.

Entheogen-using cultures

The use of entheogens in human cultures is generally ubiquitous throughout recorded history. The number of entheogen-using cultures is therefore very large. Some of the instances better known to Western scholarship are discussed here.

Africa

The best-known entheogen-using culture of Africa is the Bwitists, who used a preparation of the root bark of Iboga (Tabernanthe iboga).[1] A famous entheogen of ancient Egypt is the blue lotus (Nymphaea caerulea). There is evidence for the use of entheogenic mushrooms in Côte d'Ivoire (Samorini 1995). Numerous other examples of the use of plants in shamanic ritual in Africa are yet to be investigated by western science.

Americas

Entheogens have played a pivotal role in the spiritual practices of most American cultures for millennia. The first American entheogen to be subject to scientific analysis was the peyote cactus (Lophophora williamsii). For his part, one of the founders of modern ethno-botany,

the late Richard Evans Schultes of Harvard University documented the ritual use of peyote cactus among the Kiowa of Oklahoma. Used traditionally by many cultures of what is now Mexico, its use spread to throughout North America in the 19th century, replacing the toxic entheogen Sophora secundiflora (mescal bean). Other well-known entheogens used by Mexican cultures include psilocybin mushrooms (known to the Aztecs under the Nahuatl name teonanacatl), the seeds of several morning glories (Nahuatl: tlitliltzin and ololiuhqui) and Salvia divinorum (Mazateco: Ska Pastora; Nahuatl: pipiltzintzintli).

Indigenous peoples of South America employ a wide variety of entheogens. Better-known examples include ayahuasca (Banisteriopsis caapi plus admixtures) among indigenous peoples (such as the Urarina) of Peruvian Amazonia. Other well-known entheogens include: borrachero (Brugmansia spp); San Pedro Trichocereus spp); and various tryptamine-bearing snuffs, for example Epená (Virola spp), Vilca and Yopo (Anadananthera spp). The familiar tobacco plant, when used uncured in large doses in shamanic contexts, also serves as an entheogen in South America. Also, a tobacco that contains higher nicotine content, and therefore smaller doses required, called Nicotiana rustica was commonly used.

In addition to indigenous use of entheogens in the Americas, one should also note their important role in contemporary religions movements, such as the Rastafari movement and the Church of the Universe.

Asia

The indigenous peoples of Siberia (from whom the term shaman was appropriated) have used the fly agaric mushroom (Amanita muscaria) as an entheogen. The ancient inebriant Soma, mentioned often in the Vedas, may have been an entheogen. (In his 1967 book, Wasson argues that Soma was fly agaric. The active ingredient of Soma is presumed by some to be Ephedrine, an alkaloid with stimulant and (somewhat debatable) entheogenic properties derived from the soma plant, identified as Ephedra pachyclada.) However, there are also arguements to suggest that Soma could have also been Syrian Rue, Cannabis, or some combination of any of the above plants. Owing to a lack of clear chemical or even anecdotal information regarding the active ingredient(s) or effects of Soma, this debate is one which is unlikely to be completely and undisputably resolved

Europe

The use of entheogens in Europe was all but eliminated with the rise of post-Roman Christianity and especially during the great witch hunts of Early Modernity. European witches used various entheogens, including deadly nightshade (Atropa belladonna), mandrake (Mandragora officinarum) and henbane (Hyoscyamus niger). These plants were used, among other things, for the manufacture of "flying ointments". In Christian society, witches were commonly believed to fly through the air on broomsticks after coating them with the ointment and applying them to the skin. Consequently, any association with these plants could have proven extremely dangerous and lead to one's execution as a practitioner of witchcraft. The imposition of Roman Christianity also saw the end of the two-thousand-year-old tradition of the Eleusinian Mysteries, the initiation ceremony for the cult of Demeter

and Persephone involving the use of a possibly entheogenic substance known as kykeon. Similarly, there is evidence that nitrous oxide or ethylene may have been in part responsible for the visions of the equally long-lived Delphic oracle (Hale et al., 2003).

In the Christian era the Eucharist plays a symbolic role in religious tradition that has occasionally attracted the label of "entheogen" or "placebo entheogen", even though it does not conform to the original definition involving the use of vision-inducing substances.

Middle East

The entheogenic use of substances, particularly hashish, by ancient Sufis is well-documented. Its use by the "Hashshashin" to stupefy and recruit new initiates was widely reported during the Crusades. However, the drug used by the Hashshashin was likely wine, opium, henbane, or some combination of these, and, in any event, the use of this drug was for stupefaction rather than for entheogenic use. It has been suggested that the ritual use of small amounts of Syrian Rue is an artifact of its ancient use in higher doses as an entheogen. John Marco Allegro has argued in his book The Sacred Mushroom and the Cross that early Jewish and Christian sects and cults were based on the use of Amanita muscaria,[2] though this hypothesis has not achieved widespread currency.

Oceania

Indigenous Australians are generally supposed not to have used entheogens, although there is a strong barrier of secrecy surrounding Aboriginal shamanism, which has likely limited what has been told to outsiders. Natives of Papua New Guinea are known to use several species of entheogenic mushrooms (Psilocybe spp, Boletus manicus).[3] It has been suggested that the Mori of New Zealand used Mori Kava (Macropiper excelsum) as an entheogen (Bock 2000).

"Entheogen" in the Archaeological Record

There have been several examples of the use of Entheogens in the Archaeological Record, but many reports and studies are largley viewed as Psuedoscience. Many of these researchers, like R.G. Wasson or Giorgio Samorini, have produced a plethora of research but are not widley accepted by academia, largley being cited by fringe groups. The first direct evidence of entheogen use comes from Tassili, Algeria, with a cave painting of a mushroom-man, dating to 8000 BP.

"Entheogen" in Classical mythology and cult

Although entheogens are taboo in Christian and Islamic societies, their ubiquity and prominence in the spiritual traditions of other cultures is unquestioned. The entheogen, "the spirit, for example, need not be chemical, as is the case with the ivy and the olive: and yet the god was felt to be within them; nor need its possession be considered something detrimental, like drugged, hallucinatory, or delusionary: but possibly instead an invitation to knowledge or whatever good the god's spirit had to offer." (Ruck and Staples)

Most of the well-known modern examples, such as peyote, psilocybe and other psychoactive mushrooms and ololiuhqui, are from the native cultures of the Americas. However, it has also been suggested that entheogens played an important role in ancient Indo-European culture, for example by inclusion in the ritual preparations of the Soma, the "pressed juice" that is the subject of Book 9 of the Rig Veda. Soma was ritually prepared and

drunk by priests and initiates and elicited a paean in the Rig Veda that embodies the nature of an entheogen:

"Splendid by Law! declaring Law, truth speaking, truthful in thy works, Enouncing faith, King Soma!... O [Soma] Pavmana, place me in that deathless, undecaying world wherein the light of heaven is set, and everlasting lustre shines.... Make me immortal in that realm where happiness and transports, where joy and felicities combine..."

The Kykeon that preceded initiation into the Eleusinian Mysteries is another entheogen, which was investigated (before the word was coined) by Carl Kerenyí, in Eleusis: Archetypal Image of Mother and Daughter. Other entheogens in the Ancient Near East and the Aegean include the poppy, Datura, the unidentified "lotus" eaten by the Lotus-Eaters in the Odyssey and Narkissos.

According to Ruck, Eyan, and Staples, the familiar shamanic entheogen that the Indo-Europeans brought with them was knowledge of the wild Amanita mushroom. It could not be cultivated; thus it had to be found, which suited it to a nomadic lifestyle. When they reached the world of the Caucasus and the Aegean, the Indo-Europeans encountered wine, the entheogen of Dionysus, who brought it with him from his birthplace in the mythical Nysa, when he returned to claim his Olympian birthright. The Indo-European proto-Greeks "recognized it as the entheogen of Zeus, and their own traditions of shamanism, the Amanita and the 'pressed juice' of Soma — but better since no longer unpredictable and wild, the way it was found among the Hyperboreans: as befit their own assimilation of agrarian modes of life, the entheogen was now cultivable" (Ruck and Staples). Robert Graves, in his foreword to The Greek Myths, argues that the ambrosia of various pre-Hellenic tribes were amanita and possibly panaeolus mushrooms.

Amanita was divine food, according to Ruck and Staples, not something to be indulged in or sampled lightly, not something to be profaned. It was the food of the gods, their ambrosia, and it mediated between the two realms. It is said that Tantalus's crime was inviting commoners to share his ambrosia.

Christianity

Even in cultures where they are acceptable, improper use of an entheogen, by the unauthorized or uninitiated, has led to disgrace, exile, and even death. The expulsion of Adam and Eve from the Garden of Eden can be understood as such a parable of an entheogen misused, for the fruit of the Tree of Knowledge by its very nature is part of what is denoted by "entheogen":

"And the Lord God said, 'Behold, the man is become as one of us, to know good and evil: and now, lest he put forth his hand, and take also of the tree of life, and eat, and live for ever:' Therefore the Lord God sent him forth from the garden of Eden, to till the ground from whence he was taken. So he drove out the man; and he placed at the East of the garden of Eden cherubims and a flaming sword which turned every way, to keep the way of the tree of life." Genesis 3:23-25. (Such an interpretation would suggest that Christians are not to rehabilitate or help drug-users, a view not supported by many Christians.)

Indeed the entheogen offers godlike powers in many Traditional tales, including immortality. The failure of Gilgamesh in retrieving the plant of immortality from beneath the waters teaches that the blissful state cannot be taken by force or guile: when Gilgamesh lay on the bank, exhausted from his heroic effort, the serpent came and ate the plant.

Another attempt at subverting the natural order is told in a (according to some) strangely metamorphosed myth, in which natural roles have been reversed to suit the Hellenic world-view. The Alexandrian Apollodorus relates how Gaia (spelled "Ge" in the following passage), Mother Earth herself, has supported the Titans in their battle with the Olympian intruders. The Giants have been defeated:

"When Ge learned of this, she sought a drug that would prevent their destruction even by mortal hands. But Zeus barred the appearance of Eos (the Dawn), Selene (the Moon), and Helios (the Sun), and chopped up the drug himself before Ge could find it."

But what is essential in Christianity is the concept of "The Anointed" or Christ or Messiah, for the priests at first, Levites first of all, instated by Moses himself, and then later for Kings, particularly Saul, David and Solomon, and of course Prophets. This anointing with the "holy chrism" is a practice that must not be open to laymen. The recipe of this "chrism" is given in Exodus 30:22-33 and it contains one element known has "Kanah bosm", that is to say the blooms of a plant that is today identified as cannabis. One reference is essential in that field, even if there are a few mistakes or fuzzy elements in it: Chris Bennett and Neil McQueen, "Cannabis and the Christ: Jesus used Marijuana" on http://www.cannabisculture.com/backissues/cc11/christ.html.

We are then no longer dealing with a metaphor like the apple in the Garden of Eden but with a real phenomenon that can be studied in details.

—Apollodorus 1.34-38.

193.249.86.190 16:20, 12 November 2006 (UTC) Dr Jacques COULARDEAU, Université Paris Dauphine & Université Paris 1 Panthéon Sorbonne

Entheogens in literature

Consumption of the imaginary mushroom anochi as the entheogen underlying the creation of Christianity is the premise of Philip K. Dick's last novel, "The Transmigration of Timothy Archer".

Aldous Huxley's final novel, Island (1962), depicted a fictional entheogenic mushroom — termed "moksha medicine" — used by the people of Pala in rites of passage, such as the transition to adulthood and at the end of life.

In his book "The Sacred Mushroom and the Cross: A Study of the Nature and Origins of Christianity within the Fertility Cults of the Ancient Near East", [2] John M. Allegro argues etymologically that Christianity developed out of the use of a psychedelic mushroom, the true body of Christ, which was later forgotten by its adherents.

Bruce Sterling's "Holy Fire" novel refers to the religion in the future as a result of entheogens, used freely by the population.

Iboga

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Gentianales
Family: Apocynaceae
Genus: Tabernanthe
Species: *T. iboga*

Binomial name Tabernanthe iboga

Iboga (Tabernanthe iboga), also known as *Black bugbane*, is a perennial rainforest shrub and hallucinogen, native to western Africa. Iboga stimulates the central nervous system when taken in small doses and induces visions in larger doses.

Normally growing to a height of 2 m, T. iboga may eventually grow into a small tree up to 10 m tall, given the right conditions. It has small green leaves. Its flowers are white and pink, while the elongated, oval-shaped fruit are orange. Its yellow-coloured roots contains a number of indole alkaloids, most notably ibogaine, which is found in the highest concentration in the root-bark. The root material, bitter in taste, causes an anaesthetic sensation in the mouth as well as systemic numbness to the skin.

Traditional use

The Iboga tree is the central pillar of the Bwiti religion practiced in West-Central Africa, mainly Gabon, Cameroon and the Republic of the Congo, which utilises the alkaloid-containing roots of the plant in a number of ceremonies. Iboga is taken in massive doses by initiates when entering the religion, and on a more regular basis is eaten in smaller doses in connection with rituals and tribal dances, which is usually performed at night time. Bwitists have been subject to persecution by Catholic missionaries, who to this day are thoroughly opposed to the growing religious movement of Bwiti. Léon M'ba, before becoming the first President of Gabon in 1960, defended the Bwiti religion and the use of iboga in French colonial courts. On June 6, 2000, the Council of Ministers of the Republic of Gabon declared Tabernanthe iboga to be a national treasure.

The links and references section of this article provide excellent resource material in articles by Barabe, Goutarel et al. and Samorini.

Addiction treatment

Outside Africa, iboga extracts as well as the purified alkaloid ibogaine are used in treating opiate addiction. The therapy may last several days and upon completion the subject is generally no longer physically dependent. One methadone patient said in the Dutch behind-the-news show 2 vandaag that in just four days he reached a state that normally would have taken him three months, but without the agony. Evidence suggests that ibogaine may also help to interrupt addiction to alcohol and nicotine. The pharmacological effects are rather undisputed with hundreds of peer reviewed papers in support but formal clinical studies have not been completed.

Legal status

Iboga is outlawed or restricted in the U.S., Belgium, Sweden, Switzerland and Denmark. Root material and extracts thereof is obtainable through various European smart shops.

Quotations

- "The Catholic church is a beautiful theory for Sunday, the iboga on the contrary is the practice of everyday living. In church, they speak of God, with iboga, you live God" (Nengue Me Ndjoung Isidore, ecumenical Bwitist religious leader)

Incapacitating agents

The term *incapacitating agent* is defined by the U.S. Department of Defense as "An agent that produces temporary physiological or mental effects, or both, which will render individuals incapable of concerted effort in the performance of their assigned duties."

Incapacitating agents are not primarily intended to kill, but supposedly nonlethal incapacitating agents can kill many of those exposed to them.

The term "incapacitation," when used in a general sense, is roughly equivalent to the term "disability" as used in occupational medicine and denotes the inability to perform a task because of a quantifiable physical or mental impairment. In this sense, any of the chemical warfare agents may incapacitate a victim; however, again by the military definition of this type of agent, incapacitation refers to impairments that are temporary and nonlethal. Thus, riot-control agents are incapacitating because they cause temporary loss of vision due to blepharospasm, but they are not considered military incapacitants because the loss of vision does not last long. Although incapacitation may result from physiological changes such as mucous membrane irritation, diarrhea, or hyperthermia, the term "incapacitating agent" as militarily defined refers to a compound that produces temporary and nonlethal impairment of military performance by virtue of its psychobehavioral or CNS effects.

History

The use of chemicals to induce altered states of mind dates to antiquity and includes the use of plants such as thornapple (Datura stramonium) that contain combinations of anticholinergic alkaloids. The use of nonlethal chemicals to render an enemy force incapable of fighting dates back to at least 600 B.C when Solon's soldiers threw hellebore roots into streams supplying water to enemy troops, who then developed diarrhea. In 184 B.C., Hannibal's army used belladonna plants to induce disorientation, and the Bishop of Münster in A.D. 1672 attempted to use belladonna-containing grenades in an assault on the city of Groningen. In 1881, members of a railway surveying expedition crossing Tuareg territory in North Africa ate dried dates that tribesmen had apparently deliberately contaminated with Hyoscyamus falezlez. In 1908, 200 French soldiers in Hanoi became delirious and experienced hallucinations after being poisoned with a related plant. More recently, accusations of Soviet use of incapacitating agents internally and in Afghanistan were never substantiated. (Although see the Moscow theatre siege case, below).

Following World War II, the United States military investigated a wide range of possible nonlethal, psychobehavioral, chemical incapacitating agents to include psychedelic indoles such as lysergic acid diethylamide (LSD-25) and marijuana derivatives, certain tranquilizers,

as well as several glycolate anticholinergics. One of the anticholinergic compounds, 3-quinuclidinyl benzilate, was assigned the NATO code BZ and was weaponized beginning in the 1960s for possible battlefield use. Although BZ figured prominently in the plot of the 1990 movie, Jacob's Ladder, as the compound responsible for hallucinations and violent deaths in a fictitious American battalion in Vietnam, this agent never saw operational use. Destruction of American stockpiles began in 1988 and is now complete.

Substances known to have been weaponized as incapacitating agents:

- BZ / Agent 15
- LSD
    - Kolokol-1

Documented use of incapacitating agents

There is one documented case of incapacitating agents being used in recent years. In 2002, Chechen terrorists took a large number of hostages in the Moscow theatre siege, and threatened to blow up the entire theatre if any attempt was made to break the siege. An incapacitating agent was used to disable the terrorists whilst the theatre was stormed by special forces. However, the incapacitating agent, unknown at that time, caused many of the hostages to die. The situation was not helped by the fact that the authorities kept the nature of the incapacitating agent secret from doctors trying to treat its victims. At the time, the gas was reported to be an unknown incapacitating agent called "Kolokol-1". The Russian Health Minister Yuri Shevchenko later stated that the incapacitating agent used in the storming of the Moscow theatre siege was a fentanyl derivative.

Psychedelics

Psychedelic drugs are psychoactive drugs whose primary action is to alter the thought processes of the brain. The term is derived from Greek ÈÅÇ· (psyche, "mind") and ´·»µ¹½ (delein, "to manifest"), or ´·»¿Â (delos, "beautiful").

Many psychedelic drugs are thought to disable filters which block or suppress signals related to everyday functions from reaching the conscious mind. These signals are presumed to originate in several other functions of the brain, including but not limited to the senses, emotions, memories and the unconscious (or subconscious) mind. This effect is sometimes referred to as mind expanding, or consciousness expanding as your conscious mind becomes aware of (or sometimes assaulted by) things normally inaccessible to it. At high levels this can overwhelm the sense of self and can result in a dissociative state.

The best definition of what is considered a classic or true psychedelic is the following -- “a psychedelic drug is one which, without causing physical addiction, craving, major physiological disturbances, delirium, disorientation, or amnesia, more or less reliably produces thought, mood, and perceptual changes otherwise rarely experienced except in

dreams, contemplative and religious exaltation, flashes of vivid involuntary memory and acute psychoses". [1] Over the decades, the term has been contaminated to include far more substances than originally intended. Many pharmacologists define psychedelic drugs as chemicals which have an LSD or mescaline like action on certain serotonin receptors. This essentially means tryptamines and phenethylamines, as no psychedelics from other chemical families have been discovered, with the possible exception of piperazines. Many people have applied the term psychedelic to other drugs including cannabis, dissociative arylcyclohexylamines such as PCP and ketamine, tropane deliriants such as atropine, other psychoactives such as Amanita muscaria and Salvia divinorum. More properly, these should be grouped with psychedelics under the category of entheogens, a term which describes the way a drug is used rather than its pharmacological properties.

Psychedelics have a long history of traditional use in native medicine and religion, where they are prized for their perceived ability to promote physical and mental healing. Native American practitioners using peyote have reported success against alcoholism, and Mazatec practitioners routinely use psilocybin mushrooms for divination and healing. Ayahuasca, a psychotropic drug, was used in Peru for religious festivals [Posner, 2006] Link: http://www.walrusmagazine.com/u/register/?ref=anthropology-plants-with-soul

Classic psychedelics include LSD, psilocybin (one active principle of 'magic mushrooms'), mescaline (one active principle of peyote and the San Pedro cactus), LSA (morning glory seeds) and also Ayahuasca (known in Beatnik literature as yajé), a traditional shamanic tea brewed from plants containing dimethyltryptamine and harmine or harmaline. Some newer synthetics such as MDMA (ecstasy), 2C-B (nexus), DOM (STP) and 5-MeO-DIPT (Foxy Methoxy) have also enjoyed some popularity.

Pharmacological classes of psychedelics, and their general subjective effects

Serotonergic psychedelics (serotonin 5-HT2A receptor agonists)

This class of psychedelics includes the major hallucinogens, including tryptamine-based compounds like LSD and psilocybin, and phenethylamine-based compounds like mescaline and 2C-B. Many of the tryptamines and phenethylamines cause remarkably similar effects, despite their different chemical structure. However, most users report that the two families have subjectively different qualities in the "feel" of the experience which are difficult to describe. At lower doses, these include sensory distortions such as the warping of surfaces, shape suggestibility, and color variations. Users often report intense colors that they have not previously experienced, and repetitive geometric shapes are common. Higher doses often cause intense and fundamental distortions of sensory perception such as synesthesia or the experience of additional spatial, temporal, or time dimensions. Some compounds, such as 2C-B, have extremely tight "dose curves," meaning the difference between a non-event and an overwhelming disconnection from reality can be very slight. There can be very real differences, however, such as 5-MeO-DMT which rarely produces the visual effects typical of other psychedelics. Some drugs, such as the ß-carbolines, produce very different effects from the more standard types of psychedelics.

Empathogens and/or entactogens (serotonin releasers)

The empathogens are phenethylamines such as MDMA, MDA, and similar drugs, the effects of which are characterized by feelings of openness, euphoria, empathy, love, and heightened self-awareness, but not by visual hallucinations. Their initial adoption by the dance club sub-culture is probably due to the enhancement of the overall social and musical experience.

Cannabinoids (CB-1 cannabinoid receptor agonists)

The cannabinoids are Tetrahydrocannabinol (THC) and related compounds, which are capable of activating the bodies endogenous cannabanoid system. Some effects may include: general change in consciousness, mild euphoria, feelings of general well-being, relaxation or stress reduction, increased appreciation of humor, music and other art, joviality, metacognition and introspection, enhanced recollection of episodic memory, increased sensuality, loss of inhibition, increased awareness of sensation, creative or philosophical thinking, disruption of linear memory, paranoia, agitation, and anxiety, potentiation of other psychedelics, increased awareness of patterns and color.

Other (psychedelic activity questioned)

The effects of myristicin and elemicin (found in nutmeg) are reported are similar to that of cannabis, more so of the cannabidiol component rather than THC, but with a much longer duration, slow onset, and undesirable side effects.

Cryogenine (Vertine) is the active constituent of sinicuichi. Although vertine has anticholinergic properties, use of sinicuichi tends to produce psychedelic effects rather than that of a deliriant (this could possibly be dose related). The primary noted effects include auditory distortions, improved memory and relaxation.

Lysergamides

 Chemical structure of ergoline

Ergoline is a chemical compound whose structural skeleton is contained in a diverse range of alkaloids and a few psychedelic drugs (ololiuhqui, LSD). Substances derived from ergoline are used clinically for the purpose of vasoconstriction (5-HT 1 Agonists - Ergotamine) and in the treatment of migraine (used with caffeine) and Parkinson's disease, some are implicated in the disease ergotism. Ergometrine and ergotamine are listed as Table I precursors under the United Nations Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances[1] .

Chemistry

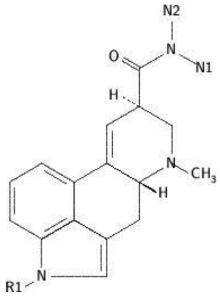
There are three main classes of ergoline derivatives, the water-soluble amides of *lysergic acid*, the water-insoluble *ergopeptide* alkaloids, and the *clavine* group.

Lysergic acid amides

- Ergine (d-lysergic acid amide, LSA, LAA, LA-111)
  - IUPAC name: 9,10-didehydro-6-methylergoline-8beta-carboxamide
  - CAS number: 478-94-4
- Ergonovine (ergobasine)
  - INN: ergometrine
  - IUPAC name: (8beta(S))9,10-didehydro-N-(2-hydroxy-1-methylethyl)6-methyl-ergoline-8-carboxamide
  - CAS number: 60-79-7
- Methergine (ME-277)
  - INN: methylergometrine
  - IUPAC name: (8beta(S))9,10-didehydro-N-(1-(hydroxymethyl)propyl)6-methyl-ergoline-8-carboxamide
  - CAS number: 113-42-8
- Methysergide (UML-491)
  - INN: methysergide
  - IUPAC name: (8beta)9,10-didehydro-N-(1-(hydroxymethyl)propyl)1,6-dimethyl-ergoline-8-carboxamide
  - CAS number: 361-37-5
- LSD (D-lysergic acid diethylamide, LSD-25)
  - INN: lysergide

- IUPAC name: (8beta)9,10-didehydro-N,N-diethyl-6-methyl-ergoline-8-carboxamide
- CAS number: 50-37-3

The relationship between these compounds is summarized in the following structural formula and table of substitutions.



Name	R1	N1	N2
Ergine			
Ergonovine		$CH(CH_3)CH_2OH$	
Methergine		$CH(CH_2CH_3)CH_2OH$	
Methysergide	CH_3	$CH(CH_2CH_3)CH_2OH$	
LSD		CH_2CH_3	CH_2CH_3

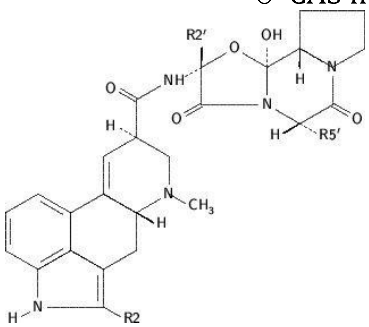
Peptide alkaloids

These compounds have a tripeptide structure attached to the basic ergoline ring, in the same location as the amide group of the lysergic acid derivatives. This tripeptide moiety contains an unusual cyclol bond >N-C(OH)< at the juncture between the two lactam rings. Some of the important *ergopeptides* are summarized below. In addition to the following ergopeptides, a commonly encountered term is *ergotoxine*, which refers to a mixture of equal proportions of ergocristine, ergocornine and ergocryptine.

- Ergotamine
  - IUPAC name: Ergotaman-3',6',18-trione, 12'-hydroxy-2'-methyl-5'-(phenylmethyl)-, (5'-alpha)- (9CI)
  - CAS number: 113-15-5
- Ergocristine
  - IUPAC name: Ergotaman-3',6',18-trione, 12'-hydroxy-2'-(1-methylethyl)5'-(phenylmethyl)-, (5'-alpha)-
  - CAS number: 511-08-0
- Ergocornine
  - IUPAC name: Ergotaman-3',6',18-trione, 12'-hydroxy-2',5'-bis(1-methylethyl)-, (5'-alpha)-
  - CAS number: 564-36-3
- Ergocryptine

- IUPAC name:Ergotaman-3',6',18-trione, 12'-hydroxy-2'-(1-methylethyl)5'-(2-methylpropyl)-, (5'alpha)- (9CI)
- CAS number: 511-09-1

- Bromocriptine (INN)
  - IUPAC name: Ergotaman-3',6',18-trione, 2-bromo-12'-hydroxy-2'-(1-methylethyl)5'-(2-methylpropyl)-, (5'alpha)-
  - CAS number: 25614-03-3
- Ergovaline
  - IUPAC name: Ergotaman-3',6',18-trione, 12'-hydroxy-2'-methyl-5'-(1-methylethyl)-, (5'alpha)-
  - CAS number: 2873-38-3



Name	R2	R2'	R5'
Ergotamine		CH_3	benzyl
Ergocristine		$CH(CH_3)_2$	benzyl
Ergocornine		$CH(CH_3)_2$	$CH(CH_3)_2$
Ergocryptine		$CH(CH_3)_2$	$CH_2CH(CH_3)_2$
Bromocriptine	Br	$CH(CH_3)_2$	$CH_2CH(CH_3)_2$
Ergovaline		CH_3	$CH(CH_3)_2$

Clavines

A variety of modifications to the basic ergoline are seen in nature, for example *agroclavine*, *elymoclavine*, *lysergol*. Those deriving from *dimethylergoline* are referred to as *clavines*.

Others

Some synthetic ergoline derivatives do fall easily into any of the above groups. Some examples are:

- Pergolide (INN)
  - IUPAC name: (8beta)8-((methylthio)methyl)6-propyl-ergoline
  - CAS number: 66104-22-1
- Lisuride (INN)
  - IUPAC name: 3-(9,10-didehydro-6-methylergolin-8alpha-yl)1,1-diethylurea
  - CAS number: 18016-80-3

History & Uses

Ergoline alkaloids were first isolated from ergot, a fungus that infects grain and causes the disease ergotism. Ergot also has a long history of medicinal use, which led to attempts to characterize its activity chemically. This began in 1907 with the isolation by G. Barger and F. H. Carrin of ergotoxine, so-named since it appeared to exhibit more of the toxicity of ergot than its therapeutic qualities. With the isolation of *ergotamine* in 1918 by A. Stoll came the first therapeutic use of isolated ergoline alkaloids.

With the determination of the basic chemical structure of the ergot alkaloids in the early 1930s, an era of intensive exploration of synthetic derivatives began. In addition to the naturally occurring *ergonovine* (used as an oxytocic) and *ergotamine* (an analgesic used to control migraine), synthetic derivatives of continuing importance today are the oxytocic *methergine*, the anti-migraine drugs *dihydroergotamine* and *methysergide*, the anti-senility nootropic (smart drug) *Hydergine*™ (a mixture of dihydroergotoxine mesylates, INN: ergoline mesylates), and *bromocriptine*, used for numerous purposes including treatment of Parkinson's disease. Newer synthetic ergolines used for Parkinson's disease include *pergolide* and *lisuride*. Perhaps the most famous ergoline derivative of all is the psychedelic drug LSD.

In 1960, Albert Hofmann (discoverer of methergine, dihydroergotamine, Hydergine and LSD) delivered a speech that was to cause shockwaves of incredulity and even disbelief in the scientific community. Ergoline alkaloids, previously only known from the lower fungi, had been found in two species of flowering plants. These were the Mexican species Rivea corymbosa and Ipomoea violacea of the Convolvulaceae (morning glory) family, the seeds of which were identified as the psychedelic plant drugs known as "ololiuhqui" and "tlitliltzin". Hofmann's result was later confirmed by other studies. The principal alkaloids in the seeds are ergine and its optical isomer isoergine, with several other lysergic acid derivatives and clavines present in lesser amounts. The Hawaiian species Argyreia nervosa was later found to include similar alkaloids. It is possible, though not proven, that ergine and/or isoergine are responsible for the hallucinogenic effects.

Ergotamine tartrate, the salt form of Ergoline, is marketed under the trade name Avetol.

Pharmacokinetic data

Metabolism hepatic

Half life 3 hours

Excretion renal

Therapeutic considerations

Pregnancy cat. X

Legal status Schedule III(CA) Schedule I(US)

Routes Oral, Intravenous, Transdermal

Lysergic acid diethylamide, commonly called *LSD*, *acid*, or *LSD-25*, is a semisynthetic psychedelic drug. The short form LSD comes from the German "*L*ysergs*ä*ure-*d*iethylamid". A typical single dose of LSD is between 100 and 500 micrograms, an amount roughly equal to one-tenth the mass of a grain of sand. Threshold effects can be felt with as little as 20 micrograms[1] but most users may prefer to take larger doses.[2]

The effects of LSD can vary greatly depending on factors such as previous experiences, state of mind and environment, as well as dose strength. Generally, LSD causes expansion and altered experience of senses, emotions, memories, time, and awareness for 8 to 14 hours. In addition, LSD may produce visual effects such as moving geometric patterns, "trails" behind moving objects, and brilliant colors. LSD does not produce hallucinations in the strict sense but instead illusions and vivid daydream-like fantasies, in which ordinary objects and experiences can take on entirely different appearances or meanings. At higher doses it can cause synesthesia. Some users cite the LSD experience as causing long-term or permanent changes in their personality and life perspective.

LSD is synthesized from lysergic acid derived from ergot, a grain fungus that typically grows on rye. LSD is sensitive to oxygen, ultraviolet light, and chlorine, especially in solution (though its potency may last years if the substance is stored away from light and moisture at low temperature). In pure form it is colorless, odorless, and mildly bitter. LSD is typically delivered orally, usually on a substrate such as absorbent blotter paper, a sugar cube, or gelatin. In its liquid form, it can be administered by intramuscular or intravenous injection, or even in the form of eye-drops

Introduced by Sandoz Laboratories as a drug with various psychiatric uses, LSD quickly became a therapeutic agent that appeared to show great promise. However, the extra-medical use of the drug in Western society in the middle years of the twentieth century led to a political firestorm that resulted in the banning of the substance for medical as well as recreational and spiritual uses. Despite this, it is still considered a promising drug in some intellectual circles, and organizations such as MAPS, Heffter Research Institute and the Albert Hofmann Foundation exist to fund, encourage and coordinate research into its medical uses.

Origins and history

LSD was first synthesized in 1938 by Swiss chemist Dr. Albert Hofmann at the Sandoz Laboratories in Basel, Switzerland, as part of a large research program searching for medically useful ergot alkaloid derivatives. Its psychedelic properties were unknown until 5 years later, when Hofmann, acting on what he has called a "peculiar presentiment," returned to work on the chemical. He attributed the discovery of the compound's psychoactive effects to the accidental absorption of a tiny amount through his skin on April 16, which led to him testing a larger amount (250 µg) on himself for psychoactivity.[3]

Until 1966, LSD and psilocybin were provided by Sandoz Laboratories free of charge to interested scientists under the trade name "Delysid".[3] The use of these compounds by psychiatrists to gain a better subjective understanding of the schizophrenic experience was an accepted practice. Many clinical trials were conducted on the potential use of LSD in psychedelic psychotherapy, generally with very positive results.

Cold War era intelligence services were keenly interested in the possibilities of using LSD for interrogation and mind control, and also for large-scale social engineering. The CIA conducted extensive research on LSD, which was mostly destroyed.[4] LSD was a central research area for Project MKULTRA, the code name for a CIA mind-control research program begun in the 1950s and continued until the late 1960s. Tests were also conducted by the U.S. Army Biomedical Laboratory (now known as the U.S. Army Medical Research Institute of Chemical Defense) located in the Edgewood Arsenal at Aberdeen Proving Grounds. Volunteers would take LSD and then perform a battery of tests to investigate the effects of the drug on soldiers. Based on remaining publicly available records, the projects seem to have concluded that LSD was of little practical use as a mind control drug and moved on to other drugs. Both the CIA and the Army experiments became highly controversial when they became public knowledge in the 1970s, as the test subjects were not normally informed of the nature of the experiments, or even that they were subjects in experiments at all. Several subjects developed severe mental illnesses and even committed suicide after the experiments. The controversy led to President Ford's creation of the Rockefeller Commission and new regulations on informed consent.

The British government also engaged in LSD testing; in 1953 and 1954, scientists working for MI6 dosed servicemen in an effort to find a "truth drug". The test subjects were not informed that they were being given LSD, and had in fact been told that they were participating in a medical project to find a cure for the common cold. One subject, aged 19 at the time, reported seeing "walls melting, cracks appearing in people's faces … eyes would run down cheeks, Salvador Dalí-type faces … a flower would turn into a slug". After keeping the trials secret for many years, MI6 agreed in 2006 to pay the former test subjects financial compensation. Like the CIA, MI6 decided that LSD was not a practical drug for brainwashing purposes.[5]

LSD first became popular recreationally among a small group of mental health professionals such as psychiatrists and psychologists during the 1950s, as well as by socially prominent and politically powerful individuals such as Henry and Clare Boothe Luce to whom the early LSD researchers were connected socially.

Several mental health professionals involved in LSD research, most notably Harvard psychology professors Drs. Timothy Leary and Richard Alpert, became convinced of LSD's potential as a tool for spiritual growth. In 1961, Dr. Timothy Leary received grant money from Harvard University to study the effects of LSD on test subjects. 3,500 doses were given to over 400 people. Of those tested, 90% said they would like to repeat the experience, 83% said they had "learned something or had insight," and 62% said it had changed their life for the better.

Their research became more esoteric and controversial, as Leary and Alpert alleged links between the LSD experience and the state of enlightenment sought after in many mystical traditions. They were dismissed from the traditional academic psychology community, and as such cut off from legal scientific acquisition of the drug. Drs. Leary and Alpert somehow

acquired a quantity of LSD and relocated to a private mansion, where they continued their research. The experiments lost their scientific character as the pair evolved into countercultural spiritual gurus associated with the hippie movement, encouraging people to question authority and challenge the status quo, a concept summarized in Leary's catchphrase, "Turn on, tune in, drop out".

The drug was banned in the United States in 1967, with scientific therapeutic research as well as individual research also becoming prohibitively difficult. Many other countries, under pressure from the U.S., quickly followed suit. Since 1967, underground recreational and therapeutic LSD use has continued in many countries, supported by a black market and popular demand for the drug. Legal, academic research experiments on the effects and mechanisms of LSD are also conducted on occasion, but rarely involve human subjects. Despite its proscription, the hippie counterculture continued to promote the regular use of LSD, led by figures such as Leary and psychedelic rock bands such as The Grateful Dead.

According to Leigh Henderson and William Glass, two researchers associated with the NIDA who performed a 1994 review of the literature, LSD use is relatively uncommon when compared to the abuse of alcohol, marijuana, cocaine and prescription drugs. Over the previous fifteen years, long-term usage trends stayed fairly stable, with roughly 5% of the population using the drug and most users being in the 16 to 23 age range. Henderson and Glass found that LSD users typically partook of the substance on an infrequent, episodic basis, then "maturing out" after two to four years. Overall, LSD appeared to have comparatively few adverse health consequences, of which "bad trips" were the most commonly reported (and, the researchers found, one of the chief reasons youths stop using the drug).[6]

Dosage

LSD is, by mass, one of the most potent drugs yet discovered. Both subjective reports and pharmacological methods such as receptor binding assays determine LSD to be, per mole, around 100 times more potent than psilocybin and psilocin and around 4,000 times more potent than mescaline. Dosages of LSD are measured in micrograms (µg), or millionths of a gram. By comparison, dosages of almost all other drugs, both recreational and medical, are measured in milligrams (mg), or thousandths of a gram.

The dosage level that will produce a threshold hallucinogenic effect in humans is generally considered to be 20–30 ¼g, with the drug's effects becoming markedly more evident at higher dosages.[7][1] According to Glass and Henderson's review, black-market LSD is largely unadulterated though sometimes contaminated by manufacturing by-products. Typical doses in the 1960s ranged from 200 to 1000 µg, while street samples of the 1970s contained 30 to 300 µg. By the mid-1980s, the average had reduced to about 100 to 125 µg, lowering still further in the 1990s to the 20–80 µg range. (Lower doses, Glass and Henderson found, generally produce fewer bad trips.)[6] Dosages by frequent users can be as high as 1,200 µg (1.2 mg), although such a high dosage may precipitate unpleasant physical and psychological reactions.

Estimates for the lethal dosage (LD***50***) of LSD range from 200 ¼g/kg to more than 1 mg/kg of human body mass, though most sources report that there are no known human cases of such an overdose. Other sources note one report of a suspected fatal overdose of

LSD in which there were indications that ~1/3 of a gram (320 mg or 320,000 μg) had been injected intravenously, i.e., over 3,000 more typical oral doses of ~100 μg had been injected.[8]

LSD is not considered addictive, in that its users do not exhibit the medical community's commonly accepted definitions of addiction and physical dependence. Rapid tolerance build-up prevents regular use, and there is cross-tolerance shown between LSD, mescaline and psilocybin. This tolerance diminishes after a few days' abstention from use. As with any psychotropic substance there is a risk of psychological dependence; however, as with most psychedelics, this risk is relatively low .

Effects

Pharmacodynamical

LSD's secondary effects normally last from fifty-two to seventy-five hours,[2] though as Sandoz's prospectus for "Delysid" warned, "intermittent disturbances of affect may occasionally persist for several days."[3] Contrary to early reports and common belief, LSD effects do not last longer than significant levels of the drug in the blood. Aghajanian and Bing[9] found LSD had an elimination half-life of 175 minutes, while, more recently, Papac and Foltz[10] reported that 1 μg/kg oral LSD given to a single male volunteer had an apparent plasma half-life of 5.1 hours, with a peak plasma concentration of 1.9 ng/mL at 3 hours post-dose. Notably, Aghajanian and Bing found that blood concentrations of LSD matched the time course of volunteers' difficulties with simple arithmetic problems.

Some reports indicate that administration of chlorpromazine (Thorazine) or similar typical antipsychotic tranquilizers will not end an LSD trip, but rather will just immobilize and numb the patient.[11] While it also may not end an LSD trip, the best chemical treatment for a "bad trip" is an anxiolytic agent such as diazepam (Valium) or another benzodiazepine. Some have suggested that administration of niacin (nicotinic acid, vitamin B3) could be useful to end the LSD user's experience of a "bad trip".[12] The nicotinic acid in niacin as opposed to niacinamide, will produce a full body heat rash, due to widening of peripheral blood vessels. The effect is somewhat akin to a poison ivy rash. Although it is not clear to what extent the effects of LSD are reduced by this intervention, the physical effect of an itchy skin rash may itself tend to distract the user from feelings of anxiety. The rash itself is temporary and disappears within a few hours. It is not clear how effective this method would be for people having serious adverse psychological reactions.

LSD affects a large number of the G protein coupled receptors, including all dopamine receptor subtypes, all adrenoreceptor subtypes as well as many others. LSD binds to most serotonin receptor subtypes except for 5-HT3 and 5-HT4. However, most of these receptors are affected at too low affinity to be activated by the brain concentration of approximate 10–20 nM.[13] Recreational doses of LSD can affect 5-HT1A, 5-HT2A, 5-HT2C, 5-HT5A, 5-HT5 B and 5-HT6 The hallucinogenic effects of LSD are attributed to its strong partial agonist effects at 5-HT2A receptors as specific 5-HT2A agonist drugs are hallucinogenic and largely 5-HT2A specific antagonists block the hallucinogenic activity of LSD.[13] Exactly how this produces the drug's effects is unknown, but it is thought that it works by increasing glutamate release

and hence excitation in the cortex, specifically in layers IV and V.[14] In the later stages, LSD acts through DARPP-32 - related pathways that are likely the same for multiple drugs including cocaine, amphetamine, nicotine, caffeine, PCP, ethanol and morphine.[15] A particularly compelling look at the actions of LSD was performed by Barry Jacobs recording from electrodes implanted into cat raphe nuclei.[16] Behaviorally relevant doses of LSD result in a complete blockade of action potential activity in the dorsal raphe, effectively shutting off the principal endogenous source of serotonin to the telencephalon.

Physical

Physical reactions to LSD are highly variable and may include the following: uterine contractions, hyperthermia (body temperature increase), elevated blood sugar levels, dry-mouth, goose bumps, heart-rate increase, jaw clenching, nausea, perspiration, pupil-dilation, salivation, mucus production, sleeplessness, paresthesia, euphoria or dysphoria, hyperreflexia, tremors and synesthesia. Cramps and muscle tension or soreness are also commonly reported, and this may be a result of the drug's effect on soft tissues such as the uterus

LSD was studied in the 1960s by Eric Kast as a painkiller for serious and chronic pain caused by cancer or other major trauma.[17] Even at low (sub-psychedelic) dosages, it was found to be at least as effective as traditional opiates while being much longer lasting (pain reduction lasting as long as a week after peak effects had subsided). Kast attributed this effect to a decrease in anxiety. This reported effect is being tested (though not using LSD) in an ongoing (as of 2006) study of the effects of the hallucinogen psilocybin on anxiety in terminal cancer patients.

Furthermore, LSD has been illicitly used as a treatment for cluster headaches, an uncommon but extremely painful disorder. Researcher Peter Goadsby describes the headaches as "worse than natural childbirth or even amputation without anesthetic."[18] Although the phenomenon has not been formally investigated, case reports indicate that LSD and psilocybin can reduce cluster pain and also interrupt the cluster-headache cycle, preventing future headaches from occurring. Currently existing treatments include various ergolines, among other chemicals, so LSD's efficacy may not be surprising. A dose-response study, testing the effectiveness of both LSD and psilocybin is, as of 2006, being planned at McLean Hospital. A 2006 study by McLean researchers interviewed 53 cluster-headache sufferers who treated themselves with either LSD or psilocybin, finding that a majority of the users of either drug reported beneficial effects.[19] Unlike attempts to use LSD or MDMA in psychotherapy, this research involves non-psychological effects and often sub-psychedelic dosages; therefore, it is plausible that a respected medical use of LSD will arise.[20]

Psychological

LSD's psychological effects (colloquially called a "trip") vary greatly from person to person, from one trip to another, and even as time passes during a single trip. Widely different effects emerge based on what Leary called set and setting; the "set" being the

general mindset of the user, and the "setting" being the physical and social environment in which the drug's effects are experienced.

An LSD trip can have long lasting or even permanent neutral, negative, and positive psychoemotional effects. LSD experiences can range from indescribably ecstatic to extraordinarily difficult; many difficult experiences (or "bad trips") result from a panicked user feeling that he or she has been permanently severed from reality and his or her ego. If the user is in a hostile or otherwise unsettling environment, or is not mentally prepared for the powerful distortions in perception and thought that the drug causes, effects are more likely to be unpleasant.

Conversely, a comfortable environment and a relaxed, balanced and open mindset will often result in a pleasant experience.

Many users experience a dissolution between themselves and the "outside world": cognitive differences between subject ("I") and object ("me", "you", "it") break down or seem absurd.[21] This unitive quality may play a role in the spiritual and religious aspects of LSD.

Some experts hypothesize that drugs such as LSD may be useful in psychotherapy, especially when the patient is unable to "unblock" repressed subconscious material through other psychetherapeutic methods,[22] and also for treating alcoholism. One study concluded, "The root of the therapeutic value of the LSD experience is its potential for producing self-acceptance and self-surrender,"[23] presumably by forcing the user to face issues and problems in that individual's psyche. Many believe that, in contrast, other drugs (such as alcohol, heroin, and cocaine) are used to escape from reality. Studies in the 1950s that used LSD to treat alcoholism professed a 50% success rate,[24] higher than estimates near 10% for Alcoholics Anonymous.[25] Some LSD studies were criticized for methodological flaws, and different groups had inconsistent results. Mangini's 1998 paper reviews this history and concludes that the efficacy of LSD in treating alcoholism remains an open question.[26]

Many notable individuals have commented publicly on their experiences with LSD. Some of these comments date from the era when it was legally available in the US and Europe for non-medical uses, and others pertain to psychiatric treatment in the 1950s and 60s. Still others describe experiences with illegal LSD, obtained for philosophic, artistic, therapeutic, spiritual, or recreational purposes.

Sensory/perception

Generally beginning within thirty to ninety minutes after ingestion and continuing for the following six to twelve hours, the user may experience anything from subtle changes in perception to overwhelming cognitive shifts.

Changes in aural and visual perception are common, ranging from mild to profound.[21][27] These sensory changes include basic "high-level" distortions such as the appearance of moving geometric patterns, new textures on objects, blurred vision, image trailing, shape suggestibility and color variations. Inanimate objects are frequently described as "breathing". Users sometimes describe experiencing new, previously-unseen colors; sights and sounds may take on greater intensity or have more of an impact. Users commonly report that the inanimate world appears to animate in an unexplained way; that is, objects

that are static in three dimensions can seem to be moving relative to one or more additional spatial dimensions.[28]

Higher doses often bring about shifts at a lower cognitive level, causing an intense and fundamental reinterpretation of sensory perception, symptomatic of synesthesia.

Spiritual

LSD is considered an entheogen because it often catalyzes intense spiritual experiences where users feel they have come into contact with a greater spiritual or cosmic order. It is common for users to achieve insights into the way the mind works and some users experience permanent or long-lasting changes in their life perspective. Some users consider LSD a religious sacrament, or a powerful tool for access to the divine. Many books have been written comparing the LSD trip to the state of enlightenment of eastern philosophy.

Such experiences under the influence of LSD have been observed and documented by researchers such as Timothy Leary and Stanislav Grof. For example, Walter Pahnke conducted the Good Friday Marsh Chapel Experiment under Leary's supervision, performing a double blind experiment on the administration of psilocybin to volunteers who were students in religious graduate programs, e.g., divinity or theology.[29] That study showed that hallucinogens could reliably be used to induce mystical religious states (at least in people with a spiritual predisposition).

Physical dangers

Although LSD is generally considered nontoxic, it may temporarily impair the ability to make sensible judgments and understand common dangers, thus making the user susceptible to accidents and personal injury.

There is also some indication that LSD may trigger a dissociative fugue state in individuals who are taking certain classes of antidepressants such as lithium salts and tricyclics. In such a state, the user has an impulse to wander, and may not be aware of his or her actions, which can lead to physical injury.[30] SSRIs are believed to interact more benignly, with a tendency to noticeably reduce LSD's subjective effects.[31] Similar and perhaps greater reductions have also been reported with MAOIs.[30]

As Albert Hofmann reports in LSD – My Problem Child, the early pharmacological testing Sandoz performed on the compound (before he ever discovered its psychoactive properties) indicated that LSD has a pronounced effect upon the mammalian uterus. Sandoz testing showed that LSD can stimulate uterine contractions with efficacy comparable to ergobasine, the active uterotonic component of the ergot fungus (Hofmann's work on ergot derivatives also produced a modified form of ergobasine which became a widely accepted medication used in obstetrics, under the trade name Methergine). LSD use by pregnant women is therefore contraindicated.[3]

Initial studies in the 1960s and 70s raised concerns that LSD might produce genetic damage or developmental abnormalities in fetuses. However, these initial reports were based on in vitro studies or were poorly controlled and have not been substantiated. In studies of chromosomal changes in human users and in monkeys, the balance of evidence

suggests no significant increase in chromosomal damage. For example, studies were conducted with people who had been given LSD in a clinical setting.[32] White blood cells from these people were examined for visible chromosomal abnormalities. Overall, there appeared to be no lasting changes. Several studies have been conducted using illicit LSD users and provide a less clear picture. Interpretation of these data is generally complicated by factors such as the unknown chemical composition of "street" LSD and concurrent use of other psychoactive drugs. It seems possible that the small number of congenital abnormalities reported in users of street LSD is either coincidental or related to factors other than a toxic effect of pure LSD.

Flashbacks and HPPD

There is a reported possibility of "flashbacks", a psychological phenomenon in which an individual experiences an episode of some of the subjective effects of LSD (this may be a positive or negative experience) long after the drug has been consumed and worn off — sometimes weeks, months or even years afterward.

Colloquial usage of the term "flashbacks" refers to any experience reminiscent of LSD effects; these are commonly occasional brief experiences. However, psychiatry recognizes a disorder in which LSD-like effects are persistent and cause clinically-significant impairment or distress. This chronic flashback syndrome is called Hallucinogen Persisting Perception Disorder (HPPD), a DSM-IV diagnosis. Several scientific journal articles have described the disorder.[33]

Several studies have tried to determine how likely a "normal" user (that is a user not suffering from known psychiatric conditions) of LSD is to experience flashbacks. The larger studies include Blumenfeld's in 1971[34] and Naditch and Fenwick's in 1977,[35] which arrived at figures of 20% and 28%, respectively. A recent review suggests that HPPD (according to the DSM-IV definition) caused by LSD appears to be rare and affects a distinctly vulnerable subpopulation of users.[36] Differences in the estimated prevalence of flashbacks may partly depend on the multiple meanings of the term and the fact that hallucinogen persisting perception disorder can only be diagnosed in a person who admits to their health care practitioner that they have used hallucinogens.

Debate continues over the nature and causes of chronic flashbacks. Some say HPPD is a manifestation of post-traumatic stress disorder, not related to the direct action of LSD on brain chemistry, and vary according to the susceptibility of the individual to the disorder. Many emotionally intense experiences can lead to flashbacks when a person is reminded acutely of the original experience. However, not all published case reports of chronic flashbacks appear to describe an anxious hyper-vigilant state reminiscent of post-traumatic stress disorder.

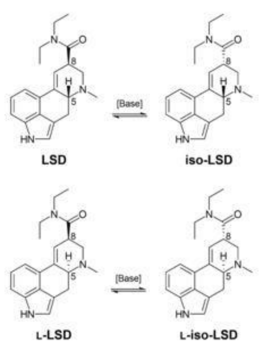
An alternative theory regarding flashbacks postulates that it is a form of perceptual learning. Although unusual perceptual experiences may be just as common among people with no history of having taken the drug, people who have taken LSD may be more likely to associate these otherwise normal psychological events with the experiences they remember having had while on LSD. Under this theory, HPPD would be a separate, more serious, and far less common psychological condition. "Mere" flashbacks, in comparison, may be

experienced by a broad segment of the population, and only attributed to LSD by those who have tried the drug.

Psychosis

There are some cases of LSD inducing or triggering a psychosis in people who were apparently healthy prior to taking LSD. This issue was reviewed extensively in a 1984 publication by Rick Strassman.[37] In most cases, the psychosis-like reaction is of short duration, but in other cases it may be chronic. It is difficult to determine if LSD itself induces these reactions or if it merely triggers latent conditions that would have manifested themselves otherwise. The similarities of time course and outcomes between putatively LSD-precipitated and other psychoses suggests that the two types of syndromes are not different and that LSD may have been a nonspecific trigger. Several studies have tried to estimate the prevalence of LSD-induced prolonged psychosis arriving at numbers of around 4 in 1,000 individuals (0.8 in 1,000 volunteers and 1.8 in 1,000 psychotherapy patients in Cohen 1960;[38] 9 per 1,000 psychotherapy patients in Melleson 1971[39]). But these rates are far lower than the lifetime prevalence for psychotic conditions: schizophrenia, to pick just one type of psychosis, has a lifetime prevalence of about 1% in populations that are not exposed to LSD. In itself, this suggests no causative link between LSD and chronic psychotic disorders.

Chemistry



The four possible isomers of LSD. Only LSD is psychoactive.

LSD is an example of an ergoline derivative. It is commonly produced from lysergic acid, which is made from ergotamine, a substance derived from the ergot fungus on rye, or from ergine (lysergic acid amide), a chemical found in morning glory and hawaiian baby woodrose seeds. It is theoretically possible to manufacture LSD from morning glory or hawaiian baby woodrose seeds although this is not economically feasible, and these seeds have never been found to be a successful starting material for LSD production. Lysergic acid can also be synthesized in the laboratory by relatively complex total syntheses.

LSD is a chiral compound with two stereocenters at the carbon atoms C-5 and C-8, so that theoretically four different optical isomers of LSD could exist. LSD, also called (+)-D-LSD, has the absolute configuration (5R,8R). The C-5 isomers of lysergamides do not exist in nature and are not formed during the synthesis from D-lysergic acid. However, LSD and iso-LSD, the two C-8 isomers, are rapidly interconverting in the presence of base. Non-psychoactive iso-

LSD which has formed during the synthesis can be removed by chromatography and can be isomerized to LSD.

Stability

"LSD," writes the chemist Alexander Shulgin, "is an unusually fragile molecule."[2] It is stable for indefinite amounts of time if stored, as a salt or in water, at low temperature and protected from air and light exposure. Two portions of its molecular structure are particularly sensitive, the carboxamide attachment at the 8-position and the double bond between the 8-position and the aromatic ring. The former is affected by high pH, and if perturbed will produce isolysergic acid diethylamide (iso-LSD), which is biologically inactive. If water or alcohol adds to the double bond (especially in the presence of light), LSD converts to "lumi-LSD", which is totally inactive in human beings, to the best of current knowledge. Furthermore, chlorine destroys LSD molecules on contact; even though chlorinated tap water typically contains only a slight amount of chlorine, because a typical LSD solution only contains an infinitesimal amount of LSD, dissolving LSD in tap water is likely to completely eliminate the substance.[2]

A controlled study was undertaken to determine the stability of LSD in pooled urine samples.[40] The concentrations of LSD in urine samples were followed over time at various temperatures, in different types of storage containers, at various exposures to different wavelengths of light, and at varying pH values. These studies demonstrated no significant loss in LSD concentration at 25 degrees C for up to 4 weeks. After 4 weeks of incubation, a 30% loss in LSD concentration at 37 degrees C and up to a 40% at 45 degrees C were observed. Urine fortified with LSD and stored in amber glass or nontransparent polyethylene containers showed no change in concentration under any light conditions. Stability of LSD in transparent containers under light was dependent on the distance between the light source and the samples, the wavelength of light, exposure time, and the intensity of light. After prolonged exposure to heat in alkaline pH conditions, 10 to 15% of the parent LSD epimerized to iso-LSD. Under acidic conditions, less than 5% of the LSD was converted to iso-LSD. There was also demonstrated that trace amounts of metal ions in buffer or urine could catalyze the decomposition of LSD and that this process can be avoided by the addition of EDTA.

Production

Only a small amount of ergotamine tartrate is required to produce LSD in large batches. For example, 25 kg of ergotamine tartrate can produce 5 or 6 kg of pure LSD crystal that, under ideal circumstances, could be processed into 100 million dosage units, assuming a typical "hit" of 125 ¼g. This is more than enough to meet what is believed to be the entire annual U.S. demand for the drug. LSD manufacturers only need to create a small quantity of the substance, and thus they enjoy an ease of transport and concealment not available to traffickers of other illegal drugs (such as cannabis and cocaine).[41]

Manufacturing LSD requires laboratory equipment and experience in the field of organic chemistry. It takes two or three days to produce 30 to 100 grams of pure compound. It is

believed that LSD usually is not produced in large quantities, but rather in a series of small batches. This technique minimizes the loss of precursor chemicals in case a synthesis step does not work as expected.[41]

Forms of LSD

LSD is produced in crystalline form and then mixed with excipients or diluted as a liquid for production in ingestible forms. Liquid solution is either distributed as-is in small vials or, more commonly, sprayed or soaked onto a distribution medium. Historically, LSD solutions were first sold on sugar cubes, but practical considerations forced a change to tablet form. Early pills or tabs were flattened on both ends and identified by color: "grey flat", "blue flat", and so forth. Next came "domes", which were rounded on one end, then "double domes" rounded on both ends, and finally small tablets known as "microdots". Later still, LSD began to be distributed in thin squares of gelatin ("window panes") and, most commonly, as blotter paper: sheets of paper impregnated with LSD and perforated into small squares of individual dosage units. The paper is then cut into small square pieces called "tabs" for distribution. Individual producers often print designs onto the paper serving to identify different makers, batches or strengths, and such "blotter art" often emphasizes psychedelic themes.

LSD is sold under a wide variety of street names including Acid, Trips, Alice Dee, 'Cid/Sid, Barrels, Blotter, Doses, "L", Liquid, Liquid A, Microdots, Mind detergent, Orange cubes, Orange micro, Owsley, Hits, Paper acid, Sacrament, Sandoz, Sugar, Sugar lumps, Sunshine, Tabs, Ticket, Twenty-five, Wedding bells, Windowpane, etc., as well as names that reflect the designs on the sheets of blotter paper.[42] On occasion, authorities have encountered the drug in other forms — including powder or crystal, and capsule. More than 200 types of LSD tablets have been encountered since 1969 and more than 350 paper designs have been observed since 1975. Designs range from simple five-point stars in black and white to exotic artwork in full four-color print.

Legal status

The United Nations Convention on Psychotropic Substances (adopted in 1971) requires its parties to prohibit LSD. Hence, it is illegal in all parties to the convention, which includes the United States, Australia and most of Europe. However, enforcement of extant laws varies from country to country.

LSD is easy to conceal and smuggle. A tiny vial can contain thousands of doses. Not much money is made from retail-level sales of LSD, so the drug is typically not associated with the violent organized criminal organizations involved in cocaine and opiate smuggling.

United States: Prior to 1967

Prior to 1967, LSD was available legally in the United States as an experimental psychiatric drug. (LSD "apostle" Al Hubbard actively promoted the drug between the 1950s and the 1970s and introduced thousands of people to it.) The US Federal Government classified it as a Schedule I drug according to the Controlled Substances Act of 1970. As such, the Drug Enforcement Administration holds that LSD meets the following three criteria: it is deemed to have a high potential for abuse; it has no legitimate medical use in treatment; and there is a lack of accepted safety for its use under medical supervision. (LSD prohibition does not make an exception for religious use.) Lysergic acid and lysergic acid amide, LSD

precursors, are both classified in Schedule III of the Controlled Substances Act. Ergotamine tartrate, a precursor to lysergic acid, is regulated under the Chemical Diversion and Trafficking Act.

LSD has been manufactured illegally since the 1960s. Historically, LSD was distributed not for profit, but because those who made and distributed it truly believed that the psychedelic experience could do good for humanity, that it expanded the mind and could bring understanding and love. A limited number of chemists, probably fewer than a dozen, are believed to have manufactured nearly all of the illicit LSD available in the United States. The best known of these is undoubtedly Augustus Owsley Stanley III, usually known simply as Owsley. The former chemistry student set up a private LSD lab in the mid-Sixties in San Francisco and supplied the LSD consumed at the famous Acid Test parties held by Ken Kesey and his Merry Pranksters, and other major events such as the Gathering of the tribes in San Francisco in January 1967. He also had close social connections to leading San Francisco bands the Grateful Dead, Jefferson Airplane and Big Brother and The Holding Company, regularly supplied them with his LSD and also worked as their live sound engineer and made many tapes of these groups in concert. Owsley's LSD activities — immortalized by Steely Dan in their song "Kid Charlemagne" — ended with his arrest at the end of 1967, but some other manufacturers probably operated continuously for 30 years or more. Announcing Owsley's first bust in 1966, The San Francisco Chronicle's headline "LSD Millionaire Arrested" inspired the rare Grateful Dead song "Alice D. Millionaire."

United States: 1970 to the present

American LSD usage declined in the 1970s and 1980s, then experienced a mild resurgence in popularity in the 1990s. Although there were many distribution channels during this decade, the U.S. DEA identified continued tours by the psychedelic rock band The Grateful Dead and the then-burgeoning rave scene as primary venues for LSD trafficking and consumption. American LSD usage fell sharply circa 2000. The decline is attributed to the arrest of two chemists, William Leonard Pickard, a Harvard-educated organic chemist, and Clyde Apperson. According to DEA reports, black market LSD availability dropped by 95% after the two were arrested in 2000. These arrests were a result of the largest LSD manufacturing raid in DEA history.[43]

Pickard was an alleged member of the Brotherhood of Eternal Love group that produced and sold LSD in California during the late 1960s and early 1970s. It is believed he had links to other "cooks" associated with this group — an original source of the drug back in the 1960's — and his arrest may have forced other operations to cease production, leading to the large decline in street availability.

The DEA claims these two individuals were responsible for the vast majority of LSD sold illegally in the United States and a significant amount of the LSD sold in Europe, and that they worked closely with organized traffickers. While this claim may have some bearing, the extent of Pickard's direct influence on the overall availability in the United States is not fully known. Some attest that "Pickard's Acid" was sold exclusively in Europe, and was not distributed through American music venues.

In November of 2003, Pickard was sentenced to life imprisonment without parole, and Apperson was sentenced to 30 years imprisonment without parole, after being convicted in Federal Court of running a large scale LSD manufacturing operation out of several clandestine laboratories, including a former missile silo near Wamego, Kansas.

LSD manufacturers and traffickers can be categorized into two groups: A few large scale producers, such as the aforementioned Pickard and Apperson, and an equally limited number of small, clandestine chemists, consisting of independent producers who, operating on a comparatively limited scale, can be found throughout the country. As a group, independent producers are of less concern to the Drug Enforcement Agency than the larger groups, as their product reaches only local markets.

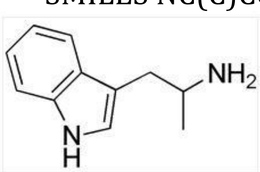
Chemical formula C***11***H***14***N***2***

Molecular mass 174.24 g/mol

CAS number 299-26-3

SMILES NC(C)CC1=CNC2=C1C=CC=C2



±-methyl-tryptamine, also known as *±-MT*, AMT or IT-290, is a synthetic drug of the tryptamine family. First developed as an antidepressant, in the 1960s it was produced commercially for this purpose in the Soviet Union under the trade name "Indopan" in 5mg and 10mg pills. Like many other tryptamines, at sufficient dosages it is a psychedelic hallucinogen. Its effects may take 2-3 hours to onset, and can last for 18 to 24 hours. It also acts as a monoamine oxidase inhibitor and a stimulant, the latter property possibly being related to similarities in chemical structure to amphetamine. On 4 April 2003, an emergency

United States DEA order resulted in ±-MT being placed, along with 5-MeO-DIPT, on Schedule I of the Controlled Substances Act.

Chemistry

±-Methyl-=tryptamine= is chemically related to serotonin, an important neurotransmitter. It acts by mimicking the effects of serotonin at the 5-HT2 receptor and by interfering with neurotransmitter reuptake and degradation mechanisms. ±-MT has a stereocenter, and S-(+)-±-MT is the more active stereoisomer.

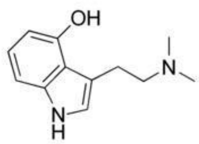
Dosage

An oral dosage of 5-10mg will produce a stimulating effect, and 20-30mg usually results in hallucinogenic effects that can last 24 hours. While a dosage of 60-80mg is generally considered a strong dosage, some users have been known to use large amounts of ±-MT, and report dosages of up to 150mg being taken. The freebase can also be smoked, and 5-20mg is generally used.

Effects

AMT is a long-acting psychedelic/euphoric stimulant. It is known to cause nausea and vomiting in many recreational users.

Psilocin



Systematic name 4-Hydroxy-N,N-dimethyl-tryptamine

Other names 3-(2-(Dimethylamino)ethyl)- 1H-indol-4-ol

Molecular formula C***12***H***16***N***2***O

SMILES *OC1=CC=CC2=C1C(CCN(C)C)=CN2*

Molar mass 204.27 g/mol

CAS number [520-53-6]

Properties

Melting point 173 - 176 °C (base)

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Psilocin, sometimes misspelled psilocine or psilotsin, is a psychedelic (hallucinogenic) mushroom alkaloid. It is found in most psychedelic mushrooms together with its close congener psilocybin. Psilocin is a Schedule I drug under the Convention on Psychotropic Substances.[1]

History

The Swiss chemist Albert Hofmann and the laboratory assistant Hans Tscherter from Sandoz isolated psilocin and its phosphate ester psilocybin from Psilocybe mushrooms in 1959 guided by self-administration.

Chemistry

Psilocin can be obtained by dephosphorylation of natural psilocybin under strongly acidic or under alkaline conditions (hydrolysis). One synthetic route uses the Speeter-Anthony tryptamine synthesis starting from 4-hydroxyindole.

Psilocin is relatively unstable in solution due to its phenolic OH group. Under alkaline conditions in the presence of oxygen it immediately forms bluish and dark black degradation products. Similar products are also formed under acidic conditions in the presence of oxygen and Fe^{3+} ions (Keller's reagent, $FeCl_3$ / MeOH / HCl). Psilocin is an amine and forms salts

with acids that are usually more stable upon storage. Psilocin base can be evaporated by heating.

Pharmacology

Psilocin is the pharmacologically active agent in the body after ingestion of psilocybin or psychedelic mushrooms.

See psilocybin for more details.

Molecular formula $C_{12}H_{17}N_2O_4P$

SMILES C[N+](C)([H])CCC1=CNC2= C1C(OP([O-])(O)=O)=CC=C2

Molar mass 284.25 g/mol

CAS numbe [520-52-5]

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Psilocybin (also known as *psilocybine*), is a psychedelic alkaloid of the tryptamine family. It is present in many species of fungi, including those of the genus Psilocybe, such as Psilocybe cubensis and Psilocybe semilanceata, but also reportedly isolated from a dozen or so other genera. Psilocybin-containing mushrooms are commonly called magic mushrooms or simply "shrooms". Effects of psilocybin are comparable to LSD, but last for a shorter time, although intensity and duration vary depending on dosage, individual physiology, and set and setting.

Chemistry

Psilocybin is a prodrug that is converted into the pharmacologically active compound psilocin in the body by dephosphorylation. This chemical reaction takes place under strongly acidic conditions or enzymatically by phosphatases in the body. Psilocybin is a zwitterionic alkaloid that is soluble in water, moderately soluble in methanol and ethanol, and insoluble in most organic solvents.

Albert Hofmann was the first to recognize the importance and chemical structure of the pure compounds psilocybin and psilocin. Hoffmann was aided in this process by his willingness to ingest extracts isolated from Psilocybe. Hofmann's colleagues at the University of Delaware (who were receiving funding from a Central Intelligence Agency front company) were also trying to isolate the active principle, but were unsuccessful.[1]

Biology

Psilocybin is a naturally-occurring compound found in high concentrations in some species of Psilocybe and Panaeolus (collectively called "psilocybin mushrooms" or "psilocybian mushrooms"), and at low levels in a large number of species of the Agaricales. The spores of these mushrooms are completely free of both psilocybin and psilocin. The total potency varies greatly between species and even between specimens of one species in the same batch. Younger, smaller mushrooms are relatively higher in alkaloids and have a milder taste than larger, mature mushrooms. Mature mycelium contains some amount of psilocybin, which can be extracted with an acidic solution, usually of citric acid or ascorbic acid (Vitamin C). Young mycelium (recently germinated from spores) does not contain appreciable amounts of alkaloids. Most species of hallucinogenic mushrooms also contain small amounts of the psilocybin analogs baeocystin and norbaeocystin. Many types of psilocybin mushrooms bruise blue when handled or damaged — this is due to the oxidization of active compounds and is most notable in mushrooms with a high psilocin content. Several other non-psychoactive (and in some cases toxic) mushrooms also bruise blue.

Pharmacology

Psilocybin is rapidly dephosphorylated in the body to psilocin which then acts as a partial agonist at the 5-HT2A serotonin receptor in the brain where it mimics the effects of serotonin (5-HT).

Medicine

Psilocybin has been studied as a treatment for several disorders. In the early 1960s, Timothy Leary and Richard Alpert ran the Harvard Psilocybin Project, carrying out a number of experiments concerning the use of psilocybin in the treatment of personality disorders and other uses in psychological counseling.

More recently, in the US, an FDA-approved study supported by Multidisciplinary Association for Psychedelic Studies (MAPS) began in 2001 to study the effects of psilocybin on patients with obsessive-compulsive disorder. MAPS has also proposed studying psilocybin's potential application for the treatment of cluster headaches based on anecdotal evidence presented to them by a group of cluster headache sufferers.

Toxicity

The toxicity of psilocybin is relatively low; when administered intravenously in rabbits, Psilocybin's LD50 is approximately 12.5mg/kg. In rats, the LD50 is 280mg/kg -- almost one and a half times that of caffeine.[1] Death from psilocybin intake alone is unknown at most recreational or medicinal levels.

The psilocybin content of psychoactive mushrooms is quite variable and depends on species, growth and drying conditions, and mushroom size, but averages around 5mg/g of dried mushroom, or 1mg/2g of fresh mushroom.

Effects

Psilocybin is absorbed through the lining of the mouth and stomach. Effects begin 20-45 minutes after ingestion of psilocybin-containing mushrooms, and last from 2-6 hours depending on dose, species, and individual metabolism. Typical recreational dosage is from 10-50mg Psilocybin, or approximately 2-5g dried mushroom.

The effects of psilocybin are often pleasant, even ecstatic, including a deep sense of connection to others, confusion, hilarity, and a general feeling of connection to nature and the universe. Difficult trips may occur when psychedelic compounds are taken in a non-supportive or inadequate environment, by an inexperienced person, or in an unexpectedly high dose.

At low doses, hallucinatory effects occur, including walls that seem to breathe, a vivid enhancement of colors and the animation of organic shapes. At higher doses, experiences tend to be less social and more entheogenic, often catalyzing intense spiritual experiences. For example, in the Marsh Chapel Experiment, which was run by a graduate student at Harvard Divinity School under the supervision of Timothy Leary, almost all of the graduate degree divinity student volunteers who received psilocybin reported profound religious experiences. (A brief video about the Marsh Chapel experiment can be viewed here.)

In 2006, a group of researchers from Johns Hopkins School of Medicine led by Roland R Griffiths conducted an experiment assessing the degree of mystical experience and attitudinal effects of the psilocybin experience; this report was published in the journal Psychopharmacology. Thirty-six volunteers without prior experience with hallucinogens were given psilocybin and methylphenidate (Ritalin) in separate sessions, the methylphenidate sessions serving as a control and active placebo; the tests were double-blind, with neither the subject nor the administrator knowing which drug was being administered. The degree of mystical experience was measured using a questionnaire on mystical experience developed by Ralph W Hood; 61% of subjects reported a "complete mystical experience" after their psilocybin session, while only 13% reported such an outcome after their experience with methylphenidate. Two months after taking psilocybin, 79% of the participants reported moderately to greatly increased life satisfaction and sense of well-being. About 36% of participants also had a strong to extreme “experience of fear” or dysphoria (eg, a “bad trip”) at some point during the psilocybin session (which was not reported by any subject during the methylphenidate session), with about one-third of these (13% of the total) reporting that this dysphoria dominated the entire session. These negative effects were reported to be easily managed by the researchers and did not have a lasting negative effect on the subject’s sense of well-being. This research was widely covered in the major media outlets.

A very small number of people are unusually sensitive to psilocybin's effects, where doses as little as 0.25 grams of dried Psilocybe cubensis mushrooms (normally a threshold dose of around 2 mg psilocybin) can result in effects usually associated with medium and high doses. Likewise, there are some people who require relatively high doses of psilocybin to gain low-dose effects. Individual brain chemistry and metabolism plays a large role in determining a person's response to psilocybin.

Psilocybin is metabolized mostly in the liver where it becomes psilocin. It is broken down by the enzyme monoamine oxidase. MAO inhibitors have been known to sustain the effects of psilocybin for longer periods of time; people who are taking an MAOI for a medical condition (or are seeking to potentiate the mushroom experience) should be careful.

Mental and physical tolerance to psilocybin builds and dissipates quickly. Taking psilocybin more than three or four times in a week (especially two days in a row) can result in diminished effects. Tolerance dissipates after a few days, so frequent users often keep doses spaced five to seven days apart to avoid the effect.

Adverse effects

The consumption may cause Hallucinogen persisting perception disorder (HPPD).[2]

It is also possible that a user will take foolish risks, such as driving a vehicle, while under the influence of this or any other psychoactive compound.

Most other adverse effects come from contaminants.

Social and legal aspects

Psilocybin and psilocin are listed as Schedule I drugs under the United Nations 1971 Convention on Psychotropic Substances.[5] Schedule I drugs are illicit drugs that are claimed to have no known therapeutic benefit. Parties to the treaty are required to restrict use of the drug to medical and scientific research under strictly controlled conditions. Most national drug laws have been amended to reflect this convention (for example, the US Psychotropic Substances Act, the UK Misuse of Drugs Act 1971, and the Canadian Controlled Drugs and Substances Act), with possession and use of psilocybin and psilocin being prohibited under almost all circumstances, and often carrying severe legal penalties.

Possession and use of psilocybin mushrooms, including the bluing species of Psilocybe, is therefore prohibited by extension. However, in many national, state, and provincial drug laws, there is a great deal of ambiguity about the legal status of psilocybin mushrooms and the spores of these mushrooms, as well as a strong element of selective enforcement in some places. For more details on the legal status of psilocybin mushrooms and Psilocybe spores, see: Psilocybe: Social and legal aspects.

Because of the ease of cultivating psilocybin mushrooms or gathering wild species, purified psilocybin is practically nonexistent on the illegal drug market.

Kolokol-1

KOLOKOL-1 (russian >;>:>;, eng. bell) is an opiate-derived incapacitating agent. Although the exact nature of the active chemical has not been revealed, in all likelihood it is a derivative of the drug fentanyl, possibly the extraordinarily potent carfentanil. It takes effect very quickly, within one to three seconds, reportedly rendering its victims unconscious for two to six hours. Little else is known about this agent.

According to Lev Fyodorov, a former Soviet chemical weapons scientist who now heads the independent Council for Chemical Security in Moscow, the gaseous agent was originally developed around a secret military research facility in Leningrad during the 1970s. Methods of dispersing it were later developed and tested by releasing harmless bacteria through subway system ventilation shafts first in Moscow and then in Novosibirsk. Fyodorov also claimed that leaders of the failed August 20, 1991 Communist coup considered using the agent in the Russian parliament building. [1]

Use in the Moscow theatre siege

In 2002, Chechen terrorists took a large number of hostages in the Moscow theatre siege, and threatened to blow up the entire theatre if any attempt was made to break the siege. By the third day of the crisis, the Chechens demanded that Russian president Vladimir Putin begin withdrawing Russian troops from Chechnya, or they would begin killing hostages.

Writing in the Moscow daily Komsomolskaya Pravda, Viktor Baranets, a former Russian Defense Ministry official, stated that the Ministry of the Interior knew that any normal riot control agent, such as pepper spray or tear gas, would allow the terrorists time to harm the hostages. They decided to use the strongest agent available. The paper identified the material as a KGB-developed "psycho-chemical gas" known as "Kolokol-1", and reported that "the gas had such an influence on [Chechen siege leader Movsar] Barayev that he couldn't get up from [his] desk". [2]

Immediately after the siege, Western media speculated widely as to the identity of the substance that was used to end the siege, and chemicals such as the tranquilizer diazepam (Valium), the anticholinergic BZ, the oripavine etorphine, and the anaesthetic halothane were proposed. Two days after the incident the Russian Health Minister Yuriy Shevchenko told a news conference that the gas was "based on a derivative of fentanyl". [3]

Although the exact nature of the active chemical has not been verified, the Russian language newspaper Gazeta claimed that the chemical used had been trimethylfentanyl, which is an opioid, attributing this information to "experts from the Moscow State University chemistry department". The name may be a mistranslation of "3-methyl fentanyl", a superpotent fentanyl analog that is about 1000-times more potent than morphine, that was manufactured and abused in the former USSR.

Questionable non-lethality

If Kolokol-1 was the incapacitating agent used in the Moscow theatre siege, it appears that it was directly or indirectly responsible for the deaths of over 100 of the 700 hostages, who appear to have died through a combination of the effects of high doses of the incapacitating substance, lack of food and water, and the lack of adequate medical treatment following the raid, which was exacerbated by the refusal of the authorities to reveal to doctors the nature of the incapacitating agent.

Psychedelia

Psychedelia is a term describing a category of music, visual art, fashion, and culture that is associated originally with the high 1960s, hippies, and the Haight-Ashbury neighborhood of San Francisco, California. It generally began in 1966, but truly took off in 1967 with the Summer of Love. Its beginnings are associated with San Francisco but the style soon spread across the U.S.A., and worldwide.

Psychedelia takes its name from psychedelic (mind manifesting) drugs, which assisted in fueling an entire subculture of fusing together different genres and mediums where strong boundaries had previously existed.

The counterculture of the 1960s had a strong influence on the popular culture of the early 1970s, and is well recognized even by those who are naïve to its psychedelic origins. and is also known as the best art of writing ever known

Hallucination

A *hallucination* is a sensory perception experienced in the absence of an external stimulus, as distinct from an illusion, which is a misperception of an external stimulus. Hallucinations may occur in any sensory modality - visual, auditory, olfactory, gustatory, tactile, or proprioception (sense of balance and position in space).

Prevalence and types of hallucinatory experience

Studies have shown hallucinatory experiences take place across the population as a whole. Previous studies, one as early as 1894[1], have reported that approximately 10% of the population experience hallucinations. A recent survey of over 13,000 people[2] reported a much higher figure with almost 39% of people reported hallucinatory experiences, 27% of which reported daytime hallucinations, mostly outside the context of illness or drug use. From this survey, olfactory (smell) and gustatory (taste) hallucinations seem the most common in the general population.

Hypnagogic hallucinations and hypnopompic hallucinations are considered normal phenomena. Hypnagogic hallucinations can occur as one is falling asleep and hypnopompic hallucinations occur when one is waking up.

Auditory hallucinations (particularly of one or more talking voices) are particularly associated with psychotic disorders such as schizophrenia, and hold special significance in diagnosing these conditions despite the fact that 'hearing voices' is not a sign of mental illness.

Florid hallucinations are usually associated with drug use (particularly hallucinogenic drugs), sleep deprivation, psychosis or neurological illness.

Scientific explanations

Various theories have been put forward to explain the occurrence of hallucinations. When psychodynamic (Freudian) theories were popular in psychiatry, hallucinations were seen as a projection of unconscious wishes and desires. As biological theories have become orthodox, hallucinations are more often thought of (by psychiatrists at least) as being caused by functional deficits in the brain. With reference to mental illness, the function (or dysfunction) of the neurotransmitter dopamine is thought to be particularly important[3].

Psychological research has argued that hallucinations may result from biases in what are known as metacognitive abilities[4]. These are abilities that allow us to monitor or draw inferences from our own internal psychological states (such as intentions, memories, beliefs and thoughts). The ability to discriminate between self-generated and external sources of information is considered to be an important metacognitive skill and one which may break down to cause hallucinatory experiences.

Visual Hallucination Subtypes

Hypnagogic Hallucination

These hallucinations occur just before falling asleep and affect a surprising number of people in the population. The hallucinations can last from seconds to minutes, all the while the subject usually remains aware of the true nature of the images. These are usually associated with narcolepsy, but can also affect non-narcoleptics. Hypnagogic hallucinations are sometimes associated with brainstem abnormalities, but this is rare. [5].

Peduncular Hallucinosis

Peduncular means pertaining to the peduncle, which is a name given to a neural tract running to and from the pons. These hallucinations occur most often in the evenings, but not during drowsiness as in the case above. The subject is usually fully conscious and can interact with the hallucinatory characters for extended periods of time. As in the case of hypnagogic hallucinations, insight into the nature of the images remains intact. The false images can occur in any part of the visual field, and are rarely polymodal. [6].

Delirium Tremens

One of the most enigmatic forms of visual hallucinations are the highly variable, possibly polymodal Delirium Tremens. As the name suggests, the subject is usually agitated and confused, especially in the later stages of this disease. Insight is gradually reduced with the progression of this disorder. Sleep is disturbed and short, with REM overflow. [7].

Parkinson's disease and Lewy body Dementia

Parkinson's disease is linked with Lewy body Dementia for their similar hallucinatory symptoms. The symptoms strike during the evening in any part of the visual field and are rarely polymodal. The segue into hallucinations may start with illusions [8] where sensory perception is greatly distorted, but no novel sensory information is present. These typically last for several minutes, during which time the subject may be either conscious and normal or drowsy/inaccessable. Insight into these hallucinations is usually preserved and REM sleep is usually reduced. Parkinson's disease is usually associated with a degraded substantia nigra pars compacta, but recent evidence suggests that PD affects a handful of other sites in the brain. Some places of noted degradation include the median raphe nuclei, the noradrenergic parts of the locus coeruleus and the cholinergic neurons in the parabrachial and pedunculopontine nuclei of the tegmentum. [9].

Migraine Coma

This type of hallucination is usually experienced during the recovery from a comatose state. The migraine coma can last for up to two days and a state of depression is sometimes comorbid. The hallucinations occur during states of full consciousness and insight into the hallucinatory nature of the images is preserved. It has been noted that ataxic lesions accompany the migraine coma.[10].

Charles Bonnet Syndrome

Charles Bonnet Syndrome is the name given to visual hallucinations experienced by blind patients. The hallucinations can usually be dispersed by opening or closing the eyelids until the visual images disappear. The hallucinations usually occur during the morning or evening, but are not dependent on low light conditions. These prolonged hallucinations usually do not disturb the patients very much as they are aware that they are hallucinating. [11].

Focal Epilepsy

The visual hallucinations from focal epilepsy are characterized by being brief, and stereotyped. They are usually localized to one part of the visual field and last only a few seconds. Other epileptic features may present themselves between visual episodes. Consciousness is usually impaired in some way, but nevertheless insight into the

hallucination is preserved. Usually this type of focal epilepsy is caused by a lesion in the posterior temporoparietal. [12].

Paranormal theories

A rarely expressed but persistent alternate explanation of hallucinations, espoused by non-materialists, is that people prone to hallucinations can sometimes perceive non-physical phenomena such as angels, visions or the voices of departed spirits or demons. For this reason, a hallucination may also be classified as an anomalous phenomenon, when no suitable scientific explanation is verified.

Nutmeg

Scientific classification

Kingdom: Plantae
Division: Magnoliophyta
Class: Magnoliopsida
Order: Magnoliales
Family: Myristicaceae
Genus: *Myristica* Gronov.

Species

About 100 species, including:

- Myristica argentea
- Myristica fragrans
- Myristica malabarica

The *nutmegs Myristica* are a genus of evergreen trees indigenous to tropical southeast Asia and Australasia. They are important for two spices derived from the fruit, *nutmeg* and *mace*.

Nutmeg is the actual seed of the tree, roughly egg-shaped and about 20-30 mm long and 15-18 mm wide, and weighing between 5 and 10 grams dried, while mace is the dried "lacy" reddish covering or arillus of the seed.

Several other commercial products are also produced from the trees, including essential oils, extracted oleoresins, and nutmeg butter (see below).

The pericarp (fruit/pod) is used in Grenada to make a jam called Morne Delice. In Indonesia, the fruit is sliced finely, cooked and crystallised to make a fragrant candy called manisan pala ("nutmeg sweets").

The most important species commercially is the Common or Fragrant Nutmeg Myristica fragrans, native to the Banda Islands of Indonesia; it is also grown in the Caribbean, especially in Grenada. Other species include Papuan Nutmeg M. argentea from New Guinea, and Bombay Nutmeg M. malabarica from India; both are used as adulterants of M. fragrans products.

Culinary uses

Nutmeg and mace have similar taste qualities, nutmeg having a slightly sweeter and mace a more delicate flavor. Mace is often preferred in light-coloured dishes for the bright orange, saffron-like colour it imparts. It is nice in cheese sauces and is best grated fresh.

In Indian cuisine, nutmeg is used almost exclusively in sweets. It is known as jaiphal in most parts of India. It is also used in small quantities in garam masala.

In other European cuisine, nutmeg and mace are used especially in potato dishes and in processed meat products; they are also used in soups, sauces and baked goods.

Japanese varieties of curry powder include nutmeg as an ingredient.

Nutmeg is a traditional ingredient in mulled cider, mulled wine, and eggnog.

Essential oils

The essential oil is obtained by the steam distillation of ground nutmeg and is used heavily in the perfumery and pharmaceutical industries. The oil is colorless or light yellow and smells and tastes of nutmeg. It contains numerous components of interest to the oleochemical industry, and is used as a natural food flavouring in baked goods, syrups (e.g. Coca Cola), beverages, sweets etc. It replaces ground nutmeg as it leaves no particles in the food. The essential oil is also used in the cosmetic and pharmaceutical industries for instance in tooth paste and as major ingredient in some cough syrups. In traditional medicine nutmeg and nutmeg oil were used for illnesses related to the nervous and digestive systems. Myristicin and elemicin are believed to be the chemical constituents responsible for the subtle hallucinogenic properties of nutmeg oil. Other known chemical ingredients of the oil are ±-pinene, sabinene, ^{3}-terpinene and safrole.

Externally, the oil is used for rheumatic pain and, like clove oil, can be applied as an emergency treatment to dull toothache. Put 1-2 drops on a cotton swab, and apply to the gums around an aching tooth until dental treatment can be obtained. In France, it is given in drop doses in honey for digestive upsets and used for bad breath. Use 3-5 drops on a sugar lump or in a teaspoon of honey for nausea, gastroenteritis, chronic diarrhea, and indigestion.

Alternatively a massage oil can be created by diluting 10 drops in 10 ml almond oil. This can be used for muscular pains associated with rheumatism or overexertion. It can also be combined with thyme or rosemary essential oils. To prepare for childbirth, massaging the

abdomen daily in the three weeks before the baby is due with a mixture of 5 drops nutmeg oil and no more than 5 drops sage oil in 25 ml almond oil has been suggested.

Nutmeg butter

Nutmeg butter is obtained from the nut by expression. It is semi solid and reddish brown in colour and tastes and smells of nutmeg. Approximately 75% (by weight) of nutmeg butter is trimyristin which can be turned into myristic acid, a 14-carbon fatty acid which can be used as replacement for cocoa butter, can be mixed with other fats like cottonseed oil or palm oil, and has applications as an industrial lubricant.

History

There is some evidence that Roman priests may have burned nutmeg as a form of incense, although this is disputed. It is known to have been used as a prized and costly spice in the Middle Ages. Saint Theodore the Studite was famous for allowing his monks to sprinkle nutmeg on their pease pudding when required to eat it. In Elizabethan times it was believed that nutmeg could ward off the plague, so nutmeg was very popular. Nutmeg was traded by Arabs during the Middle Ages in the profitable Indian Ocean trade.

In the late 15th century, Portugal theoretically took over the Indian Ocean trade, including nutmeg, under the Treaty of Tordesillas with Spain and a separate treaty with the sultan of Ternate. But their control of this trade was always only partial and they remained largely participants, rather than overlords. The authority Ternate held over the nutmeg-growing centre of the Banda Islands was quite limited, and the Portuguese failed to gain a serious foothold in the islands themselves. The trade in nutmeg later became dominated by the Dutch in the 17th century, who managed to establish control over the Banda Islands after an extended military campaign that culminated in the massacre or expulsion of most of the islands' inhabitants in 1621. Thereafter, the Banda Islands were run as a series of plantation estates, with the Dutch mounting annual expeditions in local war-vessels to extirpate nutmeg trees planted elsewhere.

As a result of the British interregnum during the Napoleonic Wars, the English took temporary control of the Banda Islands from the Dutch and transplanted nutmeg trees to their own colonial holdings elsewhere, notably Zanzibar and Grenada.

Connecticut gets its nickname ("the Nutmeg State", "Nutmegger") from the legend that some unscrupulous Connecticut traders would whittle "nutmeg" out of wood, creating a "wooden nutmeg" (a term which came to mean any fraud).

World production

World production of nutmeg is estimated to average between 10,000 and 12,000 tonnes per year with annual world demand estimated at 9,000 tonnes; production of mace is estimated at 1,500 to 2,000 tonnes. Indonesia and Grenada dominate production and exports of both products with a world market share of 75% and 20% respectively. Other producers include India, Malaysia, Papua New Guinea, Sri Lanka and Caribbean islands such as St.

Vincent. The principal import markets are the European Community, the United States, Japan and India. Singapore and the Netherlands are major re-exporters.

A possible future use for nutmeg is as a natural control for insects that infest stored cereal grains.

At one time, nutmeg was one of the most valuable spices. It has been said that in England, several hundred years ago, a few nutmeg nuts could be sold for enough money to enable financial independence for life.

The first harvest of nutmeg trees takes place 7-9 years after planting and the trees reach their full potential after 20 years.

Risks and toxicity

In low doses, nutmeg produces no noticeable physiological or neurological response. Large doses of 7.5 g or more are dangerous, potentially inducing convulsions, palpitations, nausea, eventual dehydration, and generalized body pain. In amounts of 1.0 g or more it is a mild to medium hallucinogen, producing visual distortions and a mild euphoria. Nutmeg contains chemicals called MAO inhibitors (MAOIs), which disable the brain's ability to stop amines, found in most common foods, from affecting the brain and body. A test was carried out on the substance which showed that, when ingested in large amounts, nutmeg takes on a similar chemical make-up to MDMA (ecstasy). However, use of nutmeg as a recreational drug is unpopular, because of its strong taste and sand-like texture. Also there are potential painful physical side effects, the risk of Nutmeg Psychosis (see below) and the inconveniently long span for which the effects of a single dose can persist. A user will not experience a peak until approximately six hours after ingestion, and effects can linger for up to three days afterwards. Any unpleasant side-effects would persist throughout this period.

A risk in any large-quantity ingestion of nutmeg is the sudden onset of *Nutmeg Psychosis*, an acute psychiatric disorder marked by hallucinations, excitement, thought disorder, a sense of impending death and agitation. Some cases have resulted in hospitalization and reportedly few who have experienced the effects of nutmeg poisoning recommend it or repeat the experience.

Even in smaller doses, nutmeg can still be toxic. Ingestion of as little as 3 g may cause dry mouth, fast pulse, fever, flushing and posibly death. It has Amphetamine-like effects and may cause the desire to ingest of large volumes of water. There is no specific antidote; the adverse effects wear off after 24 hours (or more) of rest.

Nutmeg is extremely toxic when injected intravenously. Nutmeg can also cause liver damage if used regularly in large quantities. Nutmeg has in the past been used as an abortifacient. Nutmeg may also be fatal if used regularly in large quantities, but this is not a problem while cooking, since small amounts are used.

Sedatives

A *sedative* is a substance which depresses the central nervous system (CNS), resulting in calmness, relaxation, reduction of anxiety, sleepiness, slowed breathing, slurred speech, staggering gait, poor judgment, and slow, uncertain reflexes. Sedatives may be referred to as *tranquilizers*, depressants, anxiolytics, soporifics, sleeping pills, downers, or sedative-hypnotics. At high doses or when they are abused, many of these drugs can cause unconsciousness (see hypnotic) and death.

Types of sedatives

- Antidepressants
    - mirtazapine (Remeron®)
    trazodone (Desyrel®)
- Barbiturates
    - secobarbital (Seconal®)
    pentobarbital (Nembutal®)
    amobarbital (Amytal®)
- Benzodiazepines ("minor tranquilizers")
    - alprazolam **(Xanax®)**
    - diazepam (Valium®)
    - lorazepam (Atavan®)
    - Typical antipsychotics ("major tranquilizers")
        - fluphenazine (Prolixin®)
        - haloperidol (Haldol®)
        loxapine succinate (Loxitane®)
        perphenazine (Etrafon®, Trilafon®)
        prochlorperazine (Compazine®)
        thiothixene (Navane®)
        trifluoperazine (Stelazine®, Trifluoperaz®)
    - Atypical antipsychotics
        - clozapine (Clozaril®)
        quetiapine (Seroquel®)
        risperidone (Risperdal®)

ziprasidone (Geodon®) (It may make some people tired, while causing insomnia in others)

- olanzapine (Zyprexa®)

- Herbal sedatives
  - catnip

Valerian (plant)
Mandrake
Kava Kava

- Uncategorized sedatives
  - chloral hydrate (Noctec®)

- diethyl ether **(Ether)**

  - eszopiclone (Lunesta®)

ethchlorvynol (Placidyl®)
ethyl alcohol (alcoholic beverage)
gamma-hydroxybutyrate (GHB)
glutethimide (Doriden®)
meprobamate (Miltown®)
methaqualone (Sopor®, Quaalude®)
methyl trichloride (Chloroform)
methyprylon (Noludar®)
ramelteon (Rozerem®)
zaleplon (Sonata®)
zolpidem (Ambien®)
zopiclone (Imovane®, Zimovane®)

Therapeutic use

Doctors and nurses often administer sedation to patients in order to dull the patient's anxiety related to painful or anxiety-provoking procedures. Although sedatives do not relieve pain in themselves, they can be a useful adjunct to analgesics in preparing patients for surgery, and are commonly given to patients before they are anaesthetized, or before other highly uncomfortable and invasive procedures like cardiac catheterization or MRI. They increase tractability and compliance of children or troublesome or demanding patients.

Patients in intensive care units are almost always sedated (unless they are unconscious from their condition anyway).

Sedative dependence

All sedatives can cause physiological and psychological dependence when taken regularly over a period of time, even at therapeutic doses. When dependent users decrease or end use suddenly, they will exhibit withdrawal symptoms ranging from restlessness, insomnia and anxiety to convulsions and death. When users become psychologically dependent, they feel as if they need the drug to function although there is no biological dependence. In both types of dependence, finding and using the drug becomes the focus in life. Both physical and psychological dependence can be treated (see Sedative Dependence).

Abuse and overdoses

All sedatives can be abused, but barbiturates are responsible for most of the problems with sedative abuse due to their widespread "recreational" or non-medical use. People who have difficulty dealing with stress, anxiety or sleeplessness may overuse or become dependent on sedatives. Heroin users take them either to supplement their drug or to substitute for it. Stimulant users frequently take sedatives to calm excessive jitteriness. Others take sedatives recreationally to relax and forget their worries. Barbiturate overdose is a factor in nearly one-third of all reported drug-related deaths. These include suicides and accidental drug poisonings. Accidental deaths sometimes occur when a drowsy, confused user repeats doses. In the US, in 1998, a total of 70,982 sedative exposures were reported to US poison control centers, of which 2310 (3.2%) resulted in major toxicity and 89 (0.1%) resulted in death. About half of all the people admitted to emergency rooms in the US as a result of nonmedical use of sedatives have a legitimate prescription for the drug, but have taken an excessive dose or combined it with alcohol or other drugs. Others get sedatives from friends who have authentic prescriptions or by using fake prescriptions.

See also Other non-therapeutical use.

Sedatives and alcohol

Sedatives and alcohol are sometimes combined recreationally or carelessly. Since alcohol also is a strong CNS depressant that slows brain function and depresses respiration, the two substances contradict each other and this combination can prove fatal. Karen Ann Quinlan collapsed into a coma after swallowing alcohol and tranquilizers at a party in 1975. Her case

spurred worldwide discussion of the ethics surrounding termination of life-sustaining treatment.

Lookalikes

Lookalikes, or pills made to mimic the appearance and the effects of authentic sedatives, are sold on the street. Lookalikes may contain over-the-counter drugs, such as antihistamines, that cause drowsiness. Like any other drug that is illicitly manufactured and sold, their composition and effects cannot be predicted.

Sedatives and amnesia

Sedation can sometimes leave the patient with long-term or short-term amnesia. Lorazepam is one such pharmacological agent that can cause anterograde amnesia. Intensive Care Unit patients who receive higher doses over longer periods of time, typically via IV drip, are more likely to experience such side effects.

Sedative drugs and crime

The sedative GHB is known for its use as a date rape drug, administered to unsuspecting patrons in bars or guests at parties to reduce the intended victims' defenses.

Imidazopyridine

The *imidazopyridines* are a class of nonbenzodiazepine drugs related (in terms of their effect) to benzodiazepines. They include:

- Zolpidem (Ambien)
Alpidem

Stimulants

Stimulants are drugs that increase the activity of the sympathetic nervous system and produce a sense of euphoria or the feeling of being more awake. Stimulants can be used as recreational drugs or therapeutic drugs to increase alertness. They are also used and sometimes abused to boost endurance and productivity as well as to suppress appetite. Examples of common stimulants include caffeine, Amphetamine, cocaine, Ritalin and ecstasy.

Stimulants is a name given to several groups of drugs that tend to increase alertness and physical activity. The groups include pharmaceuticals such as amphetamines and the street drugs commonly called "uppers" or "speed," and cocaine. The more widely abused stimulants are amphetamines and cocaine. Cocaine has limited commercial use and its sale and possession are strictly controlled. Amphetamines are sometimes prescribed by physicians, and their availability makes them prime candidates for misuse.

Used properly, amphetamines increase alertness and physical ability. They are often prescribed to counter the effects of narcolepsy, a rare disorder marked by episodes of uncontrollable sleep, and to help children with minimal brain dysfunction.

Amphetamines increase the heart and respiration rates, increase blood pressure, dilate the pupils of the eyes, and decrease appetite. Other side effects include anxiety, blurred vision, sleeplessness, and dizziness. Abuse of amphetamines can cause irregular heartbeat and even physical collapse. A common form of abuse of amphetamines is by people who use them to counter the effects of sleeping pills (barbiturates) taken the night before. This roller coaster effect is damaging to the body.

While amphetamine users may feel a temporary boost in self-confidence and power, the abuse of the drug can lead to delusions, hallucinations, and a feeling of paranoia. These feelings can cause a person to act in bizarre fashion, even violently. In most people, these effects disappear when they stop using the drug.

Amphetamines are stolen or acquired through scams involving pharmacists or physicians who are duped into writing prescriptions for the drugs. These illegally acquired drugs are either sold as is or reduced to yellowish crystals that can be ingested in a number of ways, including sniffing and by injection.

Another means of illegal sale of amphetamines involves "look-alike" drugs produced in illicit laboratories. One danger in these look-alikes is that the potency may vary from batch to batch. A person accustomed to using a weak look-alike may unwittingly suffer an overdose taking the same volume of a stronger look-alike.

Symptoms Amphetamines are psychologically addictive. Users become dependent on the drug to avoid the "down" feeling they often experience when the drug's effect wears off. This dependence can lead a user to turn to stronger stimulants such as cocaine, or to larger doses of amphetamines to maintain a "high". People who abruptly stop using amphetamines often experience the physical signs of addiction, such as fatigue, long periods of sleep, irritability, and depression. How severe and prolonged these withdrawal symptoms are depends on the degree of abuse.

That boost we get from that morning cup of coffee is the result of the caffeine that naturally occurs in coffee. Caffeine is a common stimulant and is found not only in coffee and tea, but also in soft drinks and other foods. It can also be bought over-the-counter in tablet form. Too much caffeine can cause anxiousness, headaches, and the "jitters." Caffeine is also addictive and a person who abruptly stops drinking coffee may experience withdrawal symptoms.

Cocaine

Main article: Cocaine

Cocaine is made from the leaves of the coca shrub, which grows in the mountain regions of South American countries such as Bolivia, Colombia, and Peru. In Europe and North America, the most common form of cocaine is a white crystalline powder. Most users insufflate it intranasally.

Crack cocaine is a smokeable form of cocaine. It is usually smoked in a pipe, glass tube, or foil. Cocaine and crack are powerful, but short-acting stimulant drugs. Crack in particular has strong but short-lived effects. Both drugs tend to make users feel more alert and energetic. Many users say that they feel very confident and physically strong. Common effects include dry mouth, sweating, loss of appetite, and increased heart and pulse rates. Excessive doses can cause death from respiratory failure or heart failure.

Caffeine

Main article: Caffeine

Caffeine is a drug that is found in tea, chocolate, coffee, many soft drinks particularly energy drinks, and cocoa. There is no law prohibiting the sale of any of these products in most countries. Caffeine stimulates the body, increasing heart rate and blood pressure, and alertness, making some people feel better and able to concentrate. Caffeine is a diuretic. Some people have suggested that children that consume a lot of caffeine may become hyperactive even after the caffeine has been metabolized.

MDMA

Main article: Methylenedioxymethamphetamine

Methylenedioxymethamphetamine (MDMA) is an illegally-manufactured drug that comes either in tablet or capsule form (known as ecstasy), as a powder or crystal. Stimulant effects of MDMA include increased blood pressure and heart rate, loss of appetite, rapid sweating, and a dry mouth and throat. It is unusual for an ecstasy pill to contain only MDMA; they often contain amounts of other drugs which may include any of a wide range of substances such as MDA, MDEA, MDBD, PCP, DXM, PMA, Ketamine, Caffeine, Amphetamine, Methamphetamine, Ephedrine, Pseudoephedrine, Aspirin, Paracetamol, Fentanyl and, in a small number of cases, Heroin, Cocaine, Mescaline, DOB, or LSD . In some cases the substance sold as ecstasy may not contain MDMA at all.it is measured in mm/hg.

Nicotine

Nicotine is an alkaloid found in the nightshade family of plants (Solanaceae), predominantly in tobacco, and in lower quantities in tomato, potato, eggplant (aubergine), and green pepper. Nicotine alkaloids are also found in the leaves of the coca plant. Nicotine

constitutes 0.3 to 5% of the tobacco plant by dry weight, with biosynthesis taking place in the roots, and accumulates in the leaves. It is a potent nerve poison and is included in many insecticides.

In lower concentrations, the substance is a stimulant and is one of the main factors responsible for the dependence-forming properties of tobacco smoking. Although pure nicotine is noncarcinogenic, its presence may inhibit the body's ability to cull aberrant cells.

Antidepressants

Main article: Antidepressant

Antidepressants are not considered stimulants, as they do not act directly on the sympathetic nervous system and generally do not produce an immediate effect on mood. A possible exception is bupropion (Wellbutrin), whose chemical and pharmacological properties are similar to those of amphetamines.

Other

Recently, there have been improvements in the area of stimulant pharmacology, producing a class of chemicals known as eugeroics, or good arousal. These stimulants tend to increase alertness without the peripheral (body) effects or addiction/tolerance/abuse potential of the traditional stimulants. They have minimal effect on sleep structure, and do not cause rebound hypersomnolence or "come down" effects. Currently, there are two stimulants in this class being used: modafinil and adrafinil, marketed as Provigil and Olmifon, respectively.

In Russia, Carphedon is sold as a general stimulant under the brand name Phenotropil.

Caffeine is a xanthine alkaloid compound that acts as a stimulant in humans. Caffeine is sometimes called *guaranine* when found in guarana, *mateine* when found in mate, and *theine* when found in tea. It is found in the leaves and beans of the coffee plant, in tea, yerba mate, and guarana berries, and in small quantities in cocoa, the kola nut and the Yaupon Holly. Overall, caffeine is found in the beans, leaves, and fruit of over 60 plants, where it acts as a natural pesticide that paralyzes and kills certain insects feeding upon them.

Caffeine is a central nervous system (CNS) stimulant, having the effect of temporarily warding off drowsiness and restoring alertness. Beverages containing caffeine, such as coffee, tea, soft drinks and energy drinks enjoy great popularity: caffeine is the world's most widely consumed psychoactive substance. In North America, 90% of adults consume caffeine daily.[1]

Many natural sources of caffeine also contain widely varying mixtures of other xanthine alkaloids, including the cardiac stimulants theophylline and theobromine and other substances such as tannins.

* Estimated average caffeine content per serving. Actual content varies according to preparation.		

Caffeine is a plant alkaloid, found in numerous plant species, where it acts as a natural pesticide that paralyzes and kills certain insects feeding upon them.[4] The most commonly used caffeine-containing plants are coffee, tea, and to some extent cocoa. Other, less commonly used, sources of caffeine include the yerba mate[5] and guaraná plants, which are sometimes used in the preparation of teas and energy drinks. Two of caffeine's alternative names, mateine[6] and guaranine,[7] are derived from the names of these plants.

The world's primary source of caffeine is the coffee bean (the seed of the coffee plant), from which coffee is brewed. Caffeine content in coffee varies widely depending on the type of coffee bean and the method of preparation used;[8] even beans within a given bush can

show variations in concentration. In general one serving of coffee ranges from about 40 milligrams for a single shot (30 milliliters) of arabica-variety espresso to about 100 milligrams for strong drip coffee. Generally, dark-roast coffee has less caffeine than lighter roasts because the roasting process reduces the bean's caffeine content. Arabica coffee normally contains less caffeine than the robusta variety.[8] Coffee also contains trace amounts of theophylline, but no theobromine.

Tea is another common source of caffeine. Tea usually contains about half as much caffeine per serving as coffee, depending on the strength of the brew. Certain types of tea, such as black and oolong, contain somewhat more caffeine than most other teas. Tea contains small amounts of theobromine and slightly higher levels of theophylline than coffee. Preparation has a significant impact on tea, and color is a very poor indicator of caffeine content.[9] Teas like the green Japanese gyokuro, for example, contain far more caffeine than much darker teas like lapsang souchong, which has very little.

Chocolate derived from cocoa contains a small amount of caffeine. Chocolate is a weak stimulant, which is mostly due to its content of theobromine and theophylline.[10] It contains too little of these compounds for a reasonable serving to create effects in humans that are on par with coffee. A typical 28-gram serving of a milk chocolate bar has about as much caffeine as a cup of decaffeinated coffee.

Caffeine is also a common ingredient of soft drinks such as cola, originally prepared from kola nuts. Soft drinks typically contain about 10 to 50 milligrams of caffeine per serving. By contrast, energy drinks such as Red Bull contain as much as 80 milligrams of caffeine per serving. The caffeine in these drinks either originates from the ingredients used or is an additive derived from the product of decaffeination or from chemical synthesis. Guarana, a prime ingredient of energy drinks, contains large amounts of caffeine with small amounts of theobromine and theophylline in a naturally occurring slow-release excipient.[11]

History of use

Humans have consumed caffeine since the Stone Age.[12] Early peoples found that chewing the seeds, bark, or leaves of certain plants had the effects of easing fatigue, stimulating awareness, and elevating mood. Only much later was it found that the effect of caffeine was increased by steeping such plants in hot water. Many cultures have legends that attribute the discovery of such plants to people living many thousands of years ago.

According to one popular Mongolian legend, the Emperor of China Shennong, reputed to have reigned in about 3,000 BC, accidentally discovered that when some leaves fell into boiling water, a fragrant and restorative drink resulted.[13] Shennong is also mentioned in Lu Yu's Cha Jing, a famous early work on the subject of tea.[14]

The early history of coffee is obscure, but a popular myth traces its discovery to Ethiopia, where Coffea arabica originates. According to this myth, a goatherder named Kaldi observed goats that became elated and sleepless at night after browsing on coffee shrubs and, upon trying the berries that the goats had been eating, experienced the same vitality. The earliest literary mention of coffee may be a reference to Bunchum in the works of the 9th century Persian physician al-Razi. In 1587, Malaye Jaziri compiled a work tracing the history and legal controversies of coffee, entitled "Umdat al safwa fi hill al-qahwa". In this work, Jaziri recorded that one Sheikh, Jamal-al-Din al-Dhabhani, mufti of Aden, was the first to adopt the

use of coffee in 1454, and that in the 15th century the Sufis of Yemen routinely used coffee to stay awake during prayers.

Towards the close of the 16th century, the use of coffee was recorded by a European resident in Egypt, and about this time it came into general use in the Near East. The appreciation of coffee as a beverage in Europe, where it was first known as "Arabian wine," dates from the 17th century. During this time "coffee houses" were established, the first being opened in Constantinople and Venice. In Britain, the first coffee houses were opened in London in 1652, at St Michael's Alley, Cornhill. They soon became popular throughout Western Europe, and played a significant role in social relations in the 17th and 18th centuries.[15]

The kola nut, like the coffee berry and tea leaf, appears to have ancient origins. It is chewed in many West African cultures, individually or in a social setting, to restore vitality and ease hunger pangs. In 1911, kola became the focus of one of the earliest documented health scares when the US government seized 40 barrels and 20 kegs of Coca-Cola syrup in Chattanooga, Tennessee, alleging that the caffeine in its drink was "injurious to health".[16] On March 13, 1911, the government initiated The United States vs. Forty Barrels and Twenty Kegs of Coca-Cola, hoping to force Coca-Cola to remove caffeine from its formula by making exaggerated claims, such as that the excessive use of Coca-Cola at one girls' school led to "wild nocturnal freaks, violations of college rules and female proprieties, and even immoralities."[17] Although the judge ruled in favor of Coca-Cola, two bills were introduced to the U.S. House of Representatives in 1912 to amend the Pure Food and Drug Act, adding caffeine to the list of "habit-forming" and "deleterious" substances which must be listed on a product's label.

The earliest evidence of cocoa use comes from residue found in an ancient Mayan pot dated to 600 BC. In the New World, chocolate was consumed in a bitter and spicy drink called xocoatl, often seasoned with vanilla, chile pepper, and achiote. Xocoatl was believed to fight fatigue, a belief that is probably attributable to the theobromine and caffeine content. Chocolate was an important luxury good throughout pre-Columbian Mesoamerica, and cocoa beans were often used as currency.

Chocolate was introduced to Europe by the Spaniards and became a popular beverage by 1700. They also introduced the cacao tree into the West Indies and the Philippines. It was used in alchemical processes, where it was known as Black Bean.

The first coffee house in Europe was opened Paris in the 1800's by an French-Armenian named Pascal. Armenian merchants played in role in the more modern history of coffee and this is the reason why the coffee growing region in is named the Armenia Region of Columbia.

In 1819, the German chemist Friedrich Ferdinand Runge isolated relatively pure caffeine for the first time. According to a legend, he did this at the behest of Johann Wolfgang von Goethe.[18]

Today, global consumption of caffeine has been estimated at 120,000 tons per annum,[19] making it the world's most popular psychoactive substance. This number equates to one serving of a caffeinic beverage for every person, per day. In North America, 90% of adults consume some amount of caffeine daily.

Effects

Caffeine is a central nervous system and metabolic stimulant,[20] and is used both recreationally and medically to reduce physical fatigue and restore mental alertness when unusual weakness or drowsiness occurs. Caffeine stimulates the central nervous system first at the higher levels, resulting in increased alertness and wakefulness, faster and clearer flow of thought, increased focus, and better general body coordination, and later at the spinal cord level at higher doses.[21] The precise amount of caffeine necessary to produce effects varies from person to person depending on body size and degree of tolerance to caffeine. It takes less than an hour for caffeine to begin affecting the body and a mild dose wears off in three to four hours.[21] Consumption of caffeine does not eliminate the need for sleep: it only temporarily reduces the sensation of being tired.

With these effects, caffeine is an ergogenic: increasing the capacity for mental or physical labor. A study conducted in 1979 showed a 7% increase in distance cycled over a period of two hours in subjects who consumed caffeine compared to control tests.[22] Other studies attained much more dramatic results; one particular study of trained runners showed a 44% increase in "race-pace" endurance, as well as a 51% increase in cycling endurance, after a dosage of 9 milligrams of caffeine per kilogram of body weight.[23] The extensive boost shown in the runners is not an isolated case; additional studies have reported similar effects. Another study found 5.5 milligrams of caffeine per kilogram of body mass resulted in subjects cycling 29% longer during high intensity circuits.[24]

Caffeine is sometimes administered in combination with medicines to increase their effectiveness. Caffeine makes pain relievers 40% more effective in relieving headaches and helps the body absorb headache medications more quickly, bringing faster relief.[25] For this reason, many over-the-counter headache drugs include caffeine in their formula. It is also used with ergotamine in the treatment of migraine and cluster headaches as well as to overcome the drowsiness caused by antihistamines.

Breathing problems in premature infants, apnea of prematurity, are sometimes treated with citrated caffeine, which is available only by prescription in many countries.[26] A reduction in bronchopulmonary dysplasia has been exhibited in premature infants treated with caffeine citrate therapy regimens. It is speculated that this reduction in bronchopulmonary dysplasia is tied to a reduction in exposure to positive airway pressure. The only short term risk associated with this treatment is a temporary reduction in weight gain during the therapy.[27]

While relatively safe for humans, caffeine is considerably more toxic to some other animals such as dogs, horses and parrots due to a much poorer ability to metabolize this compound. Caffeine has a much more significant effect on spiders, for example, than most other drugs do.[28]

Overuse

Caffeine is a drug that in large amounts, especially over an extended period of time, can lead to a condition termed "caffeinism." Caffeinism usually combines physical addiction with a wide range of unpleasant physical and mental conditions including nervousness, irritability, anxiety, tremulousness, muscle twitching (hyperreflexia), insomnia, and heart palpitations.[29] (Under a rigid definition of addiction, meaning a process of escalating use,

"caffeine dependency" would be a more descriptive term. However, under the widely accepted definition "chronic pattern of behavior that is perceived to be difficult to quit," caffeine may be said to be addictive.) Furthermore, because caffeine increases the production of stomach acid, high usage over time can lead to peptic ulcers, erosive esophagitis, and gastroesophageal reflux disease.[30] However, since both "regular" and decaffeinated coffees have also been shown to stimulate the gastric mucosa and increase stomach acid secretion, caffeine is probably not the only component of coffee responsible.[31]

There are four caffeine-induced psychiatric disorders recognized by the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition: caffeine intoxication, caffeine-induced anxiety disorder, caffeine-induced sleep disorder, and caffeine-related disorder not otherwise specified (NOS).

Caffeine intoxication

An acute overdose of caffeine, usually in excess of 250 milligrams (more than 2-3 cups of brewed coffee), can result in a state of central nervous system overstimulation called caffeine intoxication. The symptoms of caffeine intoxication may include restlessness, nervousness, excitement, insomnia, flushing of the face, increased urination, gastrointestinal disturbance, muscle twitching, a rambling flow of thought and speech, irregular or rapid heart beat, and psychomotor agitation.[29][32]

In cases of extreme overdose, death can result. The median lethal dose (LD50) of caffeine is 192 milligrams per kilogram in rats.[33] The LD50 of caffeine is dependent on weight and individual sensitivity and estimated to be about 150 to 200 milligrams per kilogram of body mass, roughly 140 to 180 cups of coffee for an average adult taken within a limited timeframe that is dependent on half-life. Though achieving lethal dose with caffeine would be exceptionally difficult with regular coffee, there have been reported deaths from overdosing on caffeine pills.[34][35][36][37]

Treatment of severe caffeine intoxication is generally supportive, providing treatment of the immediate symptoms, but if the patient has very high serum levels of caffeine then peritoneal dialysis, hemodialysis, or hemofiltration may be required.

Anxiety and sleep disorders

Long-term overuse of caffeine can elicit a number of psychiatric disturbances. Two such disorders recognized by the APA are caffeine-induced sleep disorder and caffeine-induced anxiety disorder.

In the case of caffeine-induced sleep disorder, an individual regularly ingests high doses of caffeine sufficient to induce a significant disturbance in his or her sleep, sufficiently severe to warrant clinical attention.[38]

In some individuals, the large amounts of caffeine can induce anxiety severe enough to necessitate clinical attention. This caffeine-induced anxiety disorder can take many forms, from generalized anxiety, to panic attacks, obsessive-compulsive symptoms, or even phobic

symptoms.[38] Because this condition can mimic organic mental disorders, such as panic disorder, generalized anxiety disorder, bipolar disorder, or even schizophrenia, a number of medical professionals believe caffeine-intoxicated people are routinely misdiagnosed and unnecessarily medicated when the treatment for caffeine-induced psychosis would simply be to withhold further caffeine.[39] A Study in the British Journal of Addiction concluded that caffeinism, although infrequently diagnosed, may afflict as many as one person in ten of the population.[40]

Pharmacology

Metabolism

Caffeine is completely absorbed by the stomach and small intestine within 45 minutes of ingestion. After ingestion it is distributed throughout all tissues of the body and is eliminated by first-order kinetics.[41]

The half-life of caffeine — the time required for the body to eliminate one-half of the total amount of caffeine consumed at a given time — varies widely among individuals according to such factors as age, liver function, pregnancy, some concurrent medications, and the level of enzymes in the liver needed for caffeine metabolism. In healthy adults, caffeine's half-life is approximately 3-4 hours. In women taking oral contraceptives this is increased to 5-10 hours,[42] and in pregnant women the half-life is roughly 9-11 hours.[43] Caffeine can accumulate in individuals with severe liver disease when its half-life can increase to 96 hours.[44] In infants and young children, the half-life may be longer than in adults; half-life in a newborn baby may be as long as 30 hours. Other factors such as smoking can shorten caffeine's half-life.[45]

Caffeine is metabolized in the liver by the cytochrome P450 oxidase enzyme system (specifically, the 1A2 isozyme) into three metabolic dimethylxanthines,[46] which each have their own effects on the body:

- Paraxanthine (84%) – Has the effect of increasing lipolysis, leading to elevated glycerol and free fatty acid levels in the blood plasma.
- Theobromine (12%) – Dilates blood vessels and increases urine volume. Theobromine is also the principal alkaloid in cocoa, and therefore chocolate.
- Theophylline (4%) – Relaxes smooth muscles of the bronchi, and is used to treat asthma. The therapeutic dose of theophylline, however, is many times greater than the levels attained from caffeine metabolism.

Each of these metabolites is further metabolized and then excreted in the urine.

Mechanism of action

Caffeine acts through multiple mechanisms involving both action on receptors and channels at the cell membrane, as well as intracellular action on Calcium and cAMP pathways. By virtue of its purine structure it can act on some of the same targets as adenosine related nucleosides and nucleotides, like the cell surface P1 GPCRs for adenosine, as well as

the intracellular Ryanodine receptor which is the physiological target of cADPR (cyclic ADP ribose), and cAMP-phosphodiesterase (cAMP-PDE). However the action is antagonistic in some cases and agonistic in some others.

The principal mode of action of caffeine is as an antagonist of adenosine receptors in the brain.[47] The caffeine molecule is structurally similar to adenosine, and binds to adenosine receptors on the surface of cells without activating them (a "false transmitter" method of antagonism). The reduction in adenosine activity results in increased activity of the neurotransmitter dopamine, largely accounting for the stimulatory effects of caffeine. Caffeine can also increase levels of epinephrine/adrenaline,[48] possibly via a different mechanism. Acute usage of caffeine also increases levels of serotonin, causing positive changes in mood.

The inhibition of adenosine may be relevant in its diuretic properties. Because adenosine is known to constrict preferentially the afferent arterioles of the glomerulus, its inhibition may cause vasodilation, with an increase in renal blood flow (RBF) and glomerular filtration rate (GFR). This effect, called competitive inhibition, interrupts a pathway that normally serves to regulate nerve conduction by suppressing post-synaptic potentials. The result is an increase in the levels of epinephrine and norepinephrine/noradrenaline released via the hypothalamic-pituitary-adrenal axis.[49] Epinephrine, the natural endocrine response to a perceived threat, stimulates the sympathetic nervous system, leading to an increased heart rate, blood pressure and blood flow to muscles, a decreased blood flow to the skin and inner organs and a release of glucose by the liver.

Caffeine is also a known competitive inhibitor of the enzyme cAMP-phosphodiesterase (cAMP-PDE), which converts cyclic AMP (cAMP) in cells to its noncyclic form, allowing cAMP to build up in cells. Cyclic AMP participates in the messaging cascade produced by cells in response to stimulation by epinephrine, so by blocking its removal caffeine intensifies and prolongs the effects of epinephrine and epinephrine-like drugs such as amphetamine, methamphetamine, or methylphenidate. Increased concentrations of cAMP in parietal cells causes an increased activation of protein kinase A (PKA) which in turn increases activation of H^+/K^+ ATPase, resulting finally in increased gastric acid secretion by the cell.

Caffeine (and theophylline) can freely diffuse into cells and causes intracellular calcium release (independent of extracellular calcium) from the calcium stores in the Endoplasmic Reticulum(ER). This release is only partially blocked by Ryanodine receptor blockade with ryanodine, dantrolene, ruthenium red, and procaine (thus may involve ryanodine receptor and probably some additional calcium channels), but completely abolished after calcium depletion of ER by SERCA inhibitors like Thapsigargin (TG) or cyclopiazonic acid (CPA).[50] The action of caffeine on the ryanodine receptor may depend on both cytosolic and the luminal ER concentrations of Ca^{2+}. At low millimolar concentration of caffeine, the RyR channel open probability (Po) is significantly increased mostly due to a shortening of the lifetime of the closed state. At concentrations >5 mM, caffeine opens RyRs even at picomolar cytosolic Ca^{2+} and dramatically increases the open time of the channel so that the calcium release is stronger than even an action potential can generate. This mode of action of caffeine is probably due to mimicking the action of the physiologic metabolite of NAD called cADPR (cyclic ADP ribose) which has a similar potentiating action on Ryanodine receptors.

Caffeine may also directly inhibit delayed rectifier and A-type K^+ currents and activate plasmalemmal Ca^{2+} influx in certain vertebrate and invertebrate neurons.

The metabolites of caffeine contribute to caffeine's effects. Theobromine is a vasodilator that increases the amount of oxygen and nutrient flow to the brain and muscles. Theophylline, the second of the three primary metabolites, acts as a smooth muscle relaxant that chiefly affects bronchioles and acts as a chronotrope and inotrope that increases heart rate and efficiency. The third metabolic derivative, paraxanthine, is responsible for an increase in the lipolysis process, which releases glycerol and fatty acids into the blood to be used as a source of fuel by the muscles.[51]

Tolerance and withdrawal

Because caffeine is primarily an antagonist of the central nervous system's receptors for the neurotransmitter adenosine, the bodies of individuals who regularly consume caffeine adapt to the continual presence of the drug by substantially increasing the number of adenosine receptors in the central nervous system. This increase in the number of the adenosine receptors makes the body much more sensitive to adenosine, with two primary consequences.[52] First, the stimulatory effects of caffeine are substantially reduced, a phenomenon known as a tolerance adaptation. Second, because these adaptive responses to caffeine make individuals much more sensitive to adenosine, a reduction in caffeine intake will effectively increase the normal physiological effects of adenosine, resulting in unwelcome withdrawal symptoms in tolerant users.[52]

Because adenosine, in part, serves to regulate blood pressure by causing vasodilation, the increased effects of adenosine cause the blood vessels of the head to dilate, leading to an excess of blood in the head and causing a headache and nausea. Reduced catecholamine activity may cause feelings of fatigue and drowsiness. A reduction in serotonin levels when caffeine use is stopped can cause anxiety, irritability, inability to concentrate and diminished motivation to initiate or to complete daily tasks; in extreme cases it may cause mild depression.

Withdrawal symptoms — possibly including headache, irritability, and an inability to concentrate — may appear within 12 to 24 hours after discontinuation of caffeine intake, peak at roughly 48 hours, and usually last from one to five days - representing the time required for the number of adenosine receptors in the brain to revert to "normal" levels, uninfluenced by caffeine consumption. Analgesics, such as aspirin, can relieve the pain symptoms, as can a small dose of caffeine.[53] Most effective is a combination of both an analgesic and a small amount of caffeine.

Currently caffeine withdrawal is recognized as meriting further study by the Diagnostic and Statistical Manual of Mental Disorders for DSM-IV, although research demonstrating its clinical significance means that it will likely be included as an Axis-1 disorder in the DSM-V.[54]

Extraction of pure caffeine

Caffeine extraction is an important industrial process and can be performed using a number of different solvents. Benzene, chloroform, trichloroethylene and dichloromethane

have all been used over the years but for reasons of safety, environmental impact, cost and flavor, they have been superseded by the following main methods:

Water extraction

Coffee beans are soaked in water. The water, which contains not only caffeine but also many other compounds which contribute to the flavor of coffee, is then passed through activated charcoal, which removes the caffeine. The water can then be put back with the beans and evaporated dry, leaving decaffeinated coffee with a good flavor.[55] Coffee manufacturers recover the caffeine and resell it for use in soft drinks and medicines.

Supercritical carbon dioxide extraction

Supercritical carbon dioxide is an excellent nonpolar solvent for caffeine (as well as many other organic compounds), and is safer than the organic solvents that are used for caffeine extraction. The extraction process is simple: CO2 is forced through the green coffee beans at temperatures above 31.1 °C and pressures above 73 atm. Under these conditions, CO2 is in a "supercritical" state: it has gaslike properties which allow it to penetrate deep into the beans but also liquid-like properties which dissolve 97-99% of the caffeine. The caffeine-laden CO2 is then sprayed with high pressure water to remove the caffeine. The caffeine can then be isolated by charcoal adsorption (as above) or by distillation, recrystallization, or reverse osmosis.[55]

Extraction by nonhazardous organic solvents

Organic solvents such as ethyl acetate present much less health and environmental hazard than previously used chlorinated and aromatic solvents. The hydrolysis products of ethyl acetate are ethanol and acetic acid, both nonhazardous in small quantities. Another method is to use triglyceride oils obtained from spent coffee grounds.

Appendix

Relative content: comparison of different sources

Caffeine equivalents

In general, each of the following contains approximately 200 milligrams of caffeine:

- *One* 200 milligram caffeine pill
- *One and one quarter* 16 fluid ounce cans of Monster Energy (590 millilitres)
- *One and a half* pounds of milk chocolate (680 grams)
- *Two* 8 fluid ounce containers of regular coffee (470 millilitres)
- *Two and a half* 10 oz. bottles of Bawls caffeinated drink (740 millilitres)
- *Three* standard Excedrin pills
- *Three* 8 fluid ounce cups of Red Bull energy drink (710 millilitres)
- *Four* 8 fluid ounce cups of Vault energy drink (1.0 litre)
- *Five* 1 fluid ounce shots of espresso from robusta beans (150 millilitres)
- *Five* 8 fluid ounce cups of black tea (1.2 litres)
- *Five* 8 fluid ounce cups of Mountain Dew (1.2 litres)
- *Five* 12 fluid ounce cans of typical soda pop (1.8 litres) (variable)
- *Eight and a half* 8 fluid ounce cups of Coca-Cola Classic (2.0 litres)
- *Ten* 8 fluid ounce cups of green tea (2.4 litres)
- *Fifty* 8 fluid ounce cups of decaffeinated coffee (12 litres)

Coffee

Coffee is a popular beverage prepared from the roasted seeds – commonly referred to as beans – of the coffee plant. It is usually served hot but can also be served cold. A typical 7 fluid ounce (ca. 207 mL) cup of coffee contains 80-140 milligrams of caffeine, depending on the method of preparation.[1] Coffee represents 71% of all the United States caffeine consumption followed by soft drinks and tea.[2] Coffee, along with tea and water, is one of the most frequently-drunk beverages, its volume amounting to about a third that of tap water.[3] In 2003, coffee was the world's sixth largest agricultural export in terms of value, behind wheat, maize, soybeans, palm oil and sugar.[4]

Etymology and history

The history of coffee begins in the 9th century. It originated in the highlands of Ethiopia and spread to the rest of the world via Egypt and Europe.[5] The word coffee is believed to be derived from the word Kaffa, a region in Ethiopia where coffee originated. Later through its expansion, the name later evolved into Arabic word BGH) Qah'wa, over Ottoman Turkish Kahve, which originally meant wine or other intoxicating liquors. In the 15th century, Muslims introduced coffee in Persia, Egypt, northern Africa and Turkey, where the first coffeehouse, Kiva Han, opened in 1475 in Constantinople. The stimulant effect of drinking coffee caused it to be forbidden among orthodox and conservative imams in Mecca in 1511 and in Cairo in 1532 by a theological court. In Egypt, coffeehouses and warehouses containing coffee cherries were sacked. But the product's popularity, particularly among

intellectuals, led to the reversal of this decision in 1524 by an order of the Ottoman Turkish Sultan Selim I.[6]

From the Muslim world, coffee spread to Europe, where it became popular in the 17th century. Dutch traders were the first to start the large scale importation of coffee into Europe. In 1538, Léonard Rauwolf, a German physician, having come back from a ten-year trip in the Near East, was the first westerner to describe the brew:[7]

"A beverage as black as ink, useful against numerous illnesses, particularly those of the stomach. Its consumers take it in the morning, quite frankly, in a porcelain cup that is passed around and from which each one drinks a cupful. It is composed of water and the fruit from a bush called bunnu."

These remarks were noted by merchants, who were sensitive to this kind of information through experience in the commerce of spices. English coffeehouses were centers of intellectual and commercial activity. Lloyds of London, the famous insurance firm, was originally a coffeehouse.[8]

Coffee seed types

There are two main species of the *coffee plant*, Coffea arabica being the older one. Coffee is thought to be indigenous to south-western Ethiopia, specifically from Kaffa, from which it may have acquired its name.[9] While more susceptible to disease, it is considered by most to taste better than the second species, Coffea canephora (robusta). Robusta, which contains about 40-50% more caffeine, can be cultivated in environments where arabica will not thrive and probably originated in Uganda.[9] This has led to its use as an inexpensive substitute for arabica in many commercial coffee blends. Compared to arabica, robusta tends to be bitter and has little flavor, with a telltale "burnt rubber" or "wet cardboard" aroma and flavor. Good quality robustas are used in some espresso blends to provide a better "crema" (foamy head), and to lower the ingredient cost. In Italy, many espresso blends are based on dark-roasted robusta. The large industrial roasters use a steam treatment process to remove undesirable flavors from robusta beans for use in mass-marketed coffee blends.[10] Other species include Coffea liberica and Coffea esliaca, believed to be indigenous to Liberia and southern Sudan respectively.[9]

Arabica coffees were traditionally named by the port they were exported from, the two oldest being Mocha, from Yemen, and Java, from Indonesia. The modern coffee trade is much more specific about origin, labeling coffees by country, region, and sometimes even the producing estate. Varietal[11] is a botanical term denoting a taxonomic category ranking below species, a designation more specific than arabica or robusta and unrelated to the coffee's place of origin. Coffees consisting entirely of beans from a single varietal, bourbon, for example, are generally referred to as such, along with a reference to their place of origin (as in: Rwanda Blue Bourbon). Coffee aficionados may even distinguish auctioned coffees by lot number.

Most arabica coffee beans originate from one of three growing regions; Central America, East Africa/Arabia and Asia/Pacific. Beans from different countries or regions usually have distinctive characteristics such as flavor (flavor criteria include terms such as "citrus-like" or "earthy"), aroma (sometimes "berry-like" or "flowery"), body or mouthfeel, and acidity. Acidity refers to a tangy or clean-tasting quality, typically present in washed or wet processed coffees. It does not refer to a coffee's pH level. (Black coffee has a pH of around 5).[12] These distinguishing taste characteristics are dependent not only on the coffee's growing region, but also on its method of process and genetic subspecies or varietal.[13]

A peaberry, (also sometimes called a "Caracoli" bean) is a coffee bean that that develops singly inside the coffee cherry instead of the usual pair of beans. This situation occurs 5-10% of the time. Since flavour is concentrated when only a single bean is grown inside the cherry, these beans (especially Arabica) are highly prized.[14]

Processing and roasting

Much processing and human labour is required before coffee berries and its seed can be processed into the roasted coffee with which most Western consumers are familiar. Coffee berries must be picked, defruited, dried, sorted, and—in some processes—also aged.

Coffee is usually sold roasted, and the roasting process has a great degree of influence on the taste of the final product. All coffee is roasted before being consumed. Coffee can be sold roasted by the supplier; alternatively it can be home roasted.

Everyday alchemy, coffee roasting coaxes golden flavor from a bland bean. Unroasted beans boast all of coffee's acids, protein, and caffeine—but none of its taste. It takes heat to spark the chemical reactions that turn carbohydrates and fats into aromatic oils, burn off moisture and carbon dioxide, and alternately break down and build up acids, unlocking the characteristic coffee flavor.

Preparation

The processing of coffee typically refers to the agricultural and industrial processes needed to deliver whole roasted coffee beans to the consumer. Grinding the roasted coffee beans is done at a roastery, in a grocery store, or at home. It is most commonly ground at the roastery and sold to the consumer ground and packaged, though "whole-bean" coffee that is ground at home is becoming more popular despite the extra effort required. A grind is referred to by its brewing method. "Turkish" grind, the finest, is meant for mixing straight with water, while the coarsest grinds, such as coffee percolator or French press, are at the other extreme. Midway between the extremes are the most common: "drip" and "paper filter" grinds, which are used in the most common home coffee brewing machines. The "drip" machines operate with near-boiling water passed in a slow stream through the ground coffee in a paper filter. The espresso method uses more advanced technology to force very hot (not boiling) water, through the ground coffee, resulting in a stronger flavor and chemical changes with more coffee bean matter in the drink. Once brewed, it may be presented in a variety of ways: on its own, with sugar, with milk or cream, hot or cold, and so on. Roasted arabica beans are also eaten plain and covered with chocolate. See the article on coffee preparation for a comprehensive list.

A number of products are sold for the convenience of consumers who don't want to prepare their own coffee. Instant coffee has been dried into soluble powder or freeze dried into granules, which can be quickly dissolved in hot water for consumption. Canned coffee is a beverage that has been popular in Asian countries for many years, particularly in Japan and South Korea. Vending machines typically sell a number of varieties of canned coffee, available both hot and cold. To match the often busy life of Korean city dwellers, companies mostly have canned coffee with a wide variety of tastes. Japanese convenience stores and groceries also have a wide availability of plastic-bottled coffee drinks, which are typically lightly sweetened and pre-blended with milk. Lastly, liquid coffee concentrate is sometimes used in large institutional situations where coffee needs to be produced for thousands of people at the same time. It is described as having a flavor about as good as low-grade robusta coffee, and costs about 10 cents a cup to produce. The machines used to process it can handle up to 500 cups an hour, or 1,000 if the water is preheated.[15]

Economics of coffee

Coffee is one of the world's most important primary commodities due to being one of the world's most popular beverages. In total, 6.7 million tonnes of coffee were produced

annually in 1998-2000, and the forecast is a rise to 7 million tonnes annually by 2010.[16] Coffee also has several types of classifications used to determine environmental and labor standards.

Brazil remains the largest coffee exporting nation, but in recent years the green coffee market has been flooded by large quantities of robusta beans from Vietnam.[17] Many experts believe the giant influx of cheap green coffee after the collapse of the International Coffee Agreement of 1975-1989 with Cold War pressures led to the prolonged pricing crisis from 2001 to 2004.[18] In 1997 the "c" price of coffee in New York broke US$3.00/lb, but by late 2001 it had fallen to US$0.43/lb. Robusta coffees (traded in London at much lower prices than New York's Arabica) are preferred by large industrial clients (multinational roasters, instant coffee producers, etc.) because of their lower cost.

The preference of the "Big Four" coffee companies for cheap robusta is believed by many to have been a major contributing factor to the crash in coffee prices,[19] and the demand for high-quality arabica beans is only slowly recovering. After the crash, many coffee farmers in Africa, Indonesia and South and Central America lost their livelihoods, or turned to illicit crops such as coca to earn a living. The Dutch brand 'Max Havelaar' started the concept of fair trade Labelling, which attempted to remedy the situation by guaranteeing coffee growers a negotiated pre-harvest price; many smaller roasters and recently Procter & Gamble and Starbucks have joined Fair Trade.[20] Another issue with coffee is ecological: the American Birding Association has led a campaign for sustainably harvested, shade-grown and organic coffees vs. the newer mono-cropped full-sun varieties, which lead to deforestation and loss of bird habitat.[21]

Coffee ingestion on average is about a third that of tap water in most of North America and Europe.[3] In 2002 in the US, coffee consumption was 22.1 gallons per person.[22]

Health and pharmacology of coffee

Many studies have been performed on the relationship between coffee consumption and many medical conditions, ranging from diabetes and cardiovascular disease to cancer and cirrhosis. Studies are contradictory as to whether coffee has any specific health benefits, and results are similarly conflicting with respect to negative effects of coffee consumption.[23] In addition, it is often unclear whether these risks or benefits are linked to caffeine or whether they are to be attributed to other chemical substances found in coffee (and whether decaffeinated coffee carries the same benefits or risks).

One fairly consistent finding has been the reduction of diabetes mellitus type 2 in coffee consumers, an association that cannot be explained by the caffeine content alone and indeed may be stronger in decaffeinated coffee.[24]

Recently, coffee was found to reduce the chances of developing cirrhosis of the liver: the consumption of 1 cup a day was found to reduce the chances by 20%, and 4 cups a day reduced the chances by 80%.[25]

Social aspects of coffee

Coffee plays an important role in many societies throughout the world today. From the coffeehouses of the 16th century, to the modern day cafés, coffee has had a profound impact

on the lifestyles of people from all walks of life. When it first appeared in Africa and Yemen, it was commonly used as a type of religious intoxicant. This usage in religious rites among the Sufi branch of Islam led to it being put on trial in Mecca for being a "heretic" substance much as wine was. It was briefly repressed at this point, and was later part of a larger ban in Ottoman Turkey under an edict that led to the death of thousands of people.[26] Its early association in Europe with rebellious political activities led to its banning in England, among other places.[27]

In India the Indian Coffee Houses became an icon of the worker's struggle. This restaurant chain is now owned by the workers of ICHs, as a result of the struggle performed by the thrown-out workers from the Coffee Houses of Coffee Board. This struggle was led by famed Communist leader of India A. K. Gopalan. Thus the ICHs became the meeting places of the progressive-minded in India later.

Other uses

Spent coffee grounds are a good fertilizer in gardens because of their high nitrogen content. Starbucks, and some other coffee shops, have a specific policy of giving away their used coffee grounds to gardeners. While they tend to be only slightly acidic, they also tend to improve the acidity of garden soil through the same chemical processes that make sawdust a good fertilizer. Coffee grounds raise soil acidity sooner if they are added fresh, instead of after brewing. Likewise, coffee diluted with four times its volume of water can be used to amend soil acidity, especially useful for tomatoes, chili peppers, blueberries, and other plants that like high soil acidity.

The grounds are also used as bait in "Vegas roach traps".

Some use coffee to create art. Latte art involves designs in the foam of espresso-based drinks. Arfé is the use of coffee as a coloring for painting or other visual effects.

Hard and soft drugs

Hard and soft drugs are loose categories of psychoactive drugs. This distinction is used in both official and casual discourse. The term *hard drug* generally refers to drugs illegal for nonmedical use that lead to profound and severe addiction, as opposed to *soft drugs* that are either only mildly psychologically addictive or non-addictive.

Hard drugs

Cocaine (in powder form or in smokable form as crack), the Amphetamine, and the opioids such as heroin and morphine, are most commonly referred to as hard drugs. According to researchers, medical evidence indicates that alcohol and nicotine, while freely available for sale in many countries, should be described as hard drugs as well because they

are both addictive, associated with high mortality rates, and cause significantly more damage to the body than virtually all illegal drugs when compared scientifically (for example pharmaceutically pure or even reasonably purified street heroin, when consumed following a few basic safety rules, actually causes no harm to the body, even when taken over years or decades, while alcohol use is associated with liver and brain damage but is only age-restricted). In most popular discourse, however, hard drugs refers to drugs illegal for nonmedical use associated with highly visible problematic users, in the United Kingdom these are predominantly heroin, cocaine, and methamphetamine.

Soft drugs

The term soft drug is most usually applied to cannabis (marijuana or hashish) because it is not associated with deaths, crime or violence amongst users and is without evidence of physical addiction. This distinction between soft drugs and hard drugs is important in the drug policy of the Netherlands, where cannabis production, retailing and use come under official tolerance (NL gedoogbeleid), subject to certain conditions. Other psychedelic drugs such as psilocybin and LSD are also considered soft drugs by many because there is no evidence of physical addiction and it is nearly impossible to overdose on these drugs. There have been no human deaths recorded from the use of psychedelics (with the exception of MDMA, which has produced no overdoses).

Hallucinogens

Some consider certain hallucinogens to be hard drugs, but as most hallucinogens are non-addictive, nor are they known for causing deaths, such drugs generally occupy a middle ground - neither hard nor soft. The possible exceptions are PCP, DXM and the phenethylamine-based empathogens such as MDMA, many of which are closely related to amphetamines; being relatively new to the drug culture more research is needed to ascertain the addictive potential and potential harms of these drugs.

The drug policy of the Netherlands classifies synthetic hallucinogens such as LSD (acid) and MDMA (ecstasy) as hard drugs, although they have very similar action to naturally occurring drugs such as mescaline, which is considered a soft drug in its natural form of peyote, or psilocybin in its natural form as psilocybe (magic mushrooms). Both are sold legally in the Netherlands in their unprocessed natural form.

Psychopharmacology

Psychopharmacology is the study of drug-induced changes in mood, thinking, and behavior.[1] These drugs may originate from plants, minerals, synthetic/chemical, or herbal derivatives or animal by-products. Changes in mood, thinking, and behavior may be mediated by interaction of these drugs with particular target sites or receptors found in the nervous system. For example, the increase in locomotor behavior and schedule-controlled

behaviors following the acute administration of cocaine is often attributed to the drug's ability to inhibit the reuptake of the neutransmitter, dopamine, into the nerve terminal.

The common muscimol-bearing mushroom Amanita muscaria, also known as the Fly Agaric, is frequently regarded as one of the first used psychoactive drugs, it is suspected to be the primary/active ingredient in the sacred drug of ancient India, known as Soma. There are many modern theories citing the discovery of its psychoactive properties as far back as 10,000 BCE. Modern *psychopharmacology* studies a wide range of substances with various types of psychoactive properties, though the professional and commercial fields of pharmacology/*psychopharmacology* don't typically focus on psychedelic or recreational drugs, the majority of studies are conducted on medicinal psychoactives. Bar none, studies are conducted on *all* psychoactives by both fields, *psychopharmacology* focuses primarily on the psychoactive and chemical interactions with the brain.

History

Psychoactive drug use predates recorded history. Hunter-gatherer societies tended to favor hallucinogenic drugs, and today their use can still be observed in many surviving tribal cultures. The exact drug used depends on what the particular ecosystem a given tribe lives in can support, and are typically found growing wild. Such drugs include various hallucinogenic mushrooms and cacti, along with many other plants. These societies generally attach spiritual significance to drug use, and often incorporate it into their religious practices.

With the dawn of the Neolithic and the proliferation of agriculture, new entheogens came into use as a natural by-product of farming. Among them were opium, cannabis, and alcohol derived from the fermentation of cereals and fruits. Most societies began developing herblores, lists of herbs which were good for treating various physical and mental ailments. For example, St. John's Wort was traditionally prescribed in Europe for depression (in addition to use as a general-purpose good-tasting tea), and Chinese medicine developed elaborate lists of herbs and preparations.

With the scientific revolution in Europe and America, the use of traditional herbal remedies fell out of favor with the mainstream medical establishment, although a few people continued to use and maintain knowledge of traditional European herblore. In the early 20th century, scientists began reassessing this rejection of traditional herbs in medicine. A number of important psychiatric drugs have been developed as a byproduct of the analysis of organic compounds present in traditional herbal remedies. The use of psychiatric drugs to restore mental health, or at least limit aberrant behaviour, has only been part of the European and American medical institution since the 1950s, when a number of new classes of drugs were discovered, notably tranquillizers and antidepressants, and LSD was popularized among many psychiatrists as a mental miracle drug capable of curing all manner of problems.

In the latter half of the 20th century, research into new psychopharmacologic drugs exploded, with many new drugs discovered, created, and tested. Many once-popular drugs are now out of favor, and there are fashions in psychiatric drugs, as with any other kind of drug.

Major Drug Classes that are Studied

Psychopharmacology studies a very wide array of drugs, ranging from antidepressants to stimulants. Drugs are researched for their pharmaceutical properties, physical side effects, and psychological side effects. These studies are often very specific, typically beginning with animal testing, and ending with human testing. In the human testing phase, there is often a group of subjects, one group is given a placebo, and the other is administered a carefully measured therapeutic dose of the drug in question. After all of the testing is completed, the drug is proposed to the FDA, and is either commercially introduced to the public, introduced to the public via prescription, or deemed safe enough for over the counter sale.

Antipsychotics

Main article: Antipsychotics

Antipsychotics are drugs that are used in the treatment of various symptoms of psychosis, such as those caused by Psychotic Disorders or Schizophrenia. Antipsychotics are also sometimes used as mood stabilizers, most frequently to help manage such disorders as Bipolar disorder, even if no symptoms of psychosis are present. Antipsychotics may also be referred to as *neuroleptic drugs* and some antipsychotics are branded as *major tranquilizers*.

There are two categories of Antipsychotics, typical antipsychotics and atypical antipsychotics, and due to the nature of the drugs the majority of them require a verifiable prescription from a licensed professional.

Common Antipsychotics:

- Chlorpromazine HCl (Thorazine®), Typical antipsychotic
- Thioridazine HCl (Mellaril®), Typical antipsychotic
- Haloperidol **(Haldol®),** Typical antipsychotic
- Perphenazine (Trilafon®), Typical antipsychotic
- Thiothixene (Navane®), Typical antipsychotic
- Trifluoperazine HCl (Stelazine®), Typical antipsychotic
- Risperidone (Belivon®, Rispen®, Risperdal®), Atypical antipsychotic
- Quetiapine (Seroquel®), Atypical antipsychotic

Antidepressants

Main article: Antidepressants

Antidepressants are drugs used in the treatment of clinical depression, and are often used in combination with other drugs such as antipsychotics or stimulants, depending on the condition of the patient. Most antidepressants will restrain the metabolism of serotonin and/or norepinephrine. Such drugs are called Selective Serotonin Reuptake Inhibitors (SSRI), and they actively attempt to prevent the aforementioned neurotransmitters from dropping to the levels at which depression is experienced. SSRIs will often take 3-5 weeks to have a noticeable effect, due to the inability of the brain to process the flood of serotonin and it reacts by downregulating the sensitivity of the autoreceptors, which can take up to 5 weeks. Currently, Bi-functional SSRIs are being researched, which will occupy the autoreceptors, bypassing the 'throttling' of serotonin. Another type of antidepressant is an Monoamine oxidase inhibitor, which are thought to block the actions of MAO, an enzyme which assists in the breakdown of serotonin and norepinephrine. MAOI's are typically only used in the event that a tricyclic antidepressant or SSRI fails to prevent or exacerbates depression.

Common Antidepressants:

- Fluoxetine (Prozac®), SSRI
- Bupropion HCl (Wellbutrin®), NDRI[2]
- Phenelzine (Nardil®), MAO Inhibitor
- Isocarboxazid (Marplan®), MAO Inhibitor

Mood stabilizers

Main article: Mood stabilizers

In 1949, the Australian John Cade discovered that lithium salts could control mania, reducing the frequency and severity of manic episodes. This introduced the now popular drug Lithium carbonate to the mainstream public, as well as being the first mood stabilizer to be approved by the Food & Drug Administration. Many antipsychotics are used as mood stabilizers, although typically the first resort would be a standard mood stabilizer such as Lithium carbonate. Many mood stabilizers, with the exception of Lithium, are anticonvulsants.

Common Mood Stabilizers:

- Lithium Carbonate (Carbolith®), Regular Mood stabilizer
- **Carbamazepine (Tegretol®),** Anticonvulsant Mood stabilizer
- **Valproic acid (Valproate),** Anticonvulsant Mood stabilizer
    - Valproate semisodium (Depakote®), Anticonvulsant Mood stabilizer

Stimulants

Main article: Stimulants

Stimulants are some of the most widely prescribed drugs today. A stimulant is any drug that stimulates the central nervous system. Adderall®, a collection of Amphetamine salts, is one of the most prescribed pharmaceuticals in the treatment of ADHD. Typically prescribed to treat adolescents with Attention Deficit Hyperactivity Disorder and though not FDA approved for Adults, it is very common as a treatment. Patients respond differently to each drug. Most frequently used are Timed-release mediums but if such a method doesn't work there are many options to try. Stimulants have the potential to be addictive and patients with a history of drug abuse are typically monitored closely or even barred from the usage and given an alternative. Discontinuing treatment without tapering the dosage is not advisable.

Common Stimulants[6]:

- Caffeine, Typical Stimulant found in many edibles worldwide
- Methylphenidate (Ritalin®), (Concerta®) atypical stimulant
- Dexmethylphenidate (Focalin®) D-isomer of Methylphenidate stimulant
- Dextroamphetamine (Dexedrine®), (Dextrostat®) D-Amphetamine-based stimulant
- Dextroamphetamine & Levoamphetamine (Adderall®), D,l-Amphetamine salt mix stimulant
- Methamphetamine {Desoxyn®), D-methamphetamine-based stimulant

Anxiolytics & Hypnotics

Barbiturates were first used as hypnotics and as anxiolytics, but as time went on, safer benzodiazepines (Lowell Randall and Leo Sternbach, 1957) were developed in the 1960s and 1970s. Eventually they led to billions of doses being consumed annually, but as prescriptions were increasing, even more was the abuse of them.

Common Anxiolytics & Hypnotics:

- Diazepam (Valium®), Benzodiazepine derivative
- Nitrazepam (Mogadon®), Benzodiazepine derivative
- Zolpidem (Ambien®, Stilnox®), an Imidazopyridine
- Chlordiazepoxide (Librium®), Benzodiazepine derivative

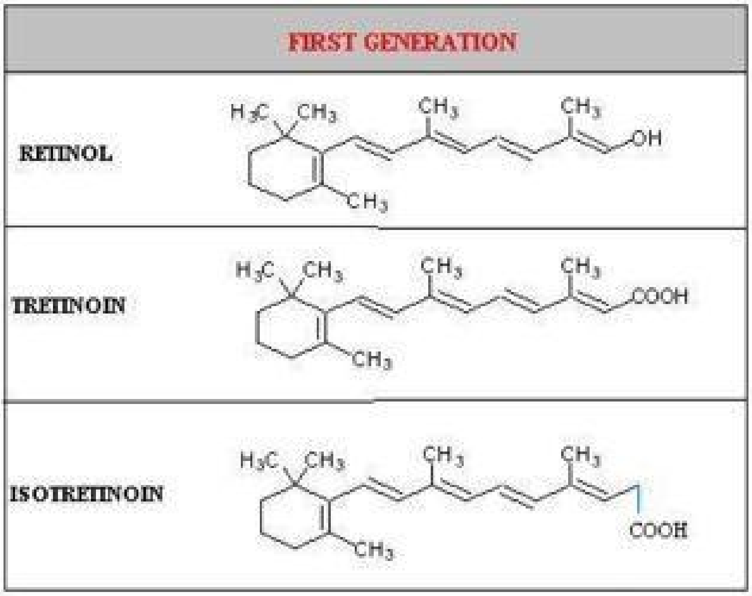
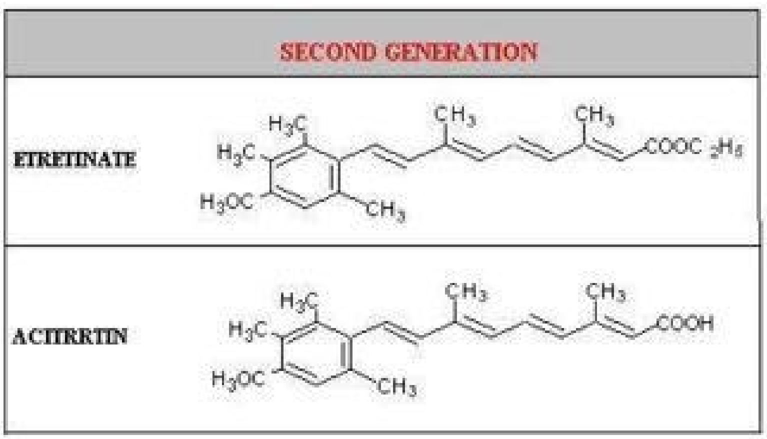
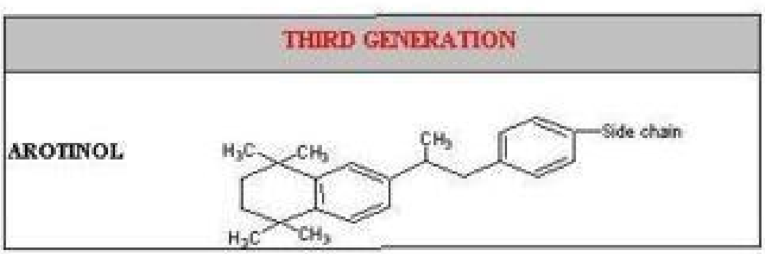
Retinoids







The *Retinoids* are a class of chemical compounds that are related chemically to vitamin A. Retinoids are used in medicine, primarily due to the way they regulate epithelial cell growth.

Retinoids have many important and diverse functions throughout the body including roles in vision, regulation of cell proliferation and differentiation, growth of bone tissue, immune function, and activation of tumor suppressor genes.

Research is also being done into their ability to treat skin cancers. Currently 9-cis retinoic acid may be used topically to help treat skin lesions from Kaposi's sarcoma.

Types

There are three generations of Retinoids:

- First generation retinoids: which include retinol, tretinoin (Retin-A), isotretinoin and alitretinoin.
- Second generation retinoids: which include etretinate and its metabolite acitretin.
- Third generation retinoids: which include tazarotene and bexarotene.

Structure

The basic structure of the retinoid molecule consist of a cyclic end group, a polyene side chain and a polar end group. The conjugated system formed by alternating C=C double bonds in the polyene side chain are responsible for the color of retinoids (typically yellow, orange, or red). Hence, many retinoids are chromophores. Alternation of side chains and end groups creates the various classes of retinoids.

First and Second generation retinoids are able to bind with several retinoid receptors due to the flexibility imparted by their alternating single and double bonds.

Third generation retinoids are less flexible than First and Second generation retinoids and therefore, interact with fewer retinoid receptors.

Uses

Retinoids are used in the treatment of many diverse diseases and are effective in the treatment of a number of dematological conditions such as inflammatory skin disorders, skin cancers, disorders of increased cell turnover(e.g. psoriasis), and photoaging.

Common skin conditions treated by retinoids include acne and psoriasis.

Toxicity

Toxic effects occur with prolonged high intake (in children 25,000-500,000 IU daily. A medical sign of chronic poisoning is the presence of painful tender swellings on the long bones. Anorexia, skin lesions, hair loss, hepatosplenomegaly, papilloedema, bleeding, general malaise, pseudotumor cerebri, and death may also occur.

Chronic overdose also causes an increased liability of biological membranes and of the outer layer of the skin to peel.

As vitamin A (retinoids) is stored in the liver, Eskimos never eat polar-bear liver, knowing it to be toxic, and husky dogs, with instinctive wisdom, also avoid it.

Recent research has suggested a role for retinoids in cutaneous adverse effects for a variety of drugs including the Antimalarial drug proguanil. It is proposed that drugs such as proguanil act to disrupt retinoid homeostasis.

Retinol

Vitamin A (Retinol)

General

Chemical formula $C_{20}H_{30}O$

Molecular weight 286.456 g/mol

Vitamin properties

Solubility Fat

RDA (adult male) 900 µg/day

RDA (adult female) 700 µg/day

RDA upper limit (adult male) 3,000 µg/day

RDA upper limit (adult female) 3,000 µg/day

Deficiency symptoms

- Night blindness
- Keratomalacia
- Pale, dry skin

Excess symptoms

- Liver toxicity
- Dry skin
- Hair loss

- Teratological **effects**
    - Osteoporosis (suspected, long-term)

Common sources

- Liver
- Dairy products
- Darkly colored fruits
- Leafy vegetables

Retinol, the animal form of vitamin A, is a yellow fat-soluble, antioxidant vitamin important in vision and bone growth. It belongs to the family of chemical compounds known as retinoids. Retinol is ingested in a precursor form; animal sources (milk and eggs) contain retinyl esters, whereas plants (carrots, spinach) contain pro-vitamin A carotenoids. Hydrolysis of retinyl esters results in retinol while pro-vitamin A carotenoids can be cleaved to produce retinal. Retinal, also known as retinaldehyde, can be reversibly reduced to produce retinol or it can be irreversibly oxidized to produce retinoic acid. The best described active retinoid metabolites are 11-cis-retinal and the all-trans and 9-cis-isomers of retinoic acid.

Discovery

In 1913, Elmer McCollum, a biochemist at the University of Wisconsin-Madison, and colleague Marguerite Davis identified a fat-soluble nutrient in butterfat and cod liver oil. Their work confirmed that of Thomas Osborne and Lafayette Mendel, at Yale, which suggested a fat-soluble nutrient in butterfat, also in 1913 [1]. Vitamin A was first synthesized in 1947.

Chemical structure and function

Many different geometric isomers of retinol, retinal and retinoic acid are possible as a result of either a trans or cis configuration of the four double bonds found in the polyene chain. The cis isomers are less stable and can readily convert to the all-trans configuration (as seen in the structure of all-trans-retinol shown here). Nevertheless, some cis isomers are found naturally and carry out essential functions. For example, the 11-cis-retinal isomer is the chromophore of rhodopsin, the vertebrate photoreceptor molecule. Rhodopsin is comprised of the 11-cis-retinal covalently linked via a Schiff base to the opsin protein (either rod opsin or blue, red or green cone opsins). The process of vision relies on the light-induced isomerisation of the chromophore from 11-cis to all-trans resulting in a change of the conformation and activation of the photoreceptor molecule. One of the earliest signs of vitamin A deficiency is night-blindness followed by decreased visual acuity.

George Wald won the 1967 Nobel Prize in Physiology or Medicine for his work with retina pigments (also called visual pigments), which led to the understanding of the role of vitamin A in vision.

Many of the non-visual functions of vitamin A are mediated by retinoic acid, which regulates gene expression by activating intracellular retinoic acid receptors. The non-visual functions of vitamin A are essential in the immunological function, reproduction and embryonic development of vertebrates as evidenced by the impaired growth, susceptibility to infection and birth defects observed in populations receiving suboptimal vitamin A in their diet.

Retinol can also be used in the treatment of acne in a topical cream. A form of retinoic acid, all-trans retinoic acid (ATRA) is currently used as chemotherapy for acute promyelocytic leukemia, a subtype of acute myelogenous leukemia. This is because cells of this subtype of leukemia are sensitive to agonists of the retinoic acid receptors (RARs).

Vision

Vitamin A is required in the production of rhodopsin, the visual pigment used in low light levels. This is why eating foods rich in vitamin A is said to allow you to see in the dark.

Epithelial Cells

Vitamin A is essential for the correct functioning of epithelial cells. In Vitamin A deficiency, mucus-secreting cells are replaced by keratin producing cells, leading to xerosis.

Glycoprotein synthesis

Glycoprotein synthesis requires adequate Vitamin A status. In severe Vitamin A deficiency, lack of glycoproteins may lead to corneal ulcers or liquefaction.

Immune System

Vitamin A is essential to maintain intact epithelial tissues as a physical barrier to infection; it is also involved in maintaining a number of immune cell types from both the innate and acquired immune systems. These include the lymphocytes (B-cells, T-cells, and natural killer cells), as well as many myelocytes (neutrophils, macrophages, and myeloid dendritic cells).

Formation of red blood cells (Haematopoiesis)

Vitamin A may be needed for normal haematopoiesis; deficiency causes abnormalities in iron metabolism.

Growth

Vitamin A affects the production of human growth hormone.

Units of measurement

When referring to dietary allowances or nutritional science, retinol is usually measured in international units (IU). IU refers to biological activity and therefore is unique to each individual compound, however 1 IU of retinol is equivalent to approximately 0.3 micrograms (300 nanograms).

Nutrition

This vitamin plays an essential role in vision, particularly night vision, normal bone and tooth development, reproduction, and the health of skin and mucous membranes (the mucus-secreting layer that lines body regions such as the respiratory tract). Vitamin A also acts in the body as an antioxidant, a protective chemical that may reduce the risk of certain cancers.

There are two sources of dietary vitamin A. Active forms, which are immediately available to the body are obtained from animal products. These are known as retinoids and include retinal and retinol. Precursors, also known as provitamins, which must be converted to active forms by the body, are obtained from fruits and vegetables containing yellow, orange and dark green pigments, known as carotenoids, the most well-known being beta-carotene. For this reason, amounts of vitamin A are measured in Retinal Equivalents (RE). One RE is equivalent to 0.001mg of retinal, or 0.006mg of beta-carotene, or 3.3 International Units of vitamin A.

In the intestine, vitamin A is protected from being chemically changed by vitamin E. Vitamin A is fat-soluble and can be stored in the body. Most of the vitamin A you eat is stored in the liver. When required by a particular part of the body, the liver releases some vitamin A, which is carried by the blood and delivered to the target cells and tissues.

Dietary intake

The Dietary Reference Intake (DRI) Recommended Daily Amount (RDA) for Vitamin A for a 25-year old male is 900 micrograms/day, or 3,000 IU.

During the absorption process in the intestines, retinol is incorporated into chylomicrons as the ester form, and it is these particles that mediate transport to the liver. Liver cells (hepatocytes) store vitamin A as the ester, and when retinol is needed in other tissues, it is de-esterifed and released into the blood as the alcohol. Retinol then attaches to a serum carrier, retinol binding protein, for transport to target tissues. A binding protein inside cells, cellular retinoic acid binding protein, serves to store and move retinoic acid intracellularly. Carotenoid bioavailability ranges between 1/5 to 1/10 of retinol's. Carotenoids are better absorbed when ingested as part of a fatty meal. Also, the carotenoids in vegetables, especially those with tough cell walls (e.g. carrots), are better absorbed when these cell walls are broken up by cooking or mincing.

Topical use

All retinoid forms of vitamin A are used in cosmetic and medical applications applied to the skin.

Retinoic acid, retinyl palmitate, isotretinoin, tretinoin and retinol are all used medicinally as a topical treatment for acne and keratosis pilaris. Isotretinoin is also used orally (under the trade names Accutane and Roaccutane), generally for severe or recalcitrant acne.

In cosmetics, vitamin A derivatives are used as so-called antiaging chemicals- vitamin A is absorbed through the skin and increases the rate of skin turnover, and gives a temporary increase in collagen giving a more youthful appearance.

Vitamin A deficiency

Vitamin A deficiency is common in developing countries but rarely seen in developed countries. Approximately 250,000 to 500,000 malnourished children in the developing world go blind each year from a deficiency of vitamin A. Night blindness is one of the first signs of vitamin A deficiency. Vitamin A deficiency contributes to blindness by making the cornea very dry and damaging the retina and cornea.

Vitamin A deficiency also diminishes the ability to fight infections. In countries where children are not immunized, infectious disease like measles have relatively higher fatality rates. As elucidated by Dr. Alfred Sommer, even mild, subclinical deficiency can also be a problem, as it may increase children's risk of developing respiratory and diarrheal infections, decrease growth rate, slow bone development, and decrease likelihood of survival from serious illness.

In addition to dietary problems, there are other causes of vitamin A deficiency. Iron deficiency can affect vitamin A uptake. Excess alcohol consumption can deplete vitamin A, and a stressed liver may be more susceptible to vitamin A toxicity. People who consume large amounts of alcohol should seek medical advice before taking vitamin A supplements.

Treatment of vitamin A deficiency can be undertaken with both oral and injectable forms, generally as vitamin A palmitate.

Vitamin A overdose (Toxicity)

The Tolerable Upper Intake Level (UL) for vitamin A, for a 25-year old male, is 3,000 micrograms/day, or about 10,000 IU.

Too much vitamin A can be harmful or fatal, resulting in what is known as hypervitaminosis A. The body converts the dimerized form, carotene, into vitamin A as it is needed, therefore high levels of carotene are not toxic compared to the ester (animal) forms. The livers of certain animals, especially those adapted to polar environments, often contain amounts of vitamin A that would be toxic to humans. Thus, vitamin A toxicity is typically reported in arctic explorers and people taking large doses of synthetic vitamin A. The first documented death due to vitamin A poisoning was Xavier Mertz, a Swiss scientist who died in January 1913 on an Antarctic expedition that had lost its food supplies and fell to eating its sled dogs. Mertz consumed lethal amounts of vitamin A by eating the dogs' livers. Just 0.3

grams of the liver of the polar bear contains the upper intake level.[2] If eaten in one meal, 30 to 90 grams is enough to kill a human being, or to make even sled dogs very ill.

Excess vitamin A has also been suspected to be a contributor to osteoporosis. This seems to happen at much lower doses than those required to induce acute intoxication. Only preformed vitamin A can cause these problems, because the conversion of carotenoids into vitamin A is downregulated when physiological requirements are met. An excessive uptake of carotenoids can, however, cause carotenosis.

The carotenoid beta carotene was interestingly associated with an increase in lung cancer when it was studied in a lung cancer prevention trial in male smokers. In non-smokers, the opposite effect has been noted.

Excess preformed vitamin A during early pregnancy has also been associated with a significant increase in birth defects. These defects may be severe, even life-threatening. Even twice the daily recommended amount can cause severe birth defects.The FDA currently recommends that pregnant women get their Vitamin A from foods containing beta carotene and that they should ensure that they consume no more than 5,000 IU of preformed Vitamin A (if any) per day. Although Vitamin A is necessary for fetal development, most women carry stores of Vitamin A in their fat cells, so oversupplementation should be strictly avoided.

Good sources

Vitamin A is found naturally in many foods. Each of the following contains at least 0.15mg of Vitamin A or beta carotene per 1.75-7 oz. (50-200g):

- Sweet potatoes

Carrots
Collard greens
Kale
Pumpkin
Spinach
Sweet peppers
Winter squash
Apricots
Cantaloupe melon
Mango
Liver (polar bear, beef, pork, chicken, or turkey)
Eggs
Broccoli

Night vision

Night blindness - the inability to see well in dim light - is associated with a deficiency of vitamin A. This vitamin is needed for the formation of rhodopsin. This is a pigment located in the eye's retina, which is the light-sensitive tissue lining in the back of the eye.

When stimulated by light, rhodopsin splits into two proteins: opsin and retinal (a form of vitamin A); when it is dark the reverse reaction occurs - the retinal and opsin combine to re-form rhodopsin, a reaction that requires extra retinal.

Without adequate amounts of retinal, regeneration of rhodopsin is incomplete and night blindness occurs. Since carrots are a good source of beta-carotene, there is truth in the old belief that carrots help you see better in the dark.

Closely related chemicals

- Isotretinoin (Tradename: Accutane(US), Roaccutane)

Retinyl palmitate ('vitamin A' aka. "pro-vitamin A")
All-trans retinoic acid

Genetically engineered vitamin A enriched rice

Due to the high prevalence of vitamin A deficiency in developing countries, there are efforts to produce genetically modified rice rich in beta carotene. The idea is that this would help poor people, who can't afford a varied diet containing sufficient natural sources of vitamin A, meet their dietary needs. The golden rice project is one such effort, and is already undergoing trials.

Teratogens

Teratogenesis is a medical term from the Greek, literally meaning monster-making, which derives from teratology, the study of the frequency, causation, and development of congenital malformations—misleadingly called birth defects. These include gross morphological abnormalities, such as cleft lip and/or palate, anencephaly, or ventricular septal defect, but may also include phenomena such as increased risk of cervical cancer or discoloration of tooth enamel. These malformations can arise from genetic abnormalities of the fetus, from adverse environmental circumstances (termed *teratogens* or *tetragens*), or a combination of these factors. Teratogenesis has gained a more specific usage for the development of abnormal cell masses during fetal growth (see pregnancy), causing physical defects in the fetus. The study of teratogenesis is called teratology.

Known teratogens

The American College of Occupational and Environmental Medicine recognizes the following teratogens.

- Ionizing radiation: atomic weapons, radioiodine, radiation therapy
- Infections: cytomegalovirus, herpes virus hominis I and II, parvovirus B-19, rubella virus (German measles), syphilis, toxoplasmosis, Venezuelan equine encephalitis virus
- Metabolic imbalance: alcoholism, endemic cretinism, diabetes, folic acid deficiency, hyperthermia, phenylketonuria, rheumatic disease and congenital heart block, virilizing tumors
- Drugs and environmental chemicals: 13-cis-retinoic acid (isotretinoin, Accutane), aminopterin and methylaminopterin, androgenic hormones, busulfan, captopril and enalapril (ACE inhibitors), chlorobiphenyls (PCBs), cocaine, coumarin anticoagulants, cyclophosphamide, diethylstilbestrol, diphenylhydantoin (Phenytoin, Dilantin, Epanutin), etretinate, lithium, methimazole, organic mercury compounds, penicillamine, tetracyclines, thalidomide, trimethadione, and valproic acid.

The status of some of the above substances (e.g. diphenylhydantoin) is subject to debate, and many other compounds are under varying degrees of suspicion. These include Agent Orange[1], nicotine[2], aspirin and other NSAIDs, and birth control pills. Other compounds are known as severe teratogens based on veterinary work and animal studies, but aren't listed above because they have not been studied in humans, e.g. cyclopamine. Teratogenic effects also help to determine the pregnancy category assigned by regulatory authorities; in the United States, a pregnancy category of X, D, or C may be assigned if teratogenic effects (or other risks in pregnancy) are documented or cannot be excluded.

Isotretinoin (13-cis-retinoic-acid; brand name Accutane), often used to treat severe acne, is such a strong teratogen that just a single dose taken by a pregnant woman may result in serious birth defects. Because of this effect, most countries have systems in place to ensure that it is not given to pregnant women, and that the patient is aware of how important it is to prevent pregnancy during and at least one month after treatment. Medical guidelines also

suggest that pregnant women should limit vitamin A intake to about 700 ¼g/day, as it has teratogenic potential when consumed in excess.[3][4]

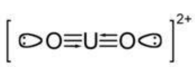
Uranyl compounds



The uranyl ion, showing the U-O bond order of 3

The *uranyl* ion is the dipositive cation UO_2^{2+}, which forms salts with acids. In this ion, uranium is in its +6 oxidation state. The other common oxidation state of uranium is uranium(IV), called uranous. The uranyl ion is the most common species encountered in the aqueous chemistry of uranium. Solid uranyl compounds are often colored red, yellow, orange or green. Like all uranium compounds, uranyl compounds are toxic. The toxicity of soluble uranyl salts is higher due to their faster incorporation into tissues.

Examples

Examples of uranyl compounds include:

- Uranium trioxide, UO_3
- Uranyl acetate, $UO_2(C_2H_3O_2)_2$
- Uranyl ammonium carbonate, $UO_2CO_3 \cdot 2(NH_4)_2CO_3$
- Uranyl carbonate, UO_2CO_3
- Uranyl chloride, UO_2Cl_2
- Uranyl hydroxide, $UO_2(OH)_2$ or $(UO_2)_2(OH)_2$ also in aqueous

- Uranyl nitrate, $UO_2(NO_3)_2$
- Uranyl sulfate, UO_2SO_4
- Uranyl zinc acetate, $ZnUO_2(CH_3COO)_4$

Minerals

Such minerals occur in oxidised portions of uranium ore deposits. Common uranyl minerals include tyuyamunite (Ca(UO2)2V2O8·8H2O), autunite (Ca(UO2)2(PO4)2·8-12H2O), torbernite (Cu(UO2)2 (PO4)·8-12H2O) and uranophane ($(H_3O)_2$Ca $(UO_2)_2(SiO_4)\cdot 3H_2O$) (Hutchinson and Blackwell, 1984). Uranyl minerals, which contain uranium(VI) can help show the genesis of uranium deposits and the water-rock interactions that occur in uranium-rich mineral seams.

Chemistry

Uranium chemistry has traditionally revolved around the aqueous chemistry of the uranyl ion, and related molecular species. One important use of this chemistry is for preparation of uranium dioxide ceramic pellets that are used as the fuel in light water nuclear reactors. Often the fuel materials start to break down chemically before the uranium is completely spent, and this too is an active area of investigation, as many of the corrosion products are of the uranyl group.

Structure

The geometry of the uranyl ion has been the subject of much debate. The close approach of two oxygen atoms to uranium, with each linear O-U-O bond from 1.7 to 1.9 Å, prevents the close approach of a third or more. d-p and f-p bonding have been suggested to explain the short U-O bonds.[1]

Health and environmental issues

Uranyl nitrate is an oxidizing and highly toxic compound and should not be ingested; it causes severe renal insufficiency and acute tubular necrosis and is a lymphocyte mitogen.

Target organs include the kidneys, liver, lungs and brain. Uranyl ion accumulation in tissues including gonocytes[2] produces congenital disorders, and in white blood cells causes immune system damage.[3] Uranyl compounds are also neurotoxins.

Combustion of uranium

Aerial oxidation of any uranium compound eventually results in the formation of a uranyl compound.[1] Uranyl ion contamination has been found on and around depleted uranium targets.[4]

Agent Orange

Agent Orange was the nickname given to a powerful herbicide and defoliant used by the U.S. military in its Herbicidal Warfare program during the Vietnam War. Agent Orange was used from 1961 to 1971, and was by far the most used of the so-called "rainbow herbicides" used during the program. Agent Orange (as well as Agents Purple, Pink, Blue, White, and Green) contained dioxins which are known to have caused harm to the health of those exposed during the Vietnam War. Studies of populations highly exposed to dioxin indicate increased risk of various types of cancer and genetic defects; the effect of long term low level exposure has not been established. Since the 1980s, several lawsuits have been filed against the companies who produced Agent Orange, among them being Dow Chemical and Monsanto. U.S. veterans obtained $180 million in compensation in 1984, while Australian, Canadian and New Zealand veterans also obtained compensation in an out-of-court settlement the same year. In 1999, 20,000 South Koreans filed a lawsuit in Korea; in January 2006, the Korean Appeal Court ordered Monsanto and Dow to pay $62 million in compensation to about 6,800 people. However, no Vietnamese have obtained compensation, and on March 10, 2005 Judge Jack Weinstein of Brooklyn Federal Court dismissed the lawsuit filed by the Vietnamese victims of Agent Orange against the chemical companies that produced the defoliants/herbicides.

Description

Agent Orange is a roughly 1:1 mixture of two phenoxy herbicides in ester form, 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). These herbicides were developed during the 1940s by independent teams in England and the United States for use in controlling broad-leaf plants. Phenoxy agents work by mimicking a plant growth hormone, indoleacetic acid (IAA). When sprayed on broad-leaf plants they induce rapid, uncontrolled growth, eventually killing them. When sprayed on crops such as wheat or corn, it selectively kills just the broad-leaf plants in the field - the weeds - leaving

the crop relatively unaffected. First introduced in 1946, these herbicides were in widespread use in agriculture by the middle of the 1950s.

It was later learned that a dioxin, 2,3,7,8-tetrachlorodibenzo-para-dioxin (TCDD), is produced as a byproduct of the manufacture of 2,4,5-T, and was thus present in any of the herbicides that used it. The *National Toxicology Program* has classified TCDD to be a human carcinogen, frequently associated with soft-tissue sarcoma, Non-Hodgkin's lymphoma, Hodgkin's disease and chronic lymphocytic leukemia (CLL). 2,4,5-T has since been banned for use in the US and many other countries.

The herbicide 2,4-D does not contain dioxin, and it remains one of the most-used herbicides in the world today.

Diseases associated with dioxin exposure are chloracne, soft tissue sarcomas, Hodgkin's lymphoma, and non-Hodgkin's lymphoma. A link has also been found to diabetes, in a study by the Institute of Medicine[1]. Diseases with limited evidence of an association with Agent Orange are respiratory cancers, prostate cancer, multiple myeloma, Porphyria cutanea tarda (a type of skin disease), acute and subacute transient peripheral neuropathy, spina bifida, Type 2 diabetes, and acute myelogenous leukemia found only in the second or third generation. Diseases with inadequate or insufficient evidence of an association are hepatobiliary cancers, nasal or nasophargyngeal cancers, bone cancer, female reproductive cancers, renal cancer, testicular cancer, leukemia, spontaneous abortion, birth defects, neonatal or infant death and stillbirths, low birth weight, childhood cancers, abnormal sperm parameters, cognitive neuropsychiatric disorders, ataxia, peripheral nervous system disorders, circulatory disorders, respiratory disorders, skin cancers, urinary and bladder cancer. Diseases with limited or suggestive evidence of no association are gastrointestinal tumors such as stomach cancer, pancreatic cancer, colon cancer, and rectal cancer, and brain tumors.

Use in South East Asia (1961-1971)

This section covers the use of all of the "rainbow" herbicides.

During the Vietnam War, the US instituted a massive herbicidal program that ran from 1961 through 1971. The aim of the program was two-fold, one to destroy the "cover" provided by the jungle-like forest, and another to deny food to the enemy. First named Operation Trail Dust, then Operation Hades, it was finally renamed Operation Ranch Hand.

A variety of chemicals were tested or used operationally during this program. The primary broad-leaf herbicides sprayed during the "testing" phase of the program between 1962 and 1964 were Agent Orange, Agent Purple and Agent White. The chemicals themselves had no color; the names refer to colored stripes painted on the 55 gallon barrels to identify their contents. Much smaller amounts of other herbicides were also tested, including Agent Pink, Agent Green, Dinoxol, Trinoxol, Bromacil, Diquat, Tandex, Monuron, Diuron and Dalapon. Agent Blue was an unrelated herbicide based primarily on arsenic used to kill rice plants which were not susceptible to the phenoxy-based agents. A variety of Paraquat-related chemicals were apparently also tested in this role. For spraying, the various agents were mixed with kerosene or diesel fuel.

By 1964 the testing phase had ended, and Agent Orange was selected as the most effective agent for "territory denial". Operational use started in January 1965, increasing in breadth as logistical problems were solved. Most of Agent Orange sprayed during the program was delivered from modified US Air Force C-123K Provider aircraft under a program known as Operation Ranch Hand. Other delivery methods included helicopters, truck and hand spraying, notably for the areas directly around US bases. From 1968 on, an improved version known as "Orange II" or "Super Orange" was used as well.

Spraying reached its maximum during the most intense period of the war, between 1967 and 1968. After that the program "drew down", and ended in 1971. By this point an estimated 19 million gallons of herbicide had been sprayed on Vietnam, Cambodia, Thailand and Laos, somewhat more than half (55%) of that Agent Orange, between 1962 and 1971. Early estimates from 1974 had placed the amounts lower, between 12 and 14 million US gallons (45,000 and 53,000 m^3). In total about 6 million acres (24,000 km^2) were sprayed in Vietnam alone.

Effects of the program

The New Jersey Agent Orange Commission

In 1980, New Jersey created the New Jersey Agent Orange Commission, the first state commission created to study its effects. The Commission's research project in association with Rutgers University was called "The Pointman Project". It was disbanded by governor Christine Todd Whitman in 1996.

During Pointman I, Commission researchers devised ways to determine small dioxin levels in blood. Prior to this, such levels could only be found in the adipose (fat) tissue. The project compared dioxin levels in a small group of Vietnam veterans who had been exposed to Agent Orange with a group of matched veterans who had not served in Vietnam. The results of this project were published in the Journal of the American Medical Association (JAMA) in 1988.(Vol. 259 No. 11, March 18, 1988).

The second phase of the project continued to examine and compare dioxin levels in various groups of Vietnam veterans including Army, Marines and brown water riverboat Navy personnel. In addition, the Commission was the only agency to examine such levels in women who served in Vietnam.

The National Academy of Science 2003 report

An April 2003 report paid for by the National Academy of Sciences concluded that during the Vietnam War, 3,181 villages were sprayed directly with herbicides. Between 2.1 and 4.8 million people "would have been present during the spraying." Furthermore, many US citizens were given access to military records and Air Force operational folders previously not studied. The re-estimate made by the report places the volume of herbicides sprayed between 1962 and 1971 to a level 7,131,907 liters more than an uncorrected estimate published in 1974 and 9.4 million more liters than a 1974 corrected inventory. It was

produced under contract for the Army by Diamond Shamrock, Dow, Hercules, Monsanto, T-H Agricultural & Nutrition, Thompson Chemicals, and Uniroyal.

The National Academy of Sciences undertook a survey of the scientific literature on the health effects of dioxin exposure, listing a number of health effects associated with significant exposure. The study is updated every two years.

The independent Institute of Medicine announced in 2006 that there appear to be no clear links to Agent Orange and cancer. They did appear to confirm a link to diabetes.

New Zealand direct involvement

In 2005, the New Zealand government confirmed that it supplied Agent Orange chemicals to the United States military during the conflict. Since the early 1960s, and up until 1987, it manufactured the 2,4,5T herbicide at a plant in New Plymouth which was then shipped to U.S. military bases in South East Asia.

Lawsuits

In 1984, Agent Orange manufacturers paid Australian, Canadian and New Zealand veterans in an out-of-court settlement [1].

US Vietnamese victims class action lawsuit

On January 31, 2004, a victim's rights group, the Vietnam Association for Victims of Agent Orange/Dioxin (VAVA), filed a lawsuit in a US Federal District Court in Brooklyn, New York, against several US companies, for liability in causing personal injury, by developing and producing the chemical. Dow Chemical and Monsanto were the two largest producers of Agent Orange for the US military, and were named in the suit along with the dozens of other companies (Diamond Shamrock, Uniroyal, Thompson Chemicals, Hercules, etc.). A number of lawsuits by American GIs were settled out of court - without admission of guilt by the chemical companies - in the years since the Vietnam War. In 1984, chemical companies that manufactured Agent Orange paid $180 million into a fund for United States veterans following a lawsuit.

On March 10, 2005, the District Court judge Jack Weinstein - who had defended the US veterans victims of Agent Orange - dismissed the suit, ruling that there was no legal basis for the plaintiffs' claims. The judge concluded that Agent Orange was not considered a poison under international law at the time of its use by the US; that the US was not prohibited from using it as an herbicide; and that the companies which produced the substance were not liable for the method of its use by the government. The US government is not a party in the lawsuit, claiming sovereign immunity.

On September 30, 2005, the Vietnamese victims lodged an appeal in the Second Circuit Court of Appeals; it is expected that the Court of Appeals will hold an oral argument sometime in Fall 2006. At this point the appeal is focused on whether or not the case will be reinstated and go to trial.

In order to assist those who have been impacted by Agent Orange/Dioxin, the Vietnamese have established "Peace villages", which each host between 50 to 100 victims, giving them medical and psychological help. As of 2006, there were 11 such Peace villages, thus granting some social protection to fewer than a thousand victims. US veterans of the war in Vietnam, NGOs and individuals who are aware and sympathetic to the impacts of Agent Orange have also supported these programs in Vietnam. An international group of Veterans from the US and its allies during the Vietnam war working together with their former enemy - veterans from the Vietnam Veterans Association - established the Vietnam Friendship Village[7] located outside of Hanoi. The center provides medical care, rehabilitation and vocational training for children and veterans from Vietnam who have been impacted by Agent Orange.

The US Veterans Administration has listed prostate cancer, respiratory cancers, multiple myeloma, type II diabetes, Hodgkin's disease, non-Hodgkin's lymphoma, soft tissue sarcoma, chloracne, porphyria cutanea tarda, peripheral neuropathy, and spina bifida in children of veterans exposed to Agent Orange as side effects of the herbicide.

South Korean lawsuit

In 1999, about 20,000 South Koreans filed two separated lawsuits against US companies, seeking more than $5 billion in damages. After losing a decision in 2002, they filed an appeal. In January 2006, the South Korean Appeals Court ordered Dow Chemical and Monsanto to pay $62 million in compensation to about 6,800 people. The ruling acknowledged that "the defendants failed to ensure safety as the defoliants manufactured by the defendants had higher levels of dioxins than standard", and, quoting the U.S. National Academy of Science report, declared that there was a "causal relationship" between Agent Orange and 11 diseases, including cancers of the lung, larynx and prostate. However, the judges failed to acknowledge "the relationship between the chemical and peripheral neuropathy, the disease most widespread among Agent Orange victims" according to the Mercury News. South Koreans were the largest foreign contingent of US allies in Vietnam, contributing some 320,000 troops. They lost 5,077 soldiers and suffered 10,962 wounded, according to the Mercury News[1].

Miscellaneous

- The Union Carbide company produced the constituents of Agent Orange at Homebush Bay in Sydney, Australia where the 2000 Summer Olympics were staged.
- The Uniroyal plant in Elmira, Ontario was one of seven suppliers producing Agent Orange for the U.S. military's use in Vietnam.
- An international committee[2] in support of Vietnamese victims of Agent Orange, has published a report on the impact of Agent Orange in Vietnam.[3][4]

Cultural references

Due to its politically sensitive nature, Agent Orange has become a common topic for reference in popular culture.

- For example: the songs "Orange Crush" by R.E.M, Anti-Flag's "Die for your Government" and "Depleted Uranium is a War Crime", Rage Against the Machine's "Sleep Now In The Fire", Oysterhead's "Shadow of a Man"; the album Agent Orange from German thrash metal band Sodom; the song "Agent Orange" by Depeche Mode; the punk band Agent Orange. A Filipino band named Slapshock also wrote a song entitled "Agent Orange," though the lyrics have no connection to the herbicide. An American rap artist named "Cage" wrote a song entitled "Agent Orange" that sampled the theme music from Stanley Kubrick's "A Clockwork Orange", but contains no reference to the herbicide.
- On her "Boys for Pele" album, Tori Amos has an instrumental song entitled "Agent Orange".
- The song "Uncommon Valor: A Vietnam Story" by Jedi Mind Tricks, contains the lyrics: "I escaped the war, came back/ But ain't escape Agent Orange, two of my kids born handicapped/ Spastic, quadriplegic, micro cephalic/ Cerebral palsy, cortical blindness, name it they had it"
- In a Season One episode of The X-Files entitled 'E.B.E', a group known as the Lone Gunmen refer to shells coated in depleted uranium as 'the Agent Orange of the 90s'.
- A South African blues musician goes by the name of Simon 'Agent' Orange.*In his stand-up routine, the British comedian Jack Dee has referred to an estate agent wearing excessive amounts of aftershave lotion as "Estate Agent Orange" because of the irritating effect on his eyes. In the video game Grand Theft Auto: Vice City a parody commercial is made advertising a product called "Agent Orange".

Depleted uranium

Depleted uranium (DU) is uranium that has a reduced proportion of the isotope Uranium-235. It is mostly made up of Uranium-238. The names *Q-metal*, *depletalloy*, and *D-38*, which once applied to depleted uranium, have fallen into disuse.

Its high strength and density have made it a valued component in some technical applications, specifically in military projectiles. Such uses remain controversial, as U-238 is still radioactive.

Sources

Depleted uranium is a byproduct of the enriching of natural uranium for use in nuclear reactors. When most of the fissile radioactive isotopes of uranium are removed from natural uranium, the residue is called depleted uranium. A less common source of the material is reprocessed spent reactor fuel. The origin can be distinguished by the content of uranium-236,[1] produced by neutron capture from uranium-235 in nuclear reactors.

As a toxic and radioactive waste product that requires long term storage as low level nuclear waste, depleted uranium is costly to keep but relatively inexpensive to obtain. Generally the only real costs are those associated with conversion of UF6 to metal. It is extremely dense, 67% denser than lead, only slightly less than tungsten and gold, and just 16% less dense than osmium or iridium, the densest naturally occurring substances known. Its low cost makes it attractive for a variety of uses. However, the material is prone to corrosion and small particles are pyrophoric.

History

Depleted uranium was first stored in stockpiles in the 1940s when the U.S. and USSR began their nuclear weapons and nuclear power programs. While it is possible to design civilian power reactors with unenriched fuel, only about 10% of reactors ever built utilize that technology, and both nuclear weapons production and naval reactors require the concentrated isotope. Originally, DU was conserved in the hope that more efficient enrichment techniques would allow further extraction of the fissile isotope; however, those hopes have not materialized.

In the 1970s, The Pentagon reported that the Soviet military had developed armor plating for Warsaw Pact tanks that NATO ammunition couldn't penetrate. The Pentagon began searching for material to make denser bullets. After testing various metals, ordnance researchers settled on depleted uranium. DU was useful in ammunition not only because of its unique physical properties and effectiveness, but also because it was cheap and readily available. Tungsten, the only other candidate, had to be sourced from China. With DU stockpiles estimated to be more than 500,000 tons, the financial burden of housing this amount of low-level radioactive waste was very apparent. It was therefore more economical to use depleted uranium rather than storing it. Thus, from the late 1970s, the U.S., the Soviet Union, Britain and France, began converting their stockpiles of depleted uranium into kinetic energy penetrators.

Photographic evidence of destroyed equipment suggests that DU was first used during the 1973 Arab-Israeli war. Various written reports cite information that was obtained as a consequence of that use.[1]

However, while clearing the decades-old Hawaii Stryker firing range, workers have found chemical weapons from World War I era and depleted uranium ammunition from the 1960s

Production and availability

Natural uranium metal contains about 0.71% U-235, 99.28% U-238, and about 0.0054% U-234. In order to produce enriched uranium, the process of isotope separation removes a substantial portion of the U-235 for use in nuclear power, weapons, or other uses. The remainder, depleted uranium, contains only 0.2% to 0.4% U-235. Because natural uranium begins with such a low percentage of U-235, the enrichment process produces large quantities of depleted uranium. For example, producing 1 kg of 5% enriched uranium requires 11.8 kg of natural uranium, and leaves about 10.8 kg of depleted uranium with only 0.3% U-235 remaining.

The Nuclear Regulatory Commission (NRC) defines depleted uranium as uranium with a percentage of the **235**U isotope that is less than 0.711% by weight (See 10 CFR 40.4.) The military specifications designate that the DU used by DoD contain less than 0.3% **235**U (AEPI, 1995). In actuality, DoD uses only DU that contains approximately 0.2% **235**U (AEPI, 1995).

World Depleted Uranium Inventory

Country	Organization	DU Stocks (in tonnes)	Reported
USA	DOE	480,000	2002
Russia	FAEA	460,000	1996

Military applications

Depleted uranium is very dense; at 19050 kg/m^3, it is 70% denser than lead. Thus a given weight of it has a smaller diameter than an equivalent lead projectile, with less aerodynamic drag and deeper penetration due to a higher pressure at point of impact. DU projectile ordnance is often incendiary because of its pyrophoric property.

Armor plate

Because of its high density, depleted uranium can also be used in tank armor, sandwiched between sheets of steel armor plate. For instance, some late-production M1A1HA and M1A2 Abrams tanks built after 1998 have DU reinforcement as part of its armor plating in the front of the hull and the front of the turret and there is a program to upgrade the rest.

Ammunition

Most military use of depleted uranium has been as 30 mm and smaller ordnance, primarily the 30 mm PGU-14/B armour-piercing incendiary round from the GAU-8 Avenger cannon of the A-10 Thunderbolt II [4] used by the U.S. Air Force. 25 mm DU rounds have been used in the M242 gun mounted on the U.S. Army's Bradley Fighting Vehicle and LAV-AT. The U.S. Marine Corps uses DU in the 25 mm PGU-20 round fired by the GAU-12 Equalizer cannon of the AV-8B Harrier, and also in the 20 mm M197 gun mounted on AH-1 helicopter

gunships. The US Navy's Phalanx CIWS's M61 Vulcan gatling gun used 20 mm armor-piercing penetrator rounds with discarding plastic sabots which were made using depleted uranium, later changed to tungsten.

Another use of depleted uranium is in kinetic energy penetrators anti-armor role. Kinetic energy penetrator rounds consist of a long, relatively thin penetrator surrounded by discarding sabot. Two materials lend themselves to penetrator construction: tungsten and depleted uranium, the latter in designated alloys known as staballoys. *Staballoys* are metal alloys of depleted uranium with a very small proportion of other metals, usually titanium or molybdenum. One formulation has a composition of 99.25% by weight of depleted uranium and 0.75% by weight of titanium. Another variant can have 3.5% by weight of titanium. Staballoys are about twice as dense as lead and are designed for use in kinetic energy penetrator armor-piercing ammunition. The US Army uses DU in an alloy with around 3.5% titanium.

Staballoys, along with lower raw material costs, have the advantage of being easy to melt and cast into shape; a difficult and expensive process for tungsten. Depleted uranium is favored for the penetrator because it is self-sharpening and pyrophoric. On impact with a hard target, such as an armoured vehicle, the nose of the rod fractures in such a way that it remains sharp. The impact and subsequent release of heat energy causes it to disintegrate to dust and burn when it reaches air because of its pyrophoric properties (compare to ferrocerium). After a disintegrated DU penetrator reaches the interior of an armored vehicle, it explodes, often igniting ammunition and fuel, incinerating the crew, and causing the vehicle to explode. DU is used by the U.S. Army in 120 mm or 105 mm cannons employed on the M1 Abrams and M60A3 tanks. The Russian military has used DU ammunition in tank main gun ammunition since the late 1970s, mostly for the 115 mm guns in the T-62 tank and the 125 mm guns in the T-64, T-72, T-80, and T-90 tanks.

The DU content in various ammunition is 180 g in 20 mm projectiles, 200 g in 25 mm ones, 280g in 30 mm, 3.5 kg in 105 mm, and 4.5 kg in 120 mm penetrators. It is used in the form of Staballoy. The US Navy used DU in its 20 mm Phalanx CIWS guns, but switched in the late 1990s to armor-piercing tungsten for this application, because of the fire risk associated with stray pyrophoric rounds. DU was used during the mid-1990s in the U.S. to make 9 mm and similar caliber armor piercing bullets, grenades, cluster bombs, and mines, but those applications have been discontinued, according to Alliant Techsystems. Whether or not other nations still make such use of DU is difficult to determine.

It is thought that between 17 and 20 states have weapons incorporating depleted uranium in their arsenals. They include the USA, the UK, France, Russia, Greece, Turkey, Israel, Saudi Arabia, Bahrain, Egypt, Kuwait, Pakistan, Thailand, Iraq and Taiwan. DU ammunition is manufactured in 18 countries. While only the US and the UK have acknowledged using DU weapons, its use by other states cannot be excluded[2].

Legal status in weapons

In 1996 the International Court of Justice (ICJ) gave an advisory opinion on the "legality of the threat or use of nuclear weapons".[3] This made it clear, in paragraphs 54, 55 and 56, that international law on poisonous weapons, – the Second Hague Declaration of 29 July

1899, Hague Convention IV of 18 October 1907 and the Geneva Protocol of 17 June 1925 – did not cover nuclear weapons, because their prime or exclusive use was not to poison or asphyxiate. This ICJ opinion was about nuclear weapons, but the sentence "The terms have been understood, in the practice of States, in their ordinary sense as covering weapons whose prime, or even exclusive, effect is to poison or asphyxiate." also removes depleted uranium weaponry from coverage by the same treaties as their primary use is not to poison or asphyxiate, but to destroy materiel and kill soldiers through kinetic energy.

The Sub-Commission on Prevention of Discrimination and Protection of Minorities of the United Nations Human Rights Commission[4], passed two motions [5] the first in 1996[6] and the second in 1997[7]. They listed weapons of mass destruction, or weapons with indiscriminate effect, or of a nature to cause superfluous injury or unnecessary suffering and urged all states to curb the production and the spread of such weapons. Included in the list was weaponry containing depleted uranium. The committee authorized a working paper, in the context of human rights and humanitarian norms, of the weapons. The requested UN working paper was delivered in 2002[8] by Y.K.J. Yeung Sik Yuen in accordance with Sub-Commission on Promotion and Protection of Human Rights resolution 2001/36. He argues that the use of DU in weapons, along with the other weapons listed by the SubCommission, may breach one or more of the following treaties: The Universal Declaration of Human Rights; the Charter of the United Nations; the Genocide Convention; the United Nations Convention Against Torture; the Geneva Conventions including Protocol I; the Convention on Conventional Weapons of 1980; and the Chemical Weapons Convention. Yeung Sik Yuen writes in Paragraph 133 under the title "Legal compliance of weapons containing DU as a new weapon":

Annex II to the Convention on the Physical Protection of Nuclear Material 1980 (which became operative on 8 February 1997) classifies DU as a category II nuclear material. Storage and transport rules are set down for that category which indicates that DU is considered sufficiently “hot” and dangerous to warrant these protections. But since weapons containing DU are relatively new weapons no treaty exists yet to regulate, limit or prohibit its use. The legality or illegality of DU weapons must therefore be tested by recourse to the general rules governing the use of weapons under humanitarian and human rights law which have already been analysed in Part I of this paper, and more particularly at paragraph 35 which states that parties to Protocol I to the Geneva Conventions of 1949 have an obligation to ascertain that new weapons do not violate the laws and customs of war or any other international law. As mentioned, the ICJ considers this rule binding customary humanitarian law.

In 2001, Carla del Ponte, the chief prosecutor for the International Criminal Tribunal for the Former Yugoslavia, said that NATO's use of depleted uranium in former Yugoslavia could be investigated as a possible war crime[9]. Louise Arbour, del Ponte's predecessor as chief prosecutor, had created a small, internal committee, made up of staff lawyers, to assess the allegation. Their findings, that were accepted and endorsed by del Ponte,[10] concluded that:

There is no specific treaty ban on the use of DU projectiles. There is a developing scientific debate and concern expressed regarding the impact of the use of such projectiles and it is

possible that, in future, there will be a consensus view in international legal circles that use of such projectiles violate general principles of the law applicable to use of weapons in armed conflict. No such consensus exists at present. (Emphasis added)[11]

Civilian applications

Civilian applications for depleted uranium are fairly limited and are typically unrelated to its radioactive properties. It primarily finds application as ballast because of its high density. Such applications include sailboat keels, as counterweights and sinker bars in oil drills, gyroscope rotors, and in other places where there is a need to place a weight that occupies as little space as possible. Other relatively minor consumer product uses have included: incorporation into dental porcelain used for false teeth to simulate the fluorescence of natural teeth; and in uranium-bearing reagents used in chemistry laboratories.

Uranium was widely used as a coloring matter for porcelain and glass in the 19th century. The practice was believed to be a matter of history, however in 1999 concentrations of 10% depleted uranium were found in "jaune no.17" a yellow enamel powder that was being produced in France by Cristallerie de Saint-Paul, a manufacturer of enamel pigments. The depleted uranium used in the powder was sold by Cogéma's Pierrelatte facility. Cogema has since confirmed that it has made a decision to stop the sale of depleted uranium to producers of enamel and glass.

DU is also used for shielding for radiation sources used in medical and industrial radiography.

U.S. Nuclear Regulatory Commission regulations at 10 CFR 40.25 establish mandatory licensing for the use of depleted uranium contained in industrial products or devices for mass-volume applications. Other jurisdictions have similar regulations

Trim weights in aircraft

Aircraft may also contain depleted uranium trim weights (a Boeing 747-100 may contain 400 to 1,500 kg). This application of DU is controversial. If an aircraft crashes there is concern that the uranium would enter the environment: the metal can oxidize to a fine powder in a fire. While arguably other hazardous materials released from a burning commercial aircraft overshadow the contributions made by DU, its use has been phased out in many newer aircraft, Both Boeing and McDonnell-Douglas discontinued using DU counterweights in the 1980s.

Uranium hexafluoride

About 95% of the depleted uranium produced is stored as uranium hexafluoride, (D)UF_6, in steel cylinders in open air yards close to enrichment plants. Each cylinder contains up to 12.7 tonnes (or 14 US tons) of UF_6. In the U.S. alone, 560,000 tonnes of depleted UF_6 had accumulated by 1993. In 2005, 686,500 tonnes in 57,122 storage cylinders were located near Portsmouth, Ohio, Oak Ridge, Tennessee, and Paducah, Kentucky.The long-term storage of

DUF***6*** presents environmental, health, and safety risks because of its chemical instability. When UF***6*** is exposed to moist air, it reacts with the water in the air to produce UO***2***F2 (uranyl fluoride) and HF (hydrogen fluoride) both of which are highly soluble and toxic. Storage cylinders must be regularly inspected for signs of corrosion and leaks. The estimated life time of the steel cylinders is measured in decades.

There have been several accidents involving uranium hexafluoride in the United States. The U.S. government has been converting DUF***6*** to solid uranium oxides for disposal. Such disposal of the entire DUF***6*** inventory could cost anywhere from 15 to 450 million dollars.

Health considerations

The radiological dangers of pure depleted uranium are relatively low, lower (60%) than those of naturally-occurring uranium due to the removal of the more radioactive isotopes, as well as due to its long half-life (4.46 billion years). Depleted uranium differs from natural uranium in its isotopic composition, but its biochemistry is for the most part the same.

Health effects of DU are determined by factors such as the extent of exposure and whether it was internal or external. Three main pathways exist by which internalization of uranium may occur: inhalation, ingestion, and embedded fragments or shrapnel contamination. Properties such as phase (e.g. particulate or gaseous), oxidation state (e.g. metallic or ceramic), and the solubility of uranium and its compounds influence their absorption, distribution, translocation, elimination and the resulting toxicity. For example, metallic uranium is relatively non-toxic compared to hexavalent uranium(VI) compounds such as uranyl nitrate. (See «Gmelin Handbuch der anorganischen Chemiek» 8th edition, English translation, Gmelin Handbook of Inorganic Chemistry, vol. U-A7 (1982) pp. 300-322.)

Uranium is pyrophoric when finely divided. It will corrode under the influence of air and water producing insoluble uranium(IV) and soluble uranium(VI) salts. Soluble uranium salts are toxic. Uranium accumulates in several organs, such as the liver, spleen, and kidneys. The World Health Organization has established a daily "tolerated intake" of soluble uranium salts for the general public of 0.5 µg/kg body weight (or 35 µg for a 70 kg adult.)

The chemical toxicity of uranium salts is greater than their radiological toxicity. Its radiological hazards are dependent on the purity of the uranium, and there has been some concern that depleted uranium produced as a by-product of nuclear reprocessing may be contaminated with more dangerous isotopes: this should not be a concern for depleted uranium produced as tailings from initial uranium enrichment.

Early scientific studies usually found no link between depleted uranium and cancer, and sometimes found no link with increases in the rate of birth defects, but newer studies have and offered explanation of birth defect links. There is no direct proof that uranium causes birth defects in humans, but it induces them in several other species of mammals, and human epidemiological evidence is consistent with increased risk of birth defects in the offspring of persons exposed to DU. Environmental groups and others have expressed concern about the health effects of depleted uranium, and there is significant debate over the matter. Some people have raised concerns about the use of this material, particularly in munitions, because of its proven mutagenicity, teratogenicity in mice, and neurotoxicity, and its suspected carcinogenic potential, because it remains radioactive for an exceedingly long time with a

half-life of approximately 4.5 billion years; and because it is also toxic in a manner similar to lead and other heavy metals.

Early studies of depleted uranium aerosol exposure assumed that uranium combustion product particles would quickly settle out of the air and thus could not affect populations more than a few kilometers from target areas, and that such particles, if inhaled, would remain undissolved in the lung for a great length of time and thus could be detected in urine

By contrast, other studies have shown that DU ammunition has no measurable detrimental health effects, either in the short or long term. The International Atomic Energy Agency reported in 2003 that, "based on credible scientific evidence, there is no proven link between DU exposure and increases in human cancers or other significant health or environmental impacts," although "Like other heavy metals, DU is potentially poisonous. In sufficient amounts, if DU is ingested or inhaled it can be harmful because of its chemical toxicity. High concentration could cause kidney damage."

In October, 1992, an El Al Boeing 747-F cargo aircraft crashed in a suburb of Amsterdam. After reports of local residents and rescue workers complaining of health issues related to the release of depleted uranium used as counterbalance in the plane, authorities began an epidemiological study in 2000 of those believed to be affected by the accident. The study concluded that because exposure levels were so low, it was highly improbable that exposure to depleted uranium was the cause of the reported health complaints.

Gulf War syndrome

Increased rates of immune system disorders and other wide-ranging symptoms have been reported in combat veterans of the 1991 Gulf War. It has not always been clear whether these were related to Gulf War service, but combustion products from depleted uranium munitions is still being considered as a potential cause by the Research Advisory Committee on Gulf War Veterans' Illnesses, as DU was used in tank kinetic energy penetrator and machine-gun bullets on a large scale for the first time in the Gulf War.

Most experts in health physics consider it unlikely that depleted uranium has any connection with the Gulf War Syndrome if such an illness exists at all. A two year study headed by Sandia National Laboratories' Al Marshall analyzed potential health effects associated with accidental exposure to depleted uranium during the 1991 Gulf War. Marshall's study concluded that the reports of serious health risks from DU exposure are not supported by veteran medical statistics and were consistent with earlier studies from Los Alamos and the New England Journal of Medicine [12].

Rubella

Classifications and external resources

ICD-10

B06.

ICD-9

056

Rubella virus

Virus classification

Group: Group IV ((+)ssRNA)Family: Togaviridae
Genus: Rubivirus
Species: *Rubella virus*

Rubella (also known as *epidemic roseola*, *German measles*, *liberty measles*[1] or *three-day measles*) is a disease caused by the *Rubella virus*. It is often mild and an attack can pass unnoticed. However, this can make the virus difficult to diagnose. The virus usually enters the body through the nose or throat. The disease can last 1-5 days. Children recover more quickly than adults. Like most viruses living along the respiratory tract, it is passed from person to person by tiny droplets in the air that are breathed out. Rubella can pose a serious risk as it can also be transmitted from a mother to her developing baby through the bloodstream via the placenta. If the mother is infected within the first 20 weeks of pregnancy, the baby will have congenital rubella syndrome. The virus has an incubation period of 2 to 3 weeks during which it becomes established.

The name *German measles* has nothing to do with Germany. It comes from the Latin germanus, meaning "similar", since rubella and measles share many symptoms.

Symptoms

Symptoms of rubella include:
Children: Low grade fever, swollen glands, joint pain, headache, conjunctivitis, rash
Adults and children:

- swollen glands or lymph nodes (may persist for up to a week)
- fever (rarely rises above 38 degrees Celsius [100.4 degrees Fahrenheit])
- rash (Appears on the face and then spreads to the trunk and limbs. It appears as pink dots under the skin. It appears on the first or third day of the illness but it disappears after a few days with no staining or peeling of the skin)
- Forchheimer's sign occurs in 20% of cases, and is characterized by small, red papules on the area of the soft palate
- flaking, dry skin
- nerves become weak or numb (very rare)

Risks

Rubella can affect anyone of any age and is generally a mild disease. However, rubella can cause congenital rubella syndrome in the fetus of an infected pregnant woman.

Prevention and treatment

Symptoms are usually treated with paracetamol until the disease has run its course. There is no treatment available for congenital rubella.

Fewer cases of rubella occur since a vaccine became available in 1969, although decreased uptake of the MMR vaccine (e.g. in the UK) is expected to lead to a rise in incidence. In most Western countries, the vast majority of people are vaccinated against rubella as children at 12 to 15 months of age. A second dose is required before age 11. The vaccine gives lifelong protection against rubella. A side-effect of the vaccine can be transient arthritis.

The immunization program has been quite successful with Cuba declaring the disease eradicated in the 1990s and the United States eradicating it in 2005 [1]. Every minister of health in the Americas plans to eliminate the disease by 2010.

Rubella in popular culture

Agatha Christie's The Mirror Crack'd from Side to Side features a plot, possibly based on real life, in which a girl is shut up in quarantine for a minor illness but climbs out of the window to meet a celebrity. The celebrity is pregnant and unknowingly catches rubella resulting in a child with congenital rubella syndrome. However, as this is the fan's favourite anecdote, when she meets the celebrity years later she tells her this story so the celebrity realises that her baby's retardation were caused by this fan.

2-(2,6-dioxo-3-piperidyl)isoindole-1,3-dione

Identifiers

CAS number 50-35-1

ATC code L04**AX02**

PubChem 5426

DrugBank APRD01251

Chemical data

Formula $C_{13}H_{10}N_2O_4$

Mol. weight 258.23 g/mol

Pharmacokinetic data

Protein binding 55% and 66% for the (+)R and (−)S enantiomers, respectively

Half life mean ranges from approximately 5 to 7 hours following a single dose; not altered with multiple doses

Therapeutic considerations

Pregnancy cat. $X_{(AU)}$ $X_{(US)}$

Legal status Prescription only

Routes oral

Thalidomide is a sedative, hypnotic, and anti-inflammatory medication. It was sold from 1957 to 1961 in almost fifty countries under at least forty names, including Distaval, Talimol, Nibrol, Sedimide, Quietoplex, Contergan, Neurosedyn, and Softenon. Thalidomide was chiefly sold and prescribed during the late 1950s and 1960s to pregnant women, as an antiemetic to combat morning sickness and as an aid to help them sleep. Unfortunately, inadequate tests were performed to assess the drug's safety, with catastrophic results for the children of women who had taken thalidomide during their pregnancies.

From 1956 to 1962, approximately 10,000 children were born with severe malformities, including phocomelia, because their mothers had taken thalidomide during pregnancy.[1] In 1962, in reaction to the tragedy, the United States Congress enacted laws requiring tests for safety during pregnancy before a drug can receive approval for sale in the U.S.[2] Other countries enacted similar legislation, and thalidomide was not prescribed or sold for decades.

Researchers, however, continued to work with the drug. Soon after its banishment, a doctor discovered anti-inflammatory effects of thalidomide and began to look for uses of the medication despite its teratogenic effects. He found that patients with erythema nodosum leprosum, a painful skin condition associated with leprosy, experienced relief of their pain by taking thalidomide. Currently, there are studies underway to determine the drug's effects on arachnoiditis, Crohn's disease, and several types of cancers. However, physicians and patients alike must go through a special process to prescribe and receive thalidomide, to ensure no more children are born with birth defects traceable to the medication.

History

Discovery and introduction

A small German pharmaceutical company, Chemie Grünenthal, synthesized thalidomide in West Germany in 1953 while searching for an inexpensive method of manufacturing antibiotics from peptides. By heating phthaloyisoglutamine, the company's chief researcher produced phthalimidoglutarimide, which they soon labeled 'thalidomide.' Chemie Grünenthal patented the molecule and began searching for a disease thalidomide could cure.[3]

The Grünenthal scientists could not find any antibiotic activity, or any other encouraging effects, in mice and rats. However, they saw that the new chemical seemed to be harmless; outrageously high doses did not kill rodents, rabbits, cats, or dogs. In addition, the animals showed no other side effects. The research team began to describe thalidomide as "nontoxic," and Grünenthal began to consider the lucrative prospects of their new find. Notably, although no sedative or tranquilizing effects were observed in animals, Grünenthal management considered "a nonlethal sedative would have enormous market potential." [3]

With only these animal tests, no clinical trial plans, and no scientific rationale, Grünenthal began distributing free samples of thalidomide to doctors in Switzerland and West Germany in 1955. It was first recommended for the prevention of seizures in patients with epilepsy; although no anticonvulsant effect was found, patients reported experiencing a deep sleep. Other patients said they felt calming and soothing effects. Some reported side effects, but they were not believed to be serious.[3] One author later said that "Thalidomide was introduced by the method of Russian Roulette. Practically nothing was known about the drug at the time of its marketing."[4]

Thalidomide could not be sold in West Germany until its effects on animals were documented – usually effects of a drug are demonstrated on animals before the drug is administered to humans, but thalidomide was not tested that way. The sedative effects had not been seen in animals, so the Grünenthal scientists came up with a "jiggle cage" to measure the movements of mice to see if treated mice "jiggled" the cage less than non-treated mice. Grünenthal also pointed out that their "powerful hypnotic drug was completely safe.[3]

An employee of Chemie Grünenthal brought home samples of the new drug for his pregnant wife, and ten months before thalidomide was put on the market in Germany, on Christmas Day in 1956, their child was born – without ears. Years later, the father learned that his daughter was the first living victim of the epidemic of thalidomide-induced infant malformations and deaths.[3]

The company began selling the drug over the counter in Germany in October 1957, under the brand name Contergan. The company claimed that "Even a determined suicide could not take enough Contergan to cause death" and "accidental overdoses by children would be unheard of with this drug." Soon the drug was being sold in 46 countries under "at least 37 names,"[3] without any additional independent testing, and was the drug of choice for pregnant women with morning sickness.[5] Not one of those statements turned out to be true.

Frances Kelsey

By 1960, Grünenthal was selling thalidomide tablets all over the world – except in the United States. A Cincinnati, Ohio company called Richardson-Merrell tried to change that in

September 1960, when it applied for Food and Drug Administration (FDA) approval to sell thalidomide in the United States under the brand name of Kevadon. The company wanted to begin sales of Kevadon in early 1961. This approval was not expected to be controversial, and the case was given to the agency's newest reviewer, Frances Oldham Kelsey, who had joined the FDA only one month before.

At the time, the prevailing US law was the 1938 Federal Food, Drug, and Cosmetic Act, which required proof of safety be sent to the FDA before a medication could be approved for sale in the United States. The law did *not* require demonstration of efficacy for approval. It also allowed "investigational" or "experimental" use of a drug while approval for its sale was being sought, meaning that a medication could be widely distributed before it was approved.[6] The law gave the FDA 60 days to review a drug application. If the FDA reviewer told a drug company that its application for a particular medication was incomplete, it was considered withdrawn and the company would have to submit more data when it resubmitted the application. With each resubmission, the 60 days started all over again.[1]

This was Kelsey's first drug review assignment for the FDA. She was interested in fetal safety because in the 1940s she had studied quinine, including its effects in pregnancy, while she was part of a team that was trying to find a synthetic cure for malaria. In particular, she recalled a study she conducted on rabbits at the University of Chicago. In that study, she noted that adult rabbits metabolized quinine rapidly, but pregnant rabbits were less able to metabolize it and embryonic rabbits could not metabolize it at all. In addition, contrary to the prevailing theories of the time, Kelsey found that the drug passed through the placental barrier between mother and fetus.[5] Recalling her work with quinine, Kelsey thought that perhaps thalidomide acted the same way – if so, thalidomide might be safe for older, non-pregnant patients, but could be toxic to children, pregnant women and their fetuses.

Kelsey had other worries about thalidomide as well. She wanted to know about the drug's mechanism of action – its effects on human metabolism, its chemistry and pharmacology, and its stability.[2] However, none of this data had been provided by Richardson-Merrell. There had been no chronic toxicity studies, excretion and absorption data was inadequate, and there were few manufacturing controls in place to assure quality.

Kelsey rejected the application and requested the aforementioned data from the company in a letter. Richardson-Merrell resubmitted the application but with no new information, and Kelsey turned it down again. She continued to request more data from the company, and with each request the 60 day clock was rewound to its beginning. As the end of 1960 approached, and with it the holiday season (the best time for selling sedatives)[3], Richardson-Merrell began ratcheting up the pressure on the FDA and Kelsey. Executives and scientists telephoned and personally visited Kelsey, and executives complained to her superiors that she was nit-picking and unreasonable.[1][5]

Still, Kelsey refused to clear Kevadon for sale in the United States until she could review satisfactory studies. She later said that the reports submitted by Grünenthal and Richardson-Merrell were more like testimonials than results of well-designed, controlled studies.[1] (One possible reason for the lack of data could be that Richardson-Merrell's "investigation" of thalidomide for its FDA application was organized and implemented not by scientists, but by the company's sales and marketing division.)[3] It wasn't enough to know how the drug acted in animals – she wanted to know how it worked in humans, and the data was not forthcoming. Kelsey had also heard anecdotal reports of peripheral neuropathy as a side

effect of thalidomide, which only made her think more about the possible effects on a fetus. She continued to reject the Kevadon application. In total, the company resubmitted its Kevadon application to the FDA six times, but no new evidence was given in those applications and Kelsey refused to budge.

Tragedy

Unusual side effects had been reported by patients taking thalidomide in the UK, including peripheral neuropathy. Worse, pregnant women who had taken the drug were giving birth to babies with a condition called phocomelia – abnormally short limbs with toes sprouting from the hips and flipper-like arms. Other infants had eye and ear defects or malformed internal organs such as unsegmented small or large intestines. Chemie Grünenthal denied that thalidomide was responsible for any of these problems. In 1959, Grünenthal responded to one doctor's inquiry by saying, "We have no idea how these cases... could have been caused by Contergan."[3]

Under US law at the time, Richardson-Merrell had been legally distributing Kevdon on an "investigational" basis since early 1960, and pregnant women were included as patients after the first three months of the trial. American doctors were told,[3]

"We have firmly established the safety, dosage, and usefulness of Kevadon by both foreign and US laboratory and clinical studies. This program is designed to obtain widespread confirmation of its usefulness in a variety of hospitalized patients. Doctors need not report results if they don't want to..."

In December 1960, three months after Richardson-Merrell applied for FDA approval of Kevadon, the British Medical Journal published a letter from a British physician who reported cases of peripheral neuropathy, or painful extremities, in patients who had taken thalidomide over a long period of time. Kelsey read this letter, and she believed it was the first indication of toxicity effects.[5] It increased her misgivings about approving the application, and she immediately requested information from Richardson-Merrell about the problem. The company denied knowing about any harmful side effects. Years later, it was shown that Richardson-Merrell knew about the risk of nerve damage but failed to disclose the fact to the FDA.[3] Throughout 1961, more unofficial, anecdotal reports of thalidomide side effects surfaced in Europe and Australia.

On November 18, 1961, the German paper Welt am Sonntag published a letter by German pediatrician Widukind Lenz.[6] Lenz described more than 150 infants with malformations, including phocomelia, and associated them with thalidomide given to their mothers.[3] A stunning statistic was that 50 percent of the mothers with deformed children had taken thalidomide during the first trimester of pregnancy.[1] The limits of danger were amazingly narrow: women who took even one tablet of thalidomide between the 20th and 36th day after conception were at risk for delivering malformed infants – beyond that time, the drug caused no deformities at all.[3] Lenz notified Chemie Grünenthal about the dangers of its flagship product; ten days later, German authorities removed thalidomide from the market against Grünenthal's wishes. Grünenthal withdrew thalidomide soon afterward from the market and notified Richardson-Merrell of its decision.

In December, The Lancet published a letter by William McBride, an Australian physician, who noted large numbers of birth defects in the children of women who had taken thalidomide.[7] Other countries quickly pulled the drug from their stores and pharmacies. However, Grünenthal continued to dispute the claims that thalidomide was responsible for the defects, saying that their action was "merely a response to the sensationalism."[3]

Richardson-Merrill withdrew its Kevadon application in March 1962, but the sheer number and variety of brand names meant the drug remained available in some countries – thalidomide could be found in Brazil, Italy, and Japan as long as nine months after the German withdrawal.[8]

Unfortunately, Grünenthal's decision was too late for thousands of families. An estimated 8,000 to 12,000 infants were born with deformities caused by thalidomide, and of those only about 5,000 survived beyond childhood.[3] The medication never received approval for sale in the United States, but 2.5 million tablets had been given to more than 1,200 American doctors during Richardson-Merrell's "investigation," and nearly 20,000 patients received thalidomide tablets, including several hundred pregnant women. In the end, 17 American children were born with thalidomide-related deformities.[1] An estimated 40,000 people developed drug-induced peripheral neuropathy. Exact numbers will never be known because the companies and doctors kept incomplete and inaccurate records. Fortunately, no thalidomide victims have passed defects to their children, because thalidomide is not a mutagen.[9]

The ensuing American media coverage of thalidomide children, and the woman who refused to approve the drug for use in the United States, enveloped Kelsey and the FDA. Kelsey was praised in a story by Morton Mintz in The Washington Post on July 15, 1962. The headline read, " 'Heroine' of FDA Keeps Bad Drug Off of Market." Follow-up articles appeared in The New York Times, Life magazine, Saturday Review, and hundreds of other publications of the day.

More importantly, a controversial bill by U.S. Senator Estes Kefauver, of Tennessee, was resurrected and rewritten, passed by Congress, and signed by President John F. Kennedy on October 10, 1962. The Kefauver Harris Amendment strengthened the FDA's control of experimentation on humans and changed the way new drugs were approved and regulated. Before the thalidomide scandal, U.S. drug companies only had to show their new products were safe; for the first time, they would have to show their new drugs were safe and effective.[6] Informed consent was required of patients participating in clinical trials, and adverse drug reactions were required to be reported to the FDA.

The legal mess caused by the effects of thalidomide, and Chemie Grünenthal's shoddy testing and approval procedures, is still winding its way through courts worldwide even 50 years later. In connection with one of the first lawsuits, a court-ordered gag rule prohibited all mention of the thalidomide effects for ten years, from 1962 to 1972.[3] In one of the more recent developments in 2003, the Swedish government authorized an ex gratia compensation of SEK 250,000 for each of the 150 individuals that were subjected to thalidomide (marked in Sweden as Neurosedyn). According to a widely disputed investigation by the Swedish Office of the Chancellor of Justice (Justitiekanslern), no blame falls on the Swedish government. The Swedish government later decided to raise the compensation to SEK 500,000 each.

Thalidomide today

FDA Approval

"On May 26, 2006, the U.S. Food and Drug Administration granted accelerated approval for thalidomide (Thalomid, Celgene Corporation) in combination with dexamethasone for the treatment of newly diagnosed multiple myeloma (MM) patients.".htm Incredibly, the FDA approval came seven years after the first reports of efficacy in the medical literature (Desikan R, Munshi N, Zeldis J, et al. Activity of thalidomide (THAL) in multiple myeloma (MM) confirmed in 180 patients with advanced disease. Blood 1999;94:Suppl 1:603a-603a.abstract), and Celgene took advantage of "off-label" marketing opportunities to promote the drug in advance of its FDA approval for the myeloma indication. Thalomid, as the drug is commercially known, sold $300 million plus per year, while only approved for leprosy! [2] Thalidomide was and still is (2006) an important advance in the treatment of multiple myeloma, ever since news of its efficacy spread throughout the medical literature in 2000. The drug has some bothersome nuisance side effects such as neuropathy, constipation, and fatigue, but is likely more effective than chemotherapy for multiple myeloma. Thalidomide, along with another new drug, bortezomib, are changing the landscape of multiple myeloma treatment, such that toxic stem cell transplants may no longer be the standard treatment for this incurable malignancy.

Possible indications

Research on thalidomide slowed in the 1960s, but never completely stopped. The medication is now an example of how potentially dangerous chemical compounds can be used therapeutically with appropriate precautions and procedures.

In 1964, an Israeli physician named Jacob Sheskin was trying to help a critically-ill French patient with erythema nodosum leprosum (ENL), a very painful complication of leprosy. He looked throughout his small hospital for anything that might help his patient stop aching long enough to sleep. He came across a bottle of thalidomide tablets, and remembered that the drug had been effective in helping mentally ill patients sleep – and also that it was banned. Thinking he had nothing to lose, Sheskin gave the man two tablets of thalidomide. The patient slept for hours, and he felt good enough to get out of bed without aid when he woke up. The result was soon followed by more favorable experiences, followed by a clinical trial. Dr. Sheskin's drug of last resort revolutionized the care of leprosy, and led to the closing of most leprosy hospitals.[3]

Serious infections including sepsis and tuberculosis cause the level of tumor necrosis factor ± (TNF±) to rise. TNF± is a chemical mediator in the body, and it may enhance the wasting process in cancer patients as well. Thalidomide may reduce the levels of TNF±, and it is possible that the drug's effect on ENL is caused by this mechanism.[2]

Thalidomide also has potent anti-inflammatory effects that may help ENL patients. In July 1998, the FDA approved the application of Celgene to distribute thalidomide under the brand name Thalomid for treatment of ENL. Celgene received approval for its use against multiple

myeloma in Australia in 2003 and in the US in 2005. [6] Thalomid, in conjunction with dexamethasone, is now standard therapy for multiple myeloma.

Thalidomide also inhibits the growth of new blood vessels (angiogenesis), which may be useful in treating macular degeneration and other diseases; this effect also helps AIDS patients with Kaposi's sarcoma, although there are better and cheaper drugs to treat the condition. Also for AIDS patients, thalidomide may be able to fight painful, debilitating aphthous lesions in the mouth and esophagus which prevent sufferers from eating. The FDA formed a Thalidomide Working Group in 1994 to provide consistency between its divisions, with particular emphasis on safety monitoring. The agency also imposed severe restrictions on the distribution of Thalomid through the System for Thalidomide Education and Prescribing Safety (STEPS) program.[2]

Thalidomide is also being investigated for treating symptoms of prostate cancer, glioblastoma, lymphoma, arachnoiditis, Behçet's disease, and Crohn's disease. In a small trial, Australian researchers found thalidomide sparked a doubling of the number of T cells in patients, allowing the patients' own immune system to attack cancer cells.

Teratogenic mechanism

Thalidomide is racemic – it contains both left- and right-handed isomers in equal amounts. One enantiomer is effective against morning sickness. The other is teratogenic, and causes birth defects. The enantiomers are converted to each other in vivo – that is, if a human is given (R)-thalidomide or (S)-thalidomide, both isomers can be found in the serum – therefore, administering only one enantiomer will not prevent the teratogenic effect in humans.

The mechanism by which thalidomide causes birth defects is not completely understood, although recent papers suggest that it alters TNF± production, modulates integrins, alters T-cell ratios and inhibits angiogenesis. It is known to intercalate into DNA at guanine sites, which may alter expression of certain genes thereby causing the dramatic malformations.

Side effects

Apart from its infamous tendency to induce birth defects and peripheral neuropathy, the main side effects of thalidomide include fatigue and constipation. It also is associated with an increased risk of deep vein thrombosis especially when combined with dexamethasone, as it is for treatment of multiple myeloma. High doses can lead to pulmonary edema, atelectasis, aspiration pneumonia, and refractory hypotension.

Thalidomide analogs

The exploration of the antiangiogenetic and immunomodulatory activities of thalidomide has led to the study and creation of thalidomide analogs. In 2005, Celgene received FDA approval for lenalidomide (Revlimid) as the first commercially useful derivative. Revlimid is only available in a restricted distribution setting to avoid its use during pregnancy. Further studies are conducted to find safer compounds with useful qualities. Another analog,

Actimid, is in the clinical trial phase. These thalidomide analogs can be used to treat different diseases, or used in a regimen to fight two conditions.

Notable children of thalidomide

- Theresia Degener, a prominent human rights lawyer with a special interest in the rights of the disabled
Mat Fraser, a comedian, actor, co-presenter of the BBC's Ouch Podcast
Alvin Law, a motivational speaker and former radio broadcaster.
Tony Melendez is a guitarist who was born without arms. He plays only with his feet.
Brett Nielsen , a musician, was the first Australian thalidomide child
Thomas Quasthoff is an internationally acclaimed bass-baritone who describes himself : "1.34 meters tall, short arms, seven fingers - four right, three left - large, relatively well formed head, brown eyes, distinctive lips; profession: singer."

Thalidomide in literature, music & arts

- On Giant's Shoulders: The Story of Terry Wiles (ISBN 0-7230-0146-4) by Marjorie Wallace, a book & movie about the life of Terry Wiles
Peter Milligan and Brendan McCarthy's short graphic novel Skin (1992) features a teenage skinhead who is a child of thalidomide.
The horror movie Scanners deals with children whose mothers took a similar "wonder drug" during their pregnancy with even more dramatic side effects.
The Punk rock band NOFX wrote a song entitled "Thalidomide Child".
The song "We Didn't Start the Fire" by Billy Joel mentions thalidomide.
The novel Mount Dragon by Douglas Preston and Lincoln Child contains a computer hacker character named Mime who is a thalidomide survivor.
The poem Thalidomide by Sylvia Plath
The novel All Families are Psychotic' by Douglas Coupland refers to thalidomide.
The short story Fortune's Always Hiding by Irvine Welsh in the novel Ecstasy: Three Tales of Chemical Romance (1996) is a story of revenge-seeking thalidomide victims.

Vitamins

Vitamins are nutrients required in very small amounts for essential metabolic reactions in the body [1]. The term vitamin does not encompass other essential nutrients such as dietary minerals, essential fatty acids, or essential amino acids. Nor does the term refer to the large number of other nutrients that promote health, but are not strictly essential.

Vitamins act both as catalysts and substrates in chemical reactions. When acting as a catalyst, vitamins are bound to enzymes and are called cofactors, for example vitamin K forms part of the proteases involved in blood clotting. Vitamins also act as coenzymes to carry chemical groups between enzymes, for example folic acid carries various forms of carbon groups (methyl, formyl or methylene) in the cell.

Until the 1900s, vitamins were obtained solely through food intake. Many food sources contain different ratios of vitamins. Therefore, if the only source of vitamins is food, a seasonal, yearly or even daily change in diet also alters the ratio of ingested vitamins. Many vitamins can be stored by the body over a range of dosages and short term deficiencies (e.g. during a particular food growing season), do not always result in disease.

Vitamins have been produced as commodity chemicals and made widely available as inexpensive pills for several decades[2] allowing for consistent supplementation to dietary intake.

History

The value of eating certain foods to maintain health was recognized long before vitamins were identified. The ancient Egyptians knew that feeding a patient liver would help cure night blindness, now known to be caused by a vitamin A deficiency. In 1747, the Scottish surgeon James Lind discovered that citrus foods helped prevent scurvy, a particularly deadly disease in which collagen is not properly formed, and is characterized by poor wound healing, bleeding of the gums, and severe pain.[3] In 1753, Lind published his Treatise on the Scurvy, which recommended using lemons and limes to avoid scurvy, which was adopted by the British Royal Navy. This led to the nickname Limey for sailors of that organization. Lind's discovery, however, was not widely accepted by individuals in the Royal Navy's Arctic expeditions in the 19th century, where it was widely believed that scurvy could be prevented by practicing good hygiene, regular exercise, and by maintaining the morale of the crew while on board, rather than by a diet of fresh food.[3] As a result, Arctic expeditions continued to be plagued by scurvy and other deficiency diseases. In the early 20th century, when Robert Falcon Scott made his two expeditions to the Antarctic the prevailing medical theory was that scurvy was caused by "tainted" canned food.[3]

In 1881, Russian surgeon Nikolai Lunin studied the effects of scurvy while at the University of Tartu (in present day Estonia).[4] He fed mice an artificial mixture of all the separate constituents of milk known at that time, namely the proteins, fats, carbohydrates, and salts. The mice that received only the individual constituents died, while the mice fed by milk itself developed normally. He made a conclusion that "a natural food such as milk must therefore contain, besides these known principal ingredients, small quantities of unknown substances essential to life".[4] However, his conclusions were rejected by other researchers

when they were unable to reproduce his results. One difference was that he had used table sugar (sucrose), while other researchers had used milk sugar (lactose) which still contained small amounts of vitamin B.

In 1897, Christiaan Eijkman discovered that eating unpolished rice instead of the polished variety helped to prevent the disease beriberi. The following year, Frederick Hopkins postulated that some foods contained "accessory factors"—in addition to proteins, carbohydrates, fats, etc.—that were necessary for the functions of the human body.[3] Hopkins was awarded the 1929 Nobel Prize for Physiology or Medicine, with Christiaan Eijkman, for their discovery of several vitamins.

Kazimierz Funk was the first to isolate the water-soluble complex of micronutrients, whose bioactivity Fletcher had identified, and Funk proposed the complex be named "Vitamine".[5] The name soon became synonymous with Hopkins' "accessory factors", and by the time it was shown that not all vitamins were amines, the word was already ubiquitous. In 1920, Jack Cecil Drummond proposed that the final "e" be dropped, to deemphasize the "amine" reference, after the discovery that vitamin C had no amine component.

Throughout the early 1900s, the use of deprivation studies allowed scientists to isolate and identify a number of vitamins. Initially, lipid from fish oil was used to cure rickets in rats, and the fat-soluble nutrient was called "antirachitic A". The irony here is that the first "vitamin" bioactivity ever isolated, which cured rickets, was initially called "vitamin A", the bioactivity of which is now called vitamin D,[6] What we now call "vitamin A" was identified in fish oil because it was inactivated by ultraviolet light.

In 1931, Albert Szent-Györgyi and his research fellow Joseph Svirbely, determined that "hexuronic acid" was actually vitamin C and noted its anti-scorbutic activity, and 1937 Szent-Györgyi was awarded the Nobel Prize for his discovery. In 1943 Edward Adelbert Doisy and Henrik Dam were awarded the Nobel Prize for their discovery of vitamin K and its chemical structure.

Human vitamins

Vitamins are classified as either water soluble, meaning that they dissolve easily in water, or fat soluble, and are absorbed through the intestinal tract with the help of lipids. Each vitamin is typically used in multiple reactions and therefore, most have multiple functions.[7]

In humans there are thirteen vitamins, divided into two groups; four fat-soluble vitamins (A, D, E and K), and nine water-soluble vitamins (eight B vitamins and vitamin C).

Vitamin name: Chemical name / Solubility / Deficiency disease / Recommended Dietary Allowances (male, age 19–70) / Upper Intake Level (UL/day)

Vitamin A

Retinoids (include: retinol, retinal, retinoic acid, 3-dehydroretinol and its derivatives) / Fat Night-blindness, Keratomalacia[9] / *900 µg /* 3,000 µg

Vitamin B1

Thiamine / Water / Beriberi / *1.2 mg* / (N/D)[10]

Vitamin B2

Riboflavin / Water / Ariboflavinosis / *1.3 mg* / N/D

Vitamin B3

Niacin / Water / Pellagra / *16.0 mg* / 35.0 mg

Vitamin B5

Pantothenic acid / Water / Paresthesia / 5.0 mg [11] / N/D

Vitamin B6

Pyridoxine / Water / Anemia[12] / *1.3-1.7 mg* / 100 mg

Vitamin B7

Biotin / Water / n/a / 30.0 µg / N/D

Vitamin B9

Folic acid / Water / Deficiency during pregnancy is associated with birth defects. / *400 µg* / 1,000 µg

Vitamin B12

Cyanocobalamin / Water / Megaloblastic anaemia[13] / *2.4 µg* / N/D

Vitamin C

Ascorbic acid / Water / Scurvy / *90.0 mg* / 2,000 mg

Vitamin D2–D4

Lumisterol, Ergocalciferol, Cholecalciferol, Dihydrotachysterol, 7-Dehydrocholesterol / Fat / Rickets / 5.0 µg-10 µg [14] / 50 µg

Vitamin E

Tocopherol, Tocotrienol / Fat / deficiency is very rare, mild hemolytic anemiain newborn infants [15] / *15.0 mg* / 1,000 mg

Vitamin K

Naphthoquinone (not to be confused with ***ketamine***) / Fat / Bleeding diathesis / 120 µg / N/D

Vitamins in nutrition and disease

Vitamins are essential for normal growth and development. Using the genetic blueprint inherited from its parents, a fetus begins to develop, at the moment of conception, from the nutrients it absorbs.

The developing fetus requires certain vitamins and minerals to be present at certain times. These nutrients facilitate the chemical reactions that produce, among other things, skin, bone, and muscle. If there is serious deficiency in one or more of these nutrients, a child may develop a deficiency disease. Minor deficiencies also have the potential to cause permanent damage, and may be associated with reduced life expectancy.[16]

For the most part, vitamins are obtained through food sources. However, a few vitamins are obtained by other means: for example, microorganisms in the intestine - commonly known as "gut flora" - produce vitamin K and biotin, while one form of vitamin D is synthesized in the skin with the help of natural ultraviolet in sunlight. Some vitamins can be obtained from precursors that are obtained in the diet. Examples include vitamin A, which can be produced from beta carotene and niacin from the amino acid tryptophan.**[8]**

Once growth and development are completed, vitamins remain essential components of the healthy maintenance of the cells, tissues, and organs that make up the human body, and enable the body to efficiently use the calories provided by the food that we eat, and to help process proteins, carbohydrates, and fats.

Vitamin deficiencies

An organism can survive for some time without vitamins, although prolonged vitamin deficits may result in often painful and potentially deadly diseases. Body stores for different vitamins can vary widely; an adult may be deficient in vitamin A and B***12*** for long periods of time before developing a deficiency condition, while vitamin B***3*** stores may only last a couple of weeks.[9][15]

Deficiencies of vitamins are classified as either primary or secondary. A primary deficiency occurs when you do not get enough of the vitamin in the food you eat. A secondary deficiency may be due to an underlying disorder that prevents or limits the absorption or use of the vitamin, or due to a “lifestyle factor”, such as smoking, excessive alcohol consumption, or the use of medications that interfere with the absorption or the body's use of the vitamin.[15]

Well-known vitamin deficiencies involve thiamine (beriberi), niacin (pellagra), vitamin C (scurvy) and vitamin D (rickets). In much of the developed world, such deficiencies are rare due to; an adequate supply of food and the addition of vitamins and minerals, often called fortification, to common foods.[8][15][17]

Vitamin side effects and overdose

Vitamins are classified as fat-soluble or water-soluble based on how they are absorbed by the body. Vitamins A, D, E, and K are fat soluble, while the water-soluble vitamins include vitamin C and the B-complex vitamins (thiamine (B1), riboflavin (B2), niacin (B3), pantothenic acid (B5), vitamin B6, vitamin B12, biotin and folate.

Fat-soluble vitamins (A, D, E and K) are often stored in the body and can cause toxicity when ingested in excess. With the exception of vitamin B12, which is stored in the liver[13], water-soluble vitamins are not stored in the body. All vitamins have documented side effects. Like side effects from drugs, vitamin side effects increase in severity with increasing dosage. At high enough dosages vitamins can cause extreme side effects such as nausea, diarrhea, and vomiting.[8] Unlike side effects caused by drugs, vitamin side effects rarely cause any permanent harm.[18] When vitamin side effects emerge, full and rapid recovery is accomplished by reducing the supplement dosage. Furthermore, the concentrations of vitamins an individual can tolerate vary widely, and appear to be related to age and state of health.[19]

The likelihood of consuming too much of any vitamin from food is remote, but overdosing from vitamin supplementation does occur. It is for this reason that physicians and scientists carefully review all the clinical data on supplement use in order to determine upper dosage thresholds for each vitamin that can be tolerated as a daily dose by the entire population without side effects. This dosage is known as the tolerable upper intake level (UL).[8]

The supplement controversy

Dietary supplements are often used to ensure that adequate amounts on nutrients are obtained on a daily basis, if the nutrients cannot be obtained through a varied diet. Scientific evidence supporting the benefits of some dietary supplements is well established for certain health conditions, but others need further study.[20] It is also important to note that some supplements include vitamins and minerals, as well as herbs, botanicals and other substances.

Supplements are, as required by law, not intended to treat, diagnose, mitigate, prevent, or cure disease.[20] In some cases, dietary supplements may have unwanted effects, especially if taken before surgery, with other dietary supplements or medicines, or if the taker has certain health conditions.[20] Vitamin supplements may also contain levels of vitamins many times higher, and in different forms, than one may ingest through food.[21] Before taking a supplement, it is important to check with a knowledgeable health care provider, especially when combining or substituting supplements with other foods or medicine.

Governmental regulation of vitamin supplements

Most countries place dietary supplements in a special category under the general umbrella of "foods," not drugs. This necessitates that the manufacturer, and not the government, be responsible for ensuring that its dietary supplement products are safe before they are marketed. Unlike drug products, that must implicitly be proven safe and effective for their intended use before marketing, there are often no provisions to "approve" dietary supplements for safety or effectiveness before they reach the consumer. Also unlike drug products, manufacturers and distributors of dietary supplements are not generally required to report any claims of injuries or illnesses that may be related to the use of their products[22] however, side effects have been reported for several types of supplements.[23]

Names in current and previous nomenclatures

The reason the set of vitamins seems to skip directly from E to the rarely-mentioned K is that the vitamins corresponding to "letters" F-J were either reclassified over time, were discarded as false leads, or were renamed because of their relationship to "vitamin B", which became a "complex" of vitamins. The following table lists chemicals that had previously been classified as vitamins, as well as the earlier names of vitamins that later became part of the B-complex.

Previous vitamin name [24] [25]	Chemical name[24][25]	Current vitamin name[24]	Reason for name change[24]
Vitamin B_4	Adenine	N/A	No longer classified as a vitamin
Vitamin B_8	Adenylic acid	N/A	No longer classified as a vitamin
Vitamin F	Essential fatty acids	N/A	Needed in large quantaties, does not fit definition of vitamin.
Vitamin G	Riboflavin	Vitamin B_2	Reclassified as B-complex
Vitamin H/ Vitamin I	Biotin	Vitamin B_7	Reclassified as B-complex
Vitamin J	Catechol, Flavin	N/A	No longer classified as a vitamin
Vitamin L_1	Orthoaminobenzoic acid, Anthranilic acid	N/A	No longer classified as a vitamin
Vitamin L_2	Adenyl thiomethylpentose	N/A	No longer classified as a vitamin
Vitamin M	Folic acid	Vitamin B_9	Reclassified as B-complex
Vitamin P	Flavonoids	N/A	No longer classified as a vitamin
Vitamin PP	Niacin	Vitamin B_3	Reclassified as B-complex
Vitamin R, Vitamin B_{10}	Pteroylmonoglutamic acid	N/A	No longer classified as a vitamin
Vitamin S, Vitamin B_{11}	Pteroylheptaglutamic acid	N/A	No longer classified as a vitamin
Vitamin U	Allantoine	N/A	No longer classified as a vitamin

B vitamins

Vitamin B is a complex of eight water soluble vitamins, active in cell metabolism. The name arises because it was once considered a single vitamin, much like Vitamin C or Vitamin D. Since later research has shown it is in fact a complex of chemically distinct vitamins that happen to often coexist in the same foods, the name has gradually declined in use, being replaced by the generic term *"the B vitamins"*, *the vitamin B complex*, or by the specific names of each vitamin.

List of B vitamins

- Vitamin B1, (Thiamine)

Vitamin B2, (Riboflavin)
Vitamin B3, also Vitamin P or Vitamin PP (Niacin)
Vitamin B5, (Pantothenic acid)
Vitamin B6, (Pyridoxine and Pyridoxamine)
Vitamin B7, also Vitamin H (Biotin)
Vitamin B9, also Vitamin M and Vitamin B-c (Folic acid) - important for pregnancies
Vitamin B12, (Cyanocobalamin)

B vitamins deficiency

Several named vitamin deficiency diseases may result from the lack of sufficient B-vitamins.

- *Vitamin B*1 (Thiamine) deficiency causes Beriberi. Symptoms of this disease of the nervous system include weight loss, emotional disturbances, Wernicke's encephalopathy (impaired sensory perception), weakness and pain in the limbs, periods of irregular heartbeat, and edema (swelling of bodily tissues). Heart failure and death may occur in advanced cases. Chronic thiamine deficiency can also cause Korsakoff's syndrome, an irreversible psychosis characterized by amnesia and confabulation.
- *Vitamin B*2 (Riboflavin) deficiency causes Ariboflavinosis. Symptoms may include cheilosis (cracks in the lips), high sensitivity to sunlight, angular cheilitis, glossitis (inflammation of the tongue), seborrheic dermatitis or pseudo-syphilis (particularly affecting the scrotum or labia majora and the mouth), pharyngitis, hyperemia, and edema of the pharyngeal and oral mucosa.
- *Vitamin B*3 (Niacin) deficiency, along with a deficiency of tryptophan causes Pellagra. Symptoms include aggression, dermatitis, insomnia, weakness, mental confusion, and diarrhea. In advanced cases, pellagra may lead to dementia and death.

Deficiencies of other B vitamins result in symptoms that are not part of a named deficiency disease.

- *Vitamin B*5 (Pantothenic acid) deficiency can result in acne and Paresthesia, although it is uncommon.
- *Vitamin B*6 (Pyridoxine) deficiency may lead to anemia, depression, dermatitis, high blood pressure (hypertension) and elevated levels of homocysteine.
- *Vitamin B*7 deficiency does not typically cause symptoms in adults but may lead to impaired growth and neurological disorders in infants.
- *Vitamin B*9 (Folic acid) deficiency results in elevated levels of homocysteine. Deficiency in pregnant women can lead to birth defects.
- *Vitamin B*12 (Cyanocobalamin) deficiency causes pernicious anemia, memory loss and other cognitive decline. It is most likely to occur among elderly people as absorption through the gut declines with age. In extreme (fortunately rare) cases paralysis can result.

Related nutrients

Other substances which are very similar in structure and function to the B vitamins have been discovered. Many of them are "essential" vitamins to various plants and animals which cannot synthesize their own. (The adjective "essential" in the context of medicine and nutrition refers to a nutrient being required because it cannot be made by the body. Non-"essential" nutrients are still important.) None of these are "essential" vitamins to humans, because humans can synthesize their own, though some only technically so (choline, for instance, can be metabolized in humans by cannibalizing cells to make use of the choline they contain, killing the cells in the process).

Many of the following substances have been referred to as vitamins because they were believed to be vitamins at one time. Most of them are vitamins with respect to certain plants and animals as well. While they are non-"essential" in that they may be synthesized by the body from other starting materials, they are still important.

- Vitamin B***4*** *(*Adenine*)* –
- *Vitamin B*7 "Vitamin I" of Centanni E. (1935) — more commonly called Vitamin B7 and also called 'Enteral factor' is a water and alcohol (ethanol & methanol) soluble Rice bran factor which prevents digestive disterbance in Pigions. It governes the anatomical and functional integrity of the intestineal tract. Later (1945) found in Yeast; Inositol, Nicotinic acid, & Biotin are possibles. Note: Carnitine has also been claimed but is not possible as it is insoluble in alcohol. Carnitine as Vitamin B7 was wrongly coped from Vitamin BT.
- *Vitamin B*8 (Ergadenylic acid) – also known as adenosine monophosphate
- *Vitamin B*10 (para-aminobenzoic acid, or PABA)–
- *Vitamin B*11 (Pteryl-hepta-glutamic acid) – Chick growth factor, which is a form of Folic acid. Later found to be one of five folates necessary for humans); (L-carnitine) in France.

- *Vitamin B*13 (Pyrimidinecarboxylic acid) – Also known as Orotic acid, often misspelled erotic acid.
- *Vitamin B*14 – cell proliferant, anti-anemia, rat growth, an antitumor pterin phosphate named by Earl R. Norris (biochemist of folic acid fame) isolated from human urine at 0.33ppm (later in blood), but later abandoned by him as further evidence did not comfirm this. He also clamed this was not Xanthopterin as the French do.
- *Vitamin B*15 (Pangamic acid) –
- *Vitamin B*16 (dimethylgycine) – also known as DMG. (However Lipoic acid was discovered and named a B-Vitamin after B15 and before B17)
- *Vitamin B*17 (Amygdalin) –
- Vitamin B***18*** –
- Vitamin B***19*** –
- *Vitamin B*20 (Carnitine) –
- Vitamin B***21*** –
- *Vitamin B*22 – often claimed as an ingredient of Aloe vera extracts but also in many other foods. Claimed by one source to be Vitamin B12b-delta. first mentioned on internet in reference to Naturopath Linda Clark's book "Know your Nutrition"
- *Vitamin B*h – another name for(biotin)
- *Vitamin B**m*** ("mouse factor") – also used to designate Inositol
- *Vitamin B*p (Choline) –
- *Vitamin B*t (L-carnitine) –
- *Vitamin B*v – a type of B6 but not Pyrodoxine
- *Vitamin B*w – a type of Biotin but not d-Biotin
- *Vitamin B*x – another name for PABA (para-Aminobenzoic acid)
- Lipoic acid –

Note: *B*16, *B*17, *B*18, *B*19, *B*20, *B*21 & *B*22 do not appear to be animal factors but are claimed by naturopaths as human therapedic factors.

Health benefits

The B vitamins often work together to deliver a number of health benefits to the body. B vitamins have been shown to:

- Bolster metabolism

Maintain healthy skin and muscle tone
Enhance immune and nervous system function
Promote cell growth and division — including that of the red blood cells that help prevent anemia.

Together, they also help combat the symptoms and causes of stress, depression, and cardiovascular disease.

All B vitamins are water soluble, and are dispersed throughout the body. They must be replenished daily with any excess excreted in the urine.

Vitamin B sources

Vitamin B comes from a number of natural sources, including potatoes, bananas, lentils, chili peppers, tempeh, liver, turkey, and tuna. Nutritional yeast (or brewer's yeast) is an especially good source of Vitamin B. The iconic Australian spread Vegemite bills itself as "One of the worlds richest known sources of vitamin B". As might be expected due to its high content of brewer's yeast, beer is a good source of B vitamins, although this may not be true of filtered beers; in fact, beer is sometimes referred to as "liquid bread".

Another popular means of increasing one's Vitamin B intake is through supplements, purchased at supermarkets, health centers, or natural food stores.

Adenine

Chemical name 9H-Purin-6-amine

Alternate name 6-aminopurine

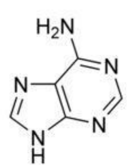
Chemical formula $C_5H_5N_5$

Molecular mass 135.1267 g/mol

Melting point 360 - 365 °C

CAS number 73-24-5

SMILES NC1=NC=NC2=C1N=CN2



Adenine is one of the two purine nucleobases used in forming nucleotides of the nucleic acids DNA and RNA. In DNA, adenine binds to thymine via two hydrogen bonds to assist in stabilizing the nucleic acid structures. In RNA, adenine binds to uracil, which is used in the cytoplasm for protein synthesis.

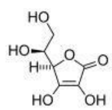
It forms several tautomers, compounds that can be rapidly interconverted and are often considered equivalent. Guanine, a related compounds (also a purine derivative), forms tautomers in the same way, and has more detailed information too.

Adenine forms adenosine, a nucleoside, when attached to ribose, and deoxyadenosine when attached to deoxyribose; it forms adenosine triphosphate (ATP), a nucleotide, when three phosphate groups are added to adenosine. Adenosine triphosphate is used in cellular metabolism as one of the basic methods of transferring chemical energy between chemical reactions.

In older literature, adenine was sometimes called *Vitamin B*4. However it is no longer considered a true vitamin nor part of Vitamin B.

Some think that, at the origin of life on Earth, the first adenine was formed by the polymerizing of five hydrogen cyanide (HCN) molecules. However, this has been criticized by some chemists [1].

Vitamin C



Chemical structure of vitamin C

Vitamin C is a water-soluble nutrient and human vitamin essential for life and for maintaining optimal health, used by the body for many purposes. It is also known by the chemical name of its principal form, L-ascorbic acid. The article on ascorbic acid contains information on its chemical properties. This article describes its biological functions, discovery and the debate on how it is used by society.

General description

Almost all animals and plants synthesize their own vitamin C. There are some exceptions, such as humans and a small number of other animals, including, apes, guinea pigs, the red-vented bulbul, a fruit-eating bat and a species of trout. This has led some scientists, including chemist Linus Pauling to hypothesize that these species either lost (or never had) the ability to produce their own Vitamin C, and that if their diets were supplemented with an amount of the nutrient proportional to the amount produced in animal species that do synthesize their own Vitamin C, better health would result. The species-specific loss of the ability to synthesize ascorbate strikingly parallels the evolutionary loss of the ability to break down uric acid. Uric acid and ascorbate are both strong reducing agents (electron-donors). This has led to the suggestion that in higher primates, uric acid has taken over some of the functions of ascorbate. Acorbic acid can be broken down by *ascorbic acid oxdase* an enzyme which catalyes the oxidation of ascorbic acid.

Some microorganisms such as the yeast Saccharomyces cerevisiae have been shown to be able to synthesize ascorbic acid.

Vitamin C was first isolated in 1928, and in 1932 it was proved to be the agent which prevents scurvy. Both Charles Glen King at the University of Pittsburgh and Albert Szent-Györgyi (working with ex-Pittsburgh researcher Joseph Svirbely) came to discover what is now known as Vitamin C around April of 1932. Although Szent-Györgyi was awarded the

1937 Nobel Prize in Medicine, many feel King is as responsible for its development if not more so.

Vitamin C is a weak acid, called ascorbic acid or a salt ascorbate. It is the L-enantiomer of ascorbic acid. The D-enantiomer shows no biological activity. Both are mirror image forms of the same chemical molecular structure.

The active part of the substance is the ascorbate ion, which can express itself as either an acid or a salt of ascorbate that is neutral or slightly basic. Commercial vitamin C is often a mix of ascorbic acid, sodium ascorbate and/or other ascorbates. Some supplements contain in part the D-enantiomer, which is useless and harmless.

Vitamin C deficiency

No bodily organ stores ascorbate as a primary function, and so the body soon depletes itself of ascorbate if fresh supplies are not consumed through the digestive system, eventually leading to the deficiency disease known as scurvy (a form of avitaminosis), which results in illness and death if consumption of vitamin C is not resumed in time.

Daily requirements and dose dependent effects

There is continuing debate within the scientific community over the best dose schedule (the amount and frequency of intake) of Vitamin C for maintaining optimal health in humans.[1]

Government agency recommended intake levels

A balanced diet without supplementation contains enough Vitamin C to prevent acute scurvy in an average healthy adult. For people who smoke, those under stress, and pregnant women it takes slightly more.

Recommendations for vitamin C intake have been set by various national agencies as follows:

40 mg per day: Food Standards Agency (UK)[2]

60–95 mg per day, Dietary Reference Intake (DRI), Recommended Daily Allowance (RDA), U.S. Food and Nutrition Board 2004.[3]

The U.S. Dietary Reference Intake Tolerable Upper Intake Level (UL) for a 25-year old male is 2,000 mg/day. Vitamin C is recognized to be one of the least toxic substances known to medicine. Its LD50 for rats is 11,900 mg kg^{-1}

Independent dose recommendations

Some researchers have calculated the amount needed for an adult human to achieve similar blood serum levels as Vitamin C synthesising mammals as follows:

400 mg per day – Linus Pauling Institute & US National Institutes of Health (NIH) Recommendation. 500 mg twice per day – Professor Roc Ordman's recommendation in free

radical research. [4] 3000 mg per day or more during illness or pregnancy (up to 300g for some illnesses) – Vitamin C Foundation's recommendation. [5] 6000-12000 mg per day – Thomas Levy, Colorado Integrative Medical Centre recommendation. 6000-18000 mg per day – Linus Pauling's own daily recommendation from 3000 mg to 200,000 mg per day based on a protocol described by Robert Cathcart[6] known as a vitamin C flush wherin escalating doses of Vitamin C are given until diarrhea develops, then choosing the highest dose that does not cause diarrhea (bowel tolerance threshold). High doses (thousands of mg) may result in diarrhea, which is harmless if the dose is reduced immediately. Some researchers[6] claim the onset of diarrhea to be an indication of where the body's true vitamin C requirement lies. Both Cathcart[6] and Cameron have demonstrated that very sick patients with cancer or influenza do not display any evidence of diarrhea at all until ascorbate intake reaches levels as high as 200 grams (½ pound).

There is a strong advocacy movement for large doses of Vitamin C (see Advocacy arguments below), although not all purported benefits are supported by the medical establishment. Many pro-Vitamin C organizations promote usage levels well beyond the current Dietary Reference Intake (DRI).

There exist an extensive and growing literature critical of governmental agency dose recommendations. Key arguments include: [1] [7][8] [9][10] [11][12] [13]

- The biological halflife for vitamin C is quite short, about 30 minutes in blood plasma, a fact which NIH and IM researchers have failed to recognize. NIH researchers established the current RDA based upon tests conducted 12 hours (24 half lives) after consumption. "To be blunt," says Hickey, "the NIH gave a dose of vitamin C, waited until it had been excreted, and then measured blood levels." [14]
- NIH don't take into account individual differences such as age, weight, etc. For example, heavier individuals generally need more vitamin C.
- The figures represent the amount needed to prevent the acute form of deficiency disease, while subclinical levels of the disease are not even acknowledged.
- The amount needed to prevent other diseases is not considered.
- Optimal health is not a consideration, as the level of health targeted is that which is marginally better than that which is considered malnourished.

Therapeutic applications and doses

Vitamin C is needed in the diet to prevent scurvy, however, from the time it became available in pure form in the 1930s, some practitioners experimented with vitamin C as a treatment for diseases other than scurvy.

Colds

At least 29 controlled clinical trials (many double-blind and placebo-controlled) involving a total of over 11,000 participants have been conducted into vitamin C and the

Common cold. These trials were reviewed in the 1990s[15][16] and again recently.[8] The trials show that vitamin C reduces the duration and severity of colds but not the frequency. The data indicate that there is a normal dose-response relationship. Vitamin C is more effective the higher the dose. The vast majority of the trials were limited to doses below 1 g/day. As doses rise, it becomes increasingly difficult to keep the trials double blind because of the obvious gastro-intestinal side effects. So, the most effective trials at doses between 2 and 10 g/day are met with skepticism. Reports from physicians have provided ample clinical confirmation.

The controlled trials and clinical experience prove that vitamin C in doses ranging from 0.1 to 2.0 g/day have a relatively small effect. The duration of colds was reduced by 7% for adults and 15% for children. The studies provide ample justification for businesses to encourage their employees to take 1 to 2 g/day during the cold season to improve workplace productivity and reduce sick days. The clinical reports provide the strongest possible evidence that vitamin C at higher doses is significantly more effective. However, the effectiveness typically comes at the price of gastro-intestinal side effects. It is easy for physicians to minimize these side effects since they cause no lasting harm. Adult patients, however, have proven reluctant to subject themselves to gas and cramping to deliver an unknown benefit (the duration and severity of colds is highly variable so the patient never knows what he/she is warding off). It is well worth the effort of identifying the small subset of individuals who can benefit from high daily doses (>10 g/day) of vitamin C without side effects and training them to regularly take 5 g/day during cold season and to increase the dose at the onset of a cold.

The trials proved that vitamin C is more effective for children. Reports from the field confirm the observations in the trials and suggest that children are less prone to vitamin C side effects Colds and flu are a serious problem for children. Every time a cold infects a child, its growing mind and body must divert energy from its usual business of growth and development. If the cold is followed by an opportunistic infection, such as bronchitis or ear infection, more energy must be diverted. Colds are the number one trigger for asthma. Pre-school children in daycare are nearly constantly fighting infections (5-10 per year). Chronic disease in childhood is believed to sometimes have permanent developmental consequences which can contribute to decreased life expectancy

Polio

Most notable was Fred R. Klenner, a doctor in general practice in Reidsville, North Carolina. He utilized both oral and intravenous vitamin C to treat a wide range of infections and poisons. He published a paper in 1949 that described how he had seen poliomyelitis yield to vitamin C in sufficiently large doses.No controlled clinical trials have been conducted to confirm effectiveness.

Vitamin C is the main of the three ingredients in Linus Pauling's patented preventive cure for heart disease, the other two being the amino acid lysine and nicotinic acid (a form of Vitamin B3). This treatment is not supported by mainstream medical science.

Viral diseases, and poisons

Orthomolecular medicine and a minority of scientific opinion sees vitamin C as being a low cost and safe way to treat viral disease and to deal with a wide range of poisons.

Vitamin C has a growing reputation for being useful in the treatment of colds and flu, owing to its recommendation by prominent biochemist Linus Pauling. In the years since Pauling's popular books about vitamin C, general agreement by medical authorities about larger than RDA amounts of vitamin C in health and medicine has remained elusive. Ascorbate usage in studies of up to several grams per day, however, have been associated with decreased cold duration and severity of symptoms, possibly as a result of an antihistamine effect. The highest dose treatments, published clinical results of specific orthomolecular therapy regimes pioneered by Drs. Klenner (repeated IV treatments, 400-700+ mg/kg/day) and Cathcart (oral use to bowel tolerance,[6] up to ~150 grams ascorbate per day for flu), have remained experimentally unaddressed by conventional medical authorities for decades.

The Vitamin C Foundation recommends an initial usage of up to 8 grams of vitamin C every 20-30 minutes in order to show an effect on the symptoms of a cold infection that is in progress. Most of the studies showing little or no effect employ doses of ascorbate such as 100 mg to 500 mg per day, considered "small" by vitamin C advocates. Equally importantly, the plasma half life of high dose ascorbate is approximately 30 minutes, which implies that most high dose studies have been methodologically defective and would be expected to show a minimum benefit. Clinical studies of divided dose supplementation, predicted on pharmacological grounds to be effective, have only rarely been reported in the literature. Essentially all the claims for high dose vitamin C remain to be scientifically refuted. The clinical effectiveness of large and frequent doses of vitamin C is an open scientific question.

In 2002 a meta-study into all the published research on effectiveness of ascorbic acid in the treatment of infectious disease and toxins was conducted, by Thomas Levy, Medical Director of the Colorado Integrative Medical Centre in Denver. He claimed that evidence exists for its therapeutic role in a wide range of viral infections and for the treatment of snake bites.

Lead poisoning

There is also evidence that Vitamin C is useful in preventing lead poisoning, possibly helping to chelate the toxic heavy metal from the body.

Cancer

In 2005 in vitro research by the National Institutes of Health indicated that Vitamin C administered in pharmacological concentrations (i.e. intravenous) was preferentially toxic to several strains of cancer cells. The authors noted: "These findings give plausibility to intravenous ascorbic acid in cancer treatment, and have unexpected implications for

treatment of infections where H_2O_2 may be beneficial." This research appeared to support Linus Pauling's claims that Vitamin C can be used to fight cancer.[17]

In 2006 the Canadian Medical Association Journal published in vivo research that demonstrated that intravenous vitamin C can subdue advanced-stage cancer. [18]

Cataracts

It has been also suggested that Vitamin C might prevent the formation of cataracts.[19]

Other effects

Contraindications

A Contraindication is a condition which makes an individual more likely to be harmed by a dose of Vitamin C than an average person.

- A primary concern is people with unusual or unaddressed iron overload conditions, including hemochromatosis. Vitamin C enhances iron absorption. If sufferers of iron overload conditions take gram sized doses of Vitamin C, they may worsen the iron overload due to enhanced iron absorption.
- Inadequate Glucose-6-phosphate dehydrogenase enzyme (G6PD) levels, a genetic condition, may predispose some individuals to hemolytic anemia after intake of specific oxidizing substances present in some food and drugs. This includes repeated, very large intravenous or oral dosages of vitamin C. There is a test available for G6PD deficiency. High dose Vitamin E has been proposed as a potential protective factor.

Side-effects

- Vitamin C causes diarrhea in everyone if taken in quantities beyond a certain limit, which is variable to the individual. Cathcart[6] has called this limit the Bowel Tolerance Limit and observed that it is higher in people with serious illness than those in good health. It ranges from 5 to 25 grams per day in healthy individuals to 300 grams per day in the seriously ill persons, such as those with AIDS and cancer. The diarrhea side-effect is harmless, though it can be inconvenient. The diarrhea will cease as soon as the dose is reduced.
- Large doses of vitamin C may cause acid indigestion (stomach upset), particularly when taken on an empty stomach. This unpleasant but harmless side-effect can be avoided by taking the vitamin along with meals, or by offsetting its acidity by taking an antacid such as baking soda or calcium carbonate (Tums)

Effects of Overdose

Vitamin C exhibits remarkably low toxicity. For example, in the rat, the LD50 has been reported as 11900 mg kg-1.[20] For a 70 kg human, this means that 833,000 mg of vitamin C would need to be ingested to stand a 50% chance of killing the person. However, vitamin C could not result in death when administered orally as large amounts of the vitamin cause diarrhea and are not absorbed.[21] An extremely large amount of vitamin C would need to be rapidly injected by IV to stand any chance of killing a person. Robert Cathcart, MD, has used intravenous doses of vitamin C of 250 grams and reports that he has had no problems.[22] The Council for Responsible Nutrition has set an Upper Level (UL) of 2 grams, based on transient diarrhea. Their publication on vitamin C safety notes that "very large doses of vitamin C have been taken daily over the course of many years, and only minor undesirable effects have been attributed with any certainty to the vitamin’s use[...] Clearly, vitamin C has a low order of toxicity".[23]

Alleged harmful effects

Reports of harmful effects of vitamin C tend to receive great prominence in the world's media. As such, these reports tend to generate much debate and more research into Vitamin C. Some of the harmful effects described below have been proven to be unfounded in later studies, while other effects are still undergoing further analysis.

- In April 1998 the journal Nature reported alleged carcinogenic and teratogenic effects of excessive doses of Vitamin C / ascorbic-acid. The effects were noted in test tube experiments and on only two of the 20 markers of free radical damage to DNA. They have not been supported by further evidence from living organisms.[24]
- The authors of the study featured in Nature later clarified their position in correspondence to the journal, stating that their results "show a definite increase in 8-oxoadenine after supplementation with Vitamin C. This lesion is at

least ten times less mutagenic than 8-oxoguanine, and hence our study shows an overall profound protective effect of this vitamin".[25]

- In April 2000, University of Southern California researchers reported a thickening of the arteries of the neck in persons taking high vitamin C doses. It was later pointed out by vitamin C advocates that this can be explained by vitamin C's collagen synthesising role leading to thicker and stronger artery walls. (ref.[26] para 10)
- In June 2004, Duke University researchers reported an increased susceptibility to osteo-arthritis in guinea pigs fed a diet high in vitamin C. However, a 2003 study at Umeå University in Sweden, found that "the plasma levels of vitamin C, retinol and uric acid were inversely correlated to variables related to rheumatoid arthritis disease activity."
- A speculated increased risk of kidney stones may be a side effect of taking Vitamin C in larger than normal amounts (>1g). The potential mechanism of action is through the metabolism of Vitamin C (ascorbic acid) to dehydroascorbic acid, which is then metabolized to oxalic acid,[27] a known constituent of kidney stones. However, this oxalate issue is still controversial, with evidence being presented for[28] and against[29] the possibility of this side effect. Vitamin C has long been advocated,[30] and used,[31] by some less conventional physicians to prevent or alleviate some kinds of non-oxalate kidney stone formation.[32][33] after addressing the oxalate issue.[34][35] Vitamin B6 may mitigate the general risk of oxalate stones by decreasing oxalate production.[36] Additionally, thiamine may inhibit oxalate formation. Furthermore, correcting any magnesium deficiency[37] may decrease the risk of kidney stones by decreasing oxalate crystallization. Increasing one's fluid intake also helps to prevent oxalate crystallization in the kidney. There is evidence that certain intestinal flora influence how much oxalate is destroyed and that their absence is a significant causal risk factor in oxalate stone formers.[38] Patients with a predispostion to form oxalate stones or those on hemodialysis [39][40] should avoid excess use of vitamin C.
- "Rebound scurvy" is a theoretical, never observed, condition that could occur when daily intake of Vitamin C is rapidly reduced from a very large amount to a relatively low amount. Advocates suggest this is an exaggeration of the rebound effect which occurs because ascorbate-dependent enzyme reactions continue for 24-48 hours after intake is lowered, and use up vitamin C which is not being replenished. The effect is to lower one's serum vitamin C blood concentration to less than normal for a short amount of time. During this period of time there is a slight risk of cold or flu infection through reduced resistance. Within a couple of days the enzyme reactions shut down and blood serum returns to the normal level of someone not taking large supplements. This is not scurvy, which takes weeks of zero vitamin C consumption to produce symptoms. It is something people who take large vitamin C supplements need to be aware of in order to gradually reduce dosage rather than quit taking Vitamin C suddenly. (ref.[26] para 4) This is a theoretical risk for those taking supplements - e.g. if

they find themselves severely ill, and in a hospital without the supplements, at a time when they need normal or better levels of vitamin C to fight the disease (ref. [6] and search for "The major problem"). At this time, many doctors and hospital staff do not know much about nor administer megadosing of supplements, so that patients may have to rely on friends or relatives to bring them their supplements.

- Some writers[41] have identified a theoretical risk of poor Copper absorption from high doses of Vitamin C, although little experimental evidence supports this. However, ceruloplasmin levels seem specifically lowered by high vitamin C intake. In one study, 600 milligrams of Vitamin C daily did not decrease copper absorption or overall body copper status in young men, but led to lower ceruloplasmin levels similar to those caused by copper deficiency.[42] In another, ceruloplasmin levels were significantly reduced.[43]
- There are stories circulating among some folk remedy proponents that doses of around 12 grams per day of Vitamin C can induce an abortion in women under 4 weeks of pregnancy.[44] This is not supported by scientific research however.[45]
- Recent studies into the use of a combination of Vitamin E ("natural" source isomer moeity, d-alpha tocopheryl ester) and vitamin C (unspecified ascorbate) in preventing oxidative stress leading to pre-eclampsia have failed to show significant ($p=0.05$) positive benefit at the dosage tested,[46] Drs. Padayatty and Levine with NIH in a "Letter to the Editor" stated that the studies and another "Letter to the Editor" overlooked a key reason for the lack of vitamin C on the prevention of preeclampsia. Because plasma ascorbate concentrations were not reported, we estimated them from known data, the placebo and treatment groups in the study probably had similar plasma and tissue ascorbate concentrations. Doses of 1 g per day have little effect on plasma or intracellular ascorbate concentrations.[47] In another study the same dosage did decrease average gestational time resulting in a higher incidence of low birthweight babies in one study.[48] Several other studies have been more favorable but large studies into antioxidants for pre-eclampsia are continuing.[49]

Conflicts with prescription drugs

Pharmaceuticals designed to reduce stomach acid such as the proton pump inhibitors , e.g. Omeprazole, among the most widely-selling drugs in the world, have been found to lower the bio availability of vitamin C by two thirds. [50]

Sources of vitamin C

Vitamin C is obtained through the diet by the vast majority of the world's population. The richest natural sources are fruits and vegetables, and of those, the camu camu fruit and the billygoat plum contain the highest concentration of the vitamin. It is also present in some cuts of meat, especially liver. Vitamin C is the most widely taken nutritional supplement and

is available in a variety of forms from tablets and drink mixes to pure ascorbic acid crystals in capsules or as plain powder.

Plant sources

Citrus fruits (orange, lemon, grapefruit, lime), tomatoes, and potatoes are good common sources of vitamin C. Other foods that are good sources of vitamin C include papaya, broccoli, brussels sprouts, black currants, strawberries, cauliflower, spinach, cantaloupe, kiwifruit, cranberries and red peppers.

Emblica officinalis often referred to as Indian gooseberry or amla, is one of the richest known sources of vitamin C (720 mg/100g of fresh pulp or up to 900 mg/100g of pressed juice.)– it contains 30 times the amount found in oranges.

The amount of vitamin C in foods of plant origin depends on:

- the precise variety of the plant,
- the soil condition
- the climate in which it grew,
- the length of time since it was picked,
- the storage conditions,
- the method of preparation. Cooking in particular is often said to destroy vitamin C - but see the section on Food preparation.

Animal sources

The overwhelming majority of species of animals and plants synthesise their own vitamin C. It is therefore not a vitamin for them. Synthesis is achieved through a sequence of 4 enzyme driven steps, which convert glucose to ascorbic acid. It is carried out either in the kidneys, in reptiles and birds, or the liver, in mammals and perching birds. The last enzyme in the process, l-gulonolactone oxidase, cannot be made by humans because the gene for this enzyme is defective (Pseudogene ¨GULO). The loss of an enzyme concerned with ascorbic acid synthesis has occurred quite frequently in evolution and has affected most fish; many birds; some bats; guinea pigs; and most primates, including humans. The mutations have not been lethal because ascorbic acid is so prevalent in the surrounding food sources (it may be noted that many of these species' diet consists largely of fruit).

For example an adult goat will manufacture more than 13,000 mg of vitamin C per day in normal health and as much as 100,000 mg daily when faced with life-threatening disease, trauma or stress.

Trauma or injury has been demonstrated to use up large quantities of vitamin C in animals, including humans.

It was only realised in the 1920s that some cuts of meat and fish are also a source of vitamin C for humans. The muscle and fat which make up the modern western diet are however poor sources. As with fruit and vegetables cooking degrades the vitamin C content.

Vitamin C is present in mother's milk and in less amounts in raw cow's milk (but pasteurized milk contains only trace amounts of the vitamin)

The following table shows the relative abundance of vitamin C in various foods of animal origin, given in mg of vitamin C per 100 grams of food:

Food	Amount
Calf liver (raw)	36
Beef liver (raw)	31
Oysters (raw)	30
Cod roe (fried)	26
Pork liver (raw)	23
Lamb brain (boiled)	17
Chicken liver (fried)	13
Lamb liver (fried)	12
Lamb heart (roast)	11

Food	Amount
Lamb tongue (stewed)	6
Human milk (fresh)	4
Goat milk (fresh)	2
Cow milk (fresh)	2
Beef steak (fried)	0
Hen's egg (raw)	0
Pork bacon (fried)	0
Calf veal cutlet (fried)	0
Chicken leg (roast)	0

Food preparation

It is important to choose a suitable method of food preparation that conserves vitamin C content. When cooking vegetables, one should seek to minimize temperature and duration of cooking and not discard water used in preparation (e.g., by steam cooking or by making soup). Food source vitamin C is identical to that in supplements. The structure of vitamin C is well understood, see ascorbic acid, and there is no difference in benefit between natural and synthetic forms (although fruits and vegetables contain various other nutrients, and vitamin C is not their only health benefit).

Recent observations suggest that the impact of temperature and cooking on vitamin C may have been overestimated:

1. Since it is water soluble, vitamin C will strongly leach into the cooking water while cooking most vegetables — but this doesn't necessarily mean the vitamin is destroyed — it's still there, but it's in the cooking water. (This may also suggest how the apparent misconception about the extent to which boiling temperatures destroy vitamin C might have been the result of flawed research: If the vitamin C content of vegetables (and not of the water) was measured subsequent to cooking them, then that content would have been much lower, though the vitamin has not actually been destroyed .)
2. Not only the temperature, but also the exposure time is significant. Contrary to what was previously and is still commonly assumed, it can take much longer than two or three minutes to destroy vitamin C at boiling point

It also appears that cooking doesn't necessarily leach vitamin C in all vegetables at the same rate; it has been suggested that the vitamin is not destroyed when boiling broccoli.[51] This may be a result of vitamin C leaching into the cooking water at a slower rate from this vegetable.

Copper pots will destroy the vitamin.[52]

Some research shows that fresh-cut fruit may not lose much of its nutrients when stored in the refrigerator for a few days.[53]

Vitamin C enriched teas and infusions have increasingly appeared on supermarket shelves. Such products would be nonsense if boiling temperatures did indeed destroy vitamin C at the rate it had previously been suggested. It should be noted however that as of 2004 most academics not directly involved in vitamin C research still teach that boiling temperatures will destroy vitamin C very rapidly.

Vitamin C supplements

Vitamin C is the most widely taken dietary supplement.[54] It is available in many forms including caplets,tablets, capsules, drink mix packets, in multi-vitamin formulations and as chemically pure crystaline powder. Tablet and capsule sizes range from 25mg to 1500mg. Vitamin C (ascorbic acid) crystals are typically available in bottles containing 300g to 1 kg of powder (a teaspoon of vitamin C crystals equals 4,500mg).

Methods of manufacture (chemical synthesis)

Vitamin C is produced from glucose by two main routes. The Reichstein process developed in the 1930s uses a single pre-fermentation followed by a purely chemical route. The more modern Two-Step fermentation process was originally developed in China in the 1960s, uses additional fermentation to replace part of the later chemical stages. Both processes yield approximately 60% vitamin C from the glucose feed.[55]

Research is underway at the Scottish Crop Research Institute to create yeast micro organisms to synthesise ascorbic acid in a single fermentation step, a technology which is expected to reduce manufacturing costs considerably.[56]

World production of synthesised vitamin C is currently estimated at approximately 110,000 tonnes annually. Main producers today are BASF/Takeda, DSM, Merck and the China Pharmaceutical Group Ltd. of the People's Republic of China. China is slowly becoming the major world supplier as its prices undercut those of the US and European manufacturers.[57]

Discovery and history

The need to include fresh plant food or raw animal flesh in the diet to prevent disease was known from ancient times. Native peoples living in marginal areas incorporated this into their medicinal lore. For example, infusions of spruce needles were used in the temperate zones, or the leaves from species of drought-resistant trees in desert areas. In 1536, the French explorer Jacques Cartier, exploring the St. Lawrence River, used the local natives' knowledge to save his men who were dying of scurvy. He boiled the needles of the arbor vitae tree to make a tea that was later shown to contain 50 mg of vitamin C per 100 grams.[58][59]

Through history the benefit of plant food for the survival of sieges and long sea voyages was recommended by enlightened authorities. John Woodall, the first appointed surgeon to the British East India Company, recommended the use of lemon juice as a preventive and cure in his book "The Surgeon's Mate" of 1617. The Dutch writer, Johann Bachstrom of Leyden, in 1734, gave the firm opinion that "scurvy is solely owing to a total abstinence from fresh vegetable food, and greens; which is alone the primary cause of the disease."

The first attempt to give scientific basis for the cause of scurvy was by a ship's surgeon in the British Royal Navy, James Lind. While at sea in May 1747, Lind provided some crew members with two oranges and one lemon per day, in addition to normal rations, while others continued on cider, vinegar or sea water, along with their normal rations. In the history of science this is considered to be the first example of a controlled experiment comparing results on two populations of a factor applied to one group only with all other factors the same. The results conclusively showed that citrus fruits prevented the disease. Lind wrote up his work and published it in 1753, in Treatise on the Scurvy.

Lind's work was slow to be noticed, partly because he gave conflicting evidence within the book and partly because of social inertia in some elements at the British admiralty who saw care for the well-being of ships' crew as a sign of weakness. There was also the fact that fresh fruit was very expensive to keep on board, whereas boiling it down to juice allowed easy storage but destroyed the vitamin. Ships' captains assumed wrongly that it didn't work, because the juice failed to cure scurvy.

It was 1795 before the British navy adopted lemons or lime as standard issue at sea. Limes were more popular as they could be found in British West Indian Colonies, unlike lemons which weren't found in British Dominions, and were therefore more expensive. (This practice led to the nickname limey for British people, especially British sailors.) Captain James Cook had previously demonstrated and proven the principle of the advantages of fresh and preserved foods, such as sauerkraut, by taking his crews to the Hawaiian islands and beyond without losing any of his men to scurvy. For this otherwise unheard of feat, he was awarded a medal by the British Admiralty. So the Navy was certainly well aware of the principle. The cost of providing fresh fruit on board was probably a factor in this long delay. Luxuries or non-standard supplies not provided by the Admiralty were usually provided by the Captains.

The name "antiscorbutic" was used in the eighteenth and nineteenth centuries as general term for those foods known to prevent scurvy, even though there was no understanding of the reason for this. These foods include lemons, limes, and oranges; sauerkraut, salted cabbage, malt, and portable soup were employed with variable effect.

In 1907, Axel Holst and Theodor Frølich, two Norwegian biochemists studying beriberi contracted aboard ship's crews in the Norwegian Fishing Fleet, wanted a small test mammal to substitute for the pigeons they used. They fed guinea pigs the test diet, which had earlier produced beriberi in their pigeons, and were surprised when scurvy resulted instead. Until that time scurvy had not been observed in any organism apart from humans, and it was considered an exclusively human disease.

In the early twentieth century, the Polish-American scientist Casimir Funk conducted research into deficiency diseases, and in 1912 Funk developed the concept of vitamins, for the elements in food which are essential to health. Then, from 1928 to 1933, the Hungarian

research team of Joseph L Svirbely and Albert Szent-Györgyi and, independently, the American Charles Glen King, first isolated vitamin C and showed it to be ascorbic acid.

In 1928 the arctic anthropologist and adventurer Vilhjalmur Stefansson attempted to prove his theory of how Eskimo (Inuit) people are able to avoid scurvy with almost no plant food in their diet. This had long been a puzzle because the disease had struck European Arctic explorers living on similar high-meat diets. Stefansson theorised that the native peoples of the Arctic got their vitamin C from fresh meat that was raw or minimally cooked. Starting in February 1928, for one year he and a colleague lived on an animal-flesh-only diet under medical supervision at New York's Bellevue Hospital; they remained healthy.

In 1933-1934, the British chemists Sir Walter Norman Haworth and Sir Edmund Hirst and, independently, the Polish Tadeus Reichstein, succeeded in synthesizing the vitamin, the first to be artificially produced. This made possible the cheap mass production of vitamin C. Haworth was awarded the 1937 Nobel Prize in Chemistry largely for this work. The synthetic form of the vitamin is identical to the natural form.

The Swiss pharmaceutical company Hoffmann-La Roche was the first to mass produce synthetic vitamin C, under the brand name of Redoxon, in 1934.

In 1959 the American J.J. Burns showed that the reason some mammals were susceptible to scurvy was the inability of their liver to produce the active enzyme L-gulonolactone oxidase, which is the last of the chain of four enzymes which synthesize ascorbic acid.

American biochemist Irwin Stone was the first to exploit Vitamin C for its food preservative properties and held patents on this. He developed the theory that vitamin C was an essential nutrient deficient in humans as a result of a genetic defect that afflicted the whole human race.

Vitamin C hypothesis

Since its discovery Vitamin C has been considered a universal panacea by some, although this led to suspicions of it being overhyped by others.[60]

The fact that man possesses three of the four enzymes that animals employ to manufacture ascorbates in relatively large amounts, has led researchers such as Irwin Stone and Linus Pauling to hypothesize that man's ancestors once manufactured this substance in the body millions of years ago in quantities roughly estimated at 3,000-4,000 mg daily, but later lost the ability to do this through a chance of evolution. If true, this would mean that vitamin C was misnamed as a vitamin and is in fact a vital macronutrient like fat or carbohydrate.{Irwin Stone: "The Healing Factor"}

Dr. Hickey, of Manchester Metropolitan University, believes that man carries a mutated and ineffective form of the genetic machinery for manufacturing the fourth of the four enzymes used by all mammals to make ascorbic acid. Cosmic rays or a retro virus could have caused this mutation, millions of years ago.{Hickey: "Ascorbate"} In humans the three surviving enzymes continue to produce the precursors to ascorbic acid but the process is incomplete and the body then disassembles them.

In the 1960s Nobel-Prize winning chemist Linus Pauling, after contact with Irwin Stone, began actively promoting vitamin C as a means to greatly improve human health and resistance to disease. His book How to Live Longer and Feel Better was a bestseller and advocated taking more than 10,000 milligrams per day. It sold widely and many advocates

today see its influence as the reason there was a marked downward trend in US heart disease from the early 1980s onwards.

Stone's work also informed the practise of Dr. Robert F. Cathcart III, in the 1970s and 1980s. He applied extremely large doses of ascorbate (300 grams = 0.66 pounds per day) to a wide range of viral diseases with successful results. Cathcart developed the concept of Bowel tolerance, the use of the onset of diarrhea as an indication of when the body's true requirement of ascorbic acid had been reached. He found that seriously ill people could often tolerate levels of tens of grams per day before their tolerance limit is reached.

Matthias Rath is a controversial German physician who once worked with Pauling. He is an active proponent and publicist for high dose vitamin C. He has published a theory that deaths from scurvy in humans during the ice age, when vitamin C was scarce, selected for individuals who could repair arteries with a layer of cholesterol. He theorises that, although eventually harmful, cholesterol lining of artery walls would be beneficial in that it would keep the individual alive until access to Vitamin C allowed arterial damage to be repaired. Atherosclerosis is thus a vitamin C deficiency disease. Rath has also argued publicly that high doses of vitamin C can be effectively used against viral epidemics such as HIV,[61] SARS and bird flu.[62][63]

It has been suggested by some advocates that ascorbic acid is really a food group in its own right like carbohydrates or protein and should not be seen as a pharmaceutical or vitamin at all.{Irwin Stone: "The Healing Factor"}

Chronic scurvy

Identified and named by Linus Pauling, "chronic scurvy" or "subclinical scurvy" is a condition of Vitamin C deficiency which is not as easily noticeable as acute scurvy (because chronic scurvy is mostly internal), characterized by micro lesions of tissues (such as that caused by blood pulsing through arteries, which stretches the arterial walls causing them to tear slightly). It is a major contributing factor to cardio vascular disease. The condition is almost entirely preventable with supplementation of larger doses of Vitamin C (8 grams or more per day). Chronic scurvy is commonplace, even in industrialized countries.

Politics of Vitamin C

Regulation

There are regulations in most countries which limit the claims on the treatment of disease that can be placed on food, drug, and nutrient product labels. Regulations include:

- Claims of therapeutic effect with respect to the treatment of any medical condition or disease are prohibited by the Food and Drug Administration (in the USA, and by the corresponding regulatory agencies in other countries) unless the substance has gone through a lengthy (10+ years) and expensive (200 million US dollars+) approval process, for which the applicant seeking approval must pay.

- In the United States, the following notice is mandatory on food, drug, and nutrient product labels which make health claims: These statements have not been evaluated by the Food and Drug Administration. This product is not intended to diagnose, treat, cure or prevent any disease. This statement must be included even if substantial scientific evidence exists showing that the message isn't true. This may lead consumers to the false belief that Vitamin C has no value in preventing or treating diseases other than scurvy (for which treatment claims are allowed).

Advocacy arguments

Vitamin C advocates argue that there is a large body of scientific evidence that the vitamin has a wide range of health and therapeutic benefits but which they claim have been ignored. They claim the following factors affect the marketing and distribution of Vitamin C, and the dissemination of information concerning the nutrient:

- There is increasing evidence of the applications and efficacy of Vitamin C, but governmental agency dose and frequency of intake recommendations have remained relatively fixed. This has lead some researchers to challenge the recommendations. In 2003 Steve Hickey and Hilary Roberts of the Manchester Metropolitan University published a fundamental criticism of the approach taken to fix the nutritional requirement of vitamin C. They again argued in 2004 that the RDA which is based on blood plasma and white blood cell saturation data from the National Institutes of Health (NIH) was based on flawed data.[64] According to these authors, the doses required to achieve blood, tissue and body "saturation" are much larger than previously believed. They allege that the Institute of Medicine (IoM) and the NIH have failed to respond to an open letter from a number of scientists and medical researchers, notably Doctors Steve Hickey, Hilary Roberts, Ian Brighthope, Robert Cathcart, Abram Hoffer, Archie Kalokerinos, Tom Levy, Richard Passwater, Hugh Riordan, Andrew Saul and Patrick Holford, which called for revision of the RDI (Reference Daily Intake).
- Research and the treatment approval process are so expensive, pharmaceutical companies rarely apply for approval of an unpatentable product. To do so without the protection of a patent would allow competitors to manufacture the product too, which would drive the price (and profit margin) down to a point much less desirable than the price point (and profit margin) of patentable products. The lower price would also reduce the likelihood of recuperating the company's exorbitant research funding and treatment approval costs. Vitamin C is not eligible for patenting because it is a natural substance, and because it has already been marketed to the public for some time. As of yet, no company has applied to the FDA (nor paid) for approval of Vitamin C as a treatment for any disease.
- Companies selling a treatment product are not required to inform consumers or patients of other treatments, even if those treatments are more effective, less expensive, and have fewer side-effects. Medical practitioners are

not required to inform their patients of treatments for which treatment approval has not been granted. This situation, coupled with the label censorship explained above makes it more difficult to keep the public informed about the benefits of and new discoveries concerning the applications and effective dosage levels of Vitamin C.

- Matthias Rath and others point to low doses of Vitamin C as the cause of the current epidemics of heart disease and cancer, and have termed the situation "a genocide", implying that health care providers (and particularly cardiologists and pharmaceutical companies) are aware of Vitamin C's benefits and are deliberately seeking to block its acceptance as a therapeutic agent.[65] Meanwhile, governments, with their bureaucratic systems of treatment approval filtering out natural and inexpensive treatments such as those applying vitamin C, have also contributed to this technology blockade.

Disclaimers

This e-book contains articles on many medical topics; however *no warranty whatsoever* is made that any of the articles are accurate. There is absolutely no assurance that any statement contained or cited in an article touching on medical matters is true, correct, precise, or up-to-date. The overwhelming majority of such articles are written, in part or in whole, by nonprofessionals. Even if a statement made about medicine is accurate, it may not apply to you or your symptoms.

The medical information provided on this book is, at best, of a general nature and cannot substitute for the advice of a *medical professional* (for instance, a qualified doctor/physician, nurse, pharmacist/chemist, and so on). *This e-book is not a doctor.*

None of the individual contributors, system operators, developers, sponsors of this e-book nor anyone else connected to it can take any responsibility for the results or consequences of any attempt to use or adopt any of the information presented on this web site.

Nothing on this e-book should be construed as an attempt to offer or render a medical opinion or otherwise engage in the practice of medicine.

License

GNU Free Documentation License

This License is a kind of "copyleft", which means that derivative works of the document must themselves be free in the same sense. It complements the GNU General Public License, which is a copyleft license designed for free software.

We have designed this License in order to use it for manuals for free software, because free software needs free documentation: a free program should come with manuals providing the same freedoms that the software does. But this License is not limited to software manuals; it can be used for any textual work, regardless of subject matter or whether it is published as a printed book. We recommend this License principally for works whose purpose is instruction or reference.

1. APPLICABILITY AND DEFINITIONS

This License applies to any manual or other work, in any medium, that contains a notice placed by the copyright holder saying it can be distributed under the terms of this License. Such a notice grants a world-wide, royalty-free license, unlimited in duration, to use that work under the conditions stated herein. The "Document", below, refers to any such manual or work. Any member of the public is a licensee, and is addressed as "you". You accept the license if you copy, modify or distribute the work in a way requiring permission under copyright law.

A "Modified Version" of the Document means any work containing the Document or a portion of it, either copied verbatim, or with modifications and/or translated into another language.

A "Secondary Section" is a named appendix or a front-matter section of the Document that deals exclusively with the relationship of the publishers or authors of the Document to the Document's overall subject (or to related matters) and contains nothing that could fall directly within that overall subject. (Thus, if the Document is in part a textbook of mathematics, a Secondary Section may not explain any mathematics.) The relationship could be a matter of historical connection with the subject or with related matters, or of legal, commercial, philosophical, ethical or political position regarding them.

The "Invariant Sections" are certain Secondary Sections whose titles are designated, as being those of Invariant Sections, in the notice that says that the Document is released under this License. If a section does not fit the above definition of Secondary then it is not allowed to be designated as Invariant. The Document may contain zero Invariant Sections. If the Document does not identify any Invariant Sections then there are none.

The "Cover Texts" are certain short passages of text that are listed, as Front-Cover Texts or Back-Cover Texts, in the notice that says that the Document is released under this License. A Front-Cover Text may be at most 5 words, and a Back-Cover Text may be at most 25 words.

A "Transparent" copy of the Document means a machine-readable copy, represented in a format whose specification is available to the general public, that is suitable for revising the document straightforwardly with generic text editors or (for images composed of pixels) generic paint programs or (for drawings) some widely available drawing editor, and that is suitable for input to text formatters or for automatic translation to a variety of formats suitable for input to text formatters. A copy made in an otherwise Transparent file format whose markup, or absence of markup, has been arranged to thwart or discourage subsequent modification by readers is not Transparent. An image format is not Transparent if used for any substantial amount of text. A copy that is not "Transparent" is called "Opaque".

Examples of suitable formats for Transparent copies include plain ASCII without markup, Texinfo input format, LaTeX input format, SGML or XML using a publicly available DTD, and standard-conforming simple HTML, PostScript or PDF designed for human modification. Examples of transparent image formats include PNG, XCF and JPG. Opaque formats include proprietary formats that can be read and edited only by proprietary word processors, SGML or XML for which the DTD and/or processing tools are not generally available, and the machine-generated HTML, PostScript or PDF produced by some word processors for output purposes only.

The "Title Page" means, for a printed book, the title page itself, plus such following pages as are needed to hold, legibly, the material this License requires to appear in the title page. For works in formats which do not have any title page as such, "Title Page" means the text near the most prominent appearance of the work's title, preceding the beginning of the body of the text.

A section "Entitled XYZ" means a named subunit of the Document whose title either is precisely XYZ or contains XYZ in parentheses following text that translates XYZ in another language. (Here XYZ stands for a specific section name mentioned below, such as "Acknowledgements", "Dedications", "Endorsements", or "History".) To "Preserve the Title" of such a section when you modify the Document means that it remains a section "Entitled XYZ" according to this definition.

The Document may include Warranty Disclaimers next to the notice which states that this License applies to the Document. These Warranty Disclaimers are considered to be included by reference in this License, but only as regards disclaiming warranties: any other implication that these Warranty Disclaimers may have is void and has no effect on the meaning of this License.

2. VERBATIM COPYING

You may copy and distribute the Document in any medium, either commercially or noncommercially, provided that this License, the copyright notices, and the license notice saying this License applies to the Document are reproduced in all copies, and that you add no other conditions whatsoever to those of this License. You may not use technical measures to obstruct or control the reading or further copying of the copies you make or distribute. However, you may accept compensation in exchange for copies. If you distribute a large enough number of copies you must also follow the conditions in section 3.

You may also lend copies, under the same conditions stated above, and you may publicly display copies.

3. COPYING IN QUANTITY

If you publish printed copies (or copies in media that commonly have printed covers) of the Document, numbering more than 100, and the Document's license notice requires Cover Texts, you must enclose the copies in covers that carry, clearly and legibly, all these Cover Texts: Front-Cover Texts on the front cover, and Back-Cover Texts on the back cover. Both covers must also clearly and legibly identify you as the publisher of these copies. The front cover must present the full title with all words of the title equally prominent and visible. You may add other material on the covers in addition. Copying with changes limited to the covers, as long as they preserve the title of the Document and satisfy these conditions, can be treated as verbatim copying in other respects.

If the required texts for either cover are too voluminous to fit legibly, you should put the first ones listed (as many as fit reasonably) on the actual cover, and continue the rest onto adjacent pages.

If you publish or distribute Opaque copies of the Document numbering more than 100, you must either include a machine-readable Transparent copy along with each Opaque copy, or state in or with each Opaque copy a computer-network location from which the general network-using public has access to download using public-standard network protocols a complete Transparent copy of the Document, free of added material. If you use the latter option, you must take reasonably prudent steps, when you begin distribution of Opaque copies in quantity, to ensure that this Transparent copy will remain thus accessible at the stated location until at least one year after the last time you distribute an Opaque copy (directly or through your agents or retailers) of that edition to the public.

It is requested, but not required, that you contact the authors of the Document well before redistributing any large number of copies, to give them a chance to provide you with an updated version of the Document.

4. MODIFICATIONS

You may copy and distribute a Modified Version of the Document under the conditions of sections 2 and 3 above, provided that you release the Modified Version under precisely this License, with the Modified Version filling the role of the Document, thus licensing distribution and modification of the Modified Version to whoever possesses a copy of it. In addition, you must do these things in the Modified Version:

- *A.* Use in the Title Page (and on the covers, if any) a title distinct from that of the Document, and from those of previous versions (which should, if there were any, be listed in the History section of the Document). You may use the same title as a previous version if the original publisher of that version gives permission.
- *B.* List on the Title Page, as authors, one or more persons or entities responsible for authorship of the modifications in the Modified Version, together with at least five of the principal authors of the Document (all of its principal authors, if it has fewer than five), unless they release you from this requirement.
- *C.* State on the Title page the name of the publisher of the Modified Version, as the publisher.
- *D.* Preserve all the copyright notices of the Document.
- *E.* Add an appropriate copyright notice for your modifications adjacent to the other copyright notices.
- *F.* Include, immediately after the copyright notices, a license notice giving the public permission to use the Modified Version under the terms of this License, in the form shown in the Addendum below.
- *G.* Preserve in that license notice the full lists of Invariant Sections and required Cover Texts given in the Document's license notice.
- *H.* Include an unaltered copy of this License.
- *I.* Preserve the section Entitled "History", Preserve its Title, and add to it an item stating at least the title, year, new authors, and publisher of the Modified Version as given on the Title Page. If there is no section Entitled

"History" in the Document, create one stating the title, year, authors, and publisher of the Document as given on its Title Page, then add an item describing the Modified Version as stated in the previous sentence.

- *J.* Preserve the network location, if any, given in the Document for public access to a Transparent copy of the Document, and likewise the network locations given in the Document for previous versions it was based on. These may be placed in the "History" section. You may omit a network location for a work that was published at least four years before the Document itself, or if the original publisher of the version it refers to gives permission.
- *K.* For any section Entitled "Acknowledgements" or "Dedications", Preserve the Title of the section, and preserve in the section all the substance and tone of each of the contributor acknowledgements and/or dedications given therein.
- *L.* Preserve all the Invariant Sections of the Document, unaltered in their text and in their titles. Section numbers or the equivalent are not considered part of the section titles.
- *M.* Delete any section Entitled "Endorsements". Such a section may not be included in the Modified Version.
- *N.* Do not retitle any existing section to be Entitled "Endorsements" or to conflict in title with any Invariant Section.
- *O.* Preserve any Warranty Disclaimers.

If the Modified Version includes new front-matter sections or appendices that qualify as Secondary Sections and contain no material copied from the Document, you may at your option designate some or all of these sections as invariant. To do this, add their titles to the list of Invariant Sections in the Modified Version's license notice. These titles must be distinct from any other section titles.

You may add a section Entitled "Endorsements", provided it contains nothing but endorsements of your Modified Version by various parties--for example, statements of peer review or that the text has been approved by an organization as the authoritative definition of a standard.

You may add a passage of up to five words as a Front-Cover Text, and a passage of up to 25 words as a Back-Cover Text, to the end of the list of Cover Texts in the Modified Version. Only one passage of Front-Cover Text and one of Back-Cover Text may be added by (or through arrangements made by) any one entity. If the Document already includes a cover text for the same cover, previously added by you or by arrangement made by the same entity you are acting on behalf of, you may not add another; but you may replace the old one, on explicit permission from the previous publisher that added the old one.

The author(s) and publisher(s) of the Document do not by this License give permission to use their names for publicity for or to assert or imply endorsement of any Modified Version.

5. COMBINING DOCUMENTS

You may combine the Document with other documents released under this License, under the terms defined in section 4 above for modified versions, provided that you include in the combination all of the Invariant Sections of all of the original documents, unmodified,

and list them all as Invariant Sections of your combined work in its license notice, and that you preserve all their Warranty Disclaimers.

The combined work need only contain one copy of this License, and multiple identical Invariant Sections may be replaced with a single copy. If there are multiple Invariant Sections with the same name but different contents, make the title of each such section unique by adding at the end of it, in parentheses, the name of the original author or publisher of that section if known, or else a unique number. Make the same adjustment to the section titles in the list of Invariant Sections in the license notice of the combined work.

In the combination, you must combine any sections Entitled "History" in the various original documents, forming one section Entitled "History"; likewise combine any sections Entitled "Acknowledgements", and any sections Entitled "Dedications". You must delete all sections Entitled "Endorsements."

6. COLLECTIONS OF DOCUMENTS

You may make a collection consisting of the Document and other documents released under this License, and replace the individual copies of this License in the various documents with a single copy that is included in the collection, provided that you follow the rules of this License for verbatim copying of each of the documents in all other respects.

You may extract a single document from such a collection, and distribute it individually under this License, provided you insert a copy of this License into the extracted document, and follow this License in all other respects regarding verbatim copying of that document.

7. AGGREGATION WITH INDEPENDENT WORKS

A compilation of the Document or its derivatives with other separate and independent documents or works, in or on a volume of a storage or distribution medium, is called an "aggregate" if the copyright resulting from the compilation is not used to limit the legal rights of the compilation's users beyond what the individual works permit. When the Document is included in an aggregate, this License does not apply to the other works in the aggregate which are not themselves derivative works of the Document.

If the Cover Text requirement of section 3 is applicable to these copies of the Document, then if the Document is less than one half of the entire aggregate, the Document's Cover Texts may be placed on covers that bracket the Document within the aggregate, or the electronic equivalent of covers if the Document is in electronic form. Otherwise they must appear on printed covers that bracket the whole aggregate.

8. TRANSLATION

Translation is considered a kind of modification, so you may distribute translations of the Document under the terms of section 4. Replacing Invariant Sections with translations requires special permission from their copyright holders, but you may include translations of some or all Invariant Sections in addition to the original versions of these Invariant Sections. You may include a translation of this License, and all the license notices in the Document, and any Warranty Disclaimers, provided that you also include the original English version of this License and the original versions of those notices and disclaimers. In case of a disagreement between the translation and the original version of this License or a notice or disclaimer, the original version will prevail.

If a section in the Document is Entitled "Acknowledgements", "Dedications", or "History", the requirement (section 4) to Preserve its Title (section 1) will typically require changing the actual title.

9. TERMINATION

You may not copy, modify, sublicense, or distribute the Document except as expressly provided for under this License. Any other attempt to copy, modify, sublicense or distribute the Document is void, and will automatically terminate your rights under this License. However, parties who have received copies, or rights, from you under this License will not have their licenses terminated so long as such parties remain in full compliance.

10. FUTURE REVISIONS OF THIS LICENSE

The Free Software Foundation may publish new, revised versions of the GNU Free Documentation License from time to time. Such new versions will be similar in spirit to the present version, but may differ in detail to address new problems or concerns. See http://www.gnu.org/copyleft/.

Each version of the License is given a distinguishing version number. If the Document specifies that a particular numbered version of this License "or any later version" applies to it, you have the option of following the terms and conditions either of that specified version or of any later version that has been published (not as a draft) by the Free Software Foundation. If the Document does not specify a version number of this License, you may choose any version ever published (not as a draft) by the Free Software Foundation.
